Systemic Lupus Erythematosus

Definition and Epidemiology

Interstitial nephritis with immune complexes is defined by granular deposits of immunoglobulins and complement in the TBM, interstitium, or both. Systemic lupus erythematosus is the most common reason for this type of interstitial nephritis (Fig. 64-7), and interstitial involvement is present in half of kidney biopsy specimens in lupus. Rarely, tubulointerstitial immune complex disease may be the only manifestation of lupus nephritis.

Clinical Manifestations

The presentation may be as an acute or a chronic interstitial nephritis. The possibility of interstitial involvement (without glomerular disease) is suggested by a rising serum creatinine concentration and a bland urine sediment. Interstitial involvement may be accompanied by signs of tubular dysfunction, such as distal RTA (type 1 or type 4); by isolated hyperkalemia resulting from impaired distal potassium secretion; or by hypokalemia resulting from salt wasting. The potentiating effects of sodium wasting on potassium secretion include an increase in sodium delivery to the potassium secretory site in the collecting tubules and associated volume depletion with subsequent stimulation of aldosterone secretion.

Treatment

Corticosteroid therapy is usually effective in suppressing tubular dysfunction and preserving renal function.

Inflammatory Bowel Disease

Although the most frequent renal complications of Crohn disease are calcium oxalate stones and renal amyloidosis, interstitial nephritis has been reported in patients treated for chronic inflammatory bowel disease. Aminosalicylates (5-aminosalicylic acid, mesalazine, and sulfasalazine) are responsible for most of these cases, but nephrotoxicity of these agents is very uncommon (mean rate only 0.3% per patient-year).[39] Nephrotoxicity most often occurs in the first 12 months of treatment with aminosalicylate, but a delayed presentation after several years has also been reported. There is no clear relationship between aminosalicylate dose and the risk of nephrotoxicity, suggesting that this is an idiosyncratic response. Some patients have been reported to have biopsy-proven interstitial nephritis before the diagnosis of Crohn disease.

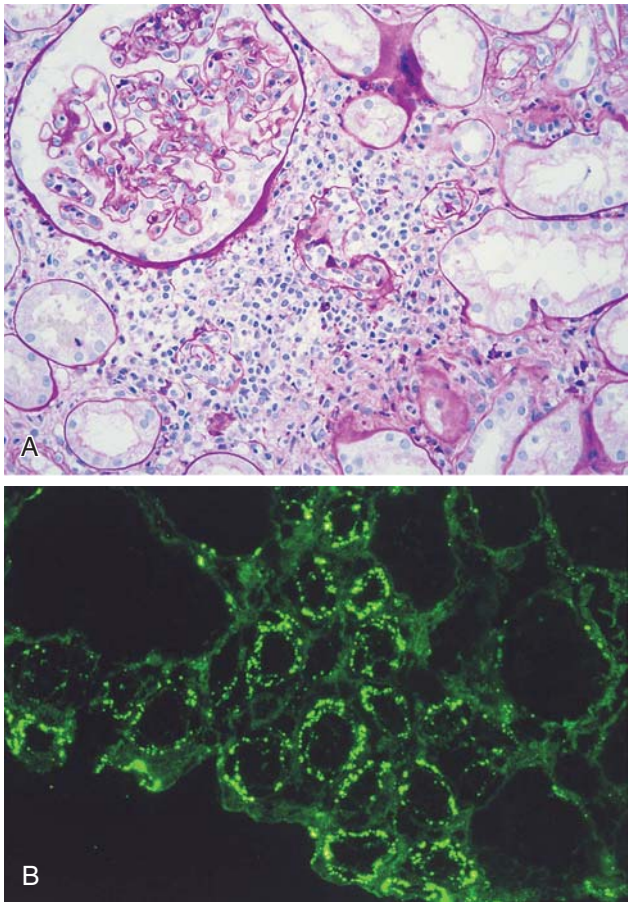

Figure 64-7 Chronic interstitial nephritis in systemic lupus. A, Interstitial nephritis observed in patients with systemic lupus erythematosus. (Periodic acid–Schiff staining; original magnification ×400.) **B,** Immunofluorescence study of the same patient revealed deposition of IgG in the interstitium, in tubular cells, and along the tubular basement membrane. *(Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)*

Aminosalicylates should be withdrawn when renal impairment develops in a patient with inflammatory bowel disease; if this does not result in a fall in serum creatinine, renal biopsy should be considered. Corticosteroids are recommended when renal function does not respond to drug withdrawal.

IgG4-related Kidney Disease

Definition and Epidemiology

On the basis of histologic and immunohistochemical examination of various organs of patients with autoimmune pancreatitis, a novel clinicopathologic entity of IgG4-related sclerosing disease has been proposed.[40] This is a systemic disease that is characterized by extensive IgG4-positive plasma cells and T lymphocyte infiltration of various organs (Fig. 64-8). Initial reports of IgG4-related sclerosing disease came from Japan, but it has now been described in Europe and the United States and is considered to be a worldwide entity.

Pathogenesis

Whether IgG4 is pathogenic or is a "bystander" remains unknown. IgG4 does not activate the classical complement pathway effectively. However, immune complex formation may play a pathogenic role, raising the possibility of complement fixation via the lectin pathway or activation of the classical pathway of complement by some unknown mechanism.

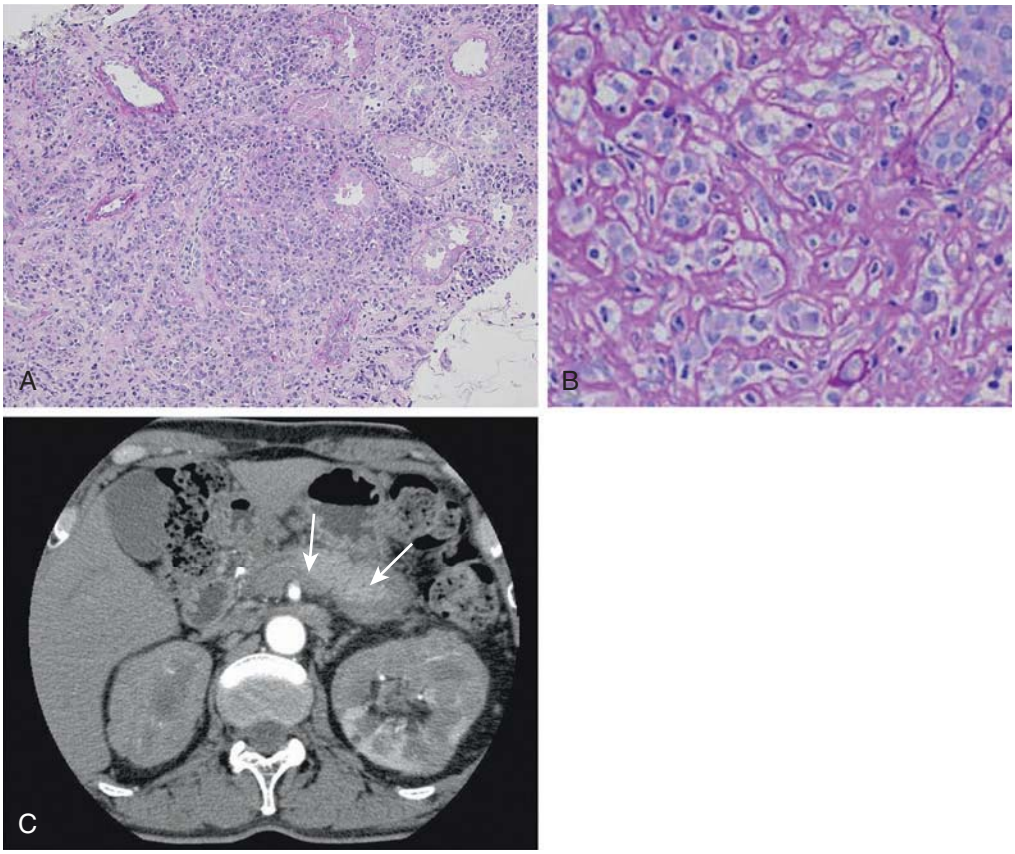

Figure 64-8 Chronic interstitial nephritis in IgG4-related sclerosing disease. A, Interstitial nephritis with numerous mononuclear cell infiltrates observed in a patient with autoimmune pancreatitis. Many of these cells are positive for IgG4 in typical cases. (Periodic acid–Schiff staining; original magnification ×200.) **B,** Small nests of swollen plasma cells or individual plasma cells are encircled by collagenous tissue. The features resemble a maple wood grain pattern called "bird's eye." Plasma cells look like birds' eyes in the wood, whereas fibrotic tissues correspond to branches of the wood. **C,** Computed tomography scan of the patient revealed pancreatic swelling *(arrows). (**A** and **C** courtesy Dr. Hiroshi Nishi, University of Tokyo, Tokyo. **B** from reference 41.)*

Pathology

The most common pattern of involvement by IgG4-related kidney disease is tubulointerstitial nephritis with dense infiltration of IgG4-positive mononuclear cells. Distinctive features of the tubulointerstitial nephritis include (1) well-demarcated borders between involved and uninvolved areas; (2) involvement of the cortex and deep medulla, often extending beyond the renal capsule; (3) interstitial inflammatory cells comprising predominantly plasma cells and lymphocytes, with a high prevalence of IgG4-positive cells often admixed with fibrosis; (4) peculiar features of interstitial fibrosis resembling a "bird's-eye" pattern; and (5) deposits visible by light microscopy and immunofluorescence in the TBM, Bowman capsule, and interstitium.[41] Immunofluorescence shows granular TBM staining for IgG accompanied by C3 of lesser staining intensity. MN has also been described as a manifestation of IgG4-related kidney disease.[42]

Clinical Manifestations

Clinical manifestations are observed in various organs, with presentations including sclerosing cholangitis, cholecystitis, sialadenitis, and retroperitoneal fibrosis. IgG4-related tubulointerstitial nephritis can be mass forming, similar to IgG4-related inflammatory lesions in other organs. Of patients with IgG4-related disease, 80% are reported to have had radiographic renal abnormalities: bilateral and multiple small low-attenuation lesions, a mass, or bilateral renal enlargement.[43] Whereas most IgG4-related sclerosing disease is associated with autoimmune pancreatitis, cases without pancreatic involvement have also been described. The disease occurs predominantly in older men. Serum IgG4 levels are raised, and IgG4-positive cells are found in the interstitium. The finding of an elevated serum IgG4 is not specific, however, because this may occur in 5% of the normal population. The patients often show hypocomplementemia and eosinophilia. Recently proposed diagnostic criteria are shown in Table 64-4.

Treatment

The response to corticosteroids is generally favorable. There is no correlation between histologic pattern and response to therapy, and even patients with extensive fibrosis on biopsy have shown a response to corticosteroid therapy.[44]

Other Forms of Immune-mediated Interstitial Nephritis

Primary anti–TBM nephritis is an extremely rare form of interstitial nephritis that usually is acute and characterized by linear deposits of immunoglobulins, commonly IgG, and complement in the TBM, together with tubular interstitial inflammation and anti-TBM antibodies in the serum. Anti-TBM antibodies, usually IgG, may also be found in 50% to 70% of patients with anti–glomerular basement membrane nephritis and occasionally in patients with MN, systemic lupus, IgA nephropathy, minimal change disease, and malignant hypertension.

Diagnostic Criteria for IgG4-related Tubulointerstitial Nephritis (TIN)	
Histology	Plasma cell–rich tubulointerstitial nephritis with >10 IgG4-positive plasma cells per high-power field in the most concentrated field* Tubular basement membrane immune complex deposits by immunofluorescence, immunohistochemistry, and/or electron microscopy†
Imaging	Small peripheral low-attenuation cortical nodules, round or wedge-shaped lesions, or diffuse patchy involvement Diffuse marked enlargement of kidneys
Serology	Elevated serum IgG4 or total IgG level
Other organ involvement	Includes autoimmune pancreatitis, sclerosing cholangitis, inflammatory masses in any organ, sialadenitis, inflammatory aortic aneurysm, lung involvement, retroperitoneal fibrosis

Table 64-4 Diagnostic criteria for IgG4-related TIN. Diagnosis of IgG4-TIN requires the histologic feature of plasma cell–rich TIN with increased IgG4+ plasma cells and at least one other feature from the categories of imaging, serology, or other organ involvement. *Mandatory criterion. †Supportive criterion, present in >80% of cases. *(From reference 43.)*

OBSTRUCTIVE UROPATHY

Complete or partial urinary tract obstruction is accompanied by pathologic changes in both the tubulointerstitium and glomeruli consisting of interstitial fibrosis, tubular atrophy, and occasionally focal glomerular sclerosis. Details are discussed in Chapter 60.

VASCULAR DISEASES

Ischemia resulting from intrarenal vascular involvement causes tubular atrophy, interstitial fibrosis, and cellular infiltration. This is further discussed in Chapter 66. Chronic ischemia in the tubulointerstitial compartment also plays a crucial role in the progression of a variety of glomerular and tubulointerstitial diseases.[2]

INFECTION-ASSOCIATED CHRONIC INTERSTITIAL NEPHRITIS

Although a variety of bacterial and viral infections can be associated with acute interstitial nephritis (see Chapter 62), chronic interstitial nephritis secondary to infectious agents appears to be rare. Insidious *Mycobacterium tuberculosis* infection can cause chronic granulomatous tubulointerstitial nephritis.[45] Chronic bacterial infections can result in xanthogranulomatous pyelonephritis or renal malacoplakia (see Chapter 53).

CHAPTER 65

Myeloma and the Kidney

Ashley B. Irish

Myeloma is an uncommon hematologic malignancy, accounting for 1% of total and 10% of hematologic malignancies. African Americans have twice the incidence of Caucasians, and males predominate over females. It is a disease of the elderly, with a median age of diagnosis of older than 65 years. The characteristic feature of myeloma is the dysregulated overproduction of immunoglobulin (Ig), and especially the light-chain (LC) component, which can be nephrotoxic. Various causes and manifestations of acute kidney injury (AKI) are possible in myeloma (Table 65-1), but the major risk is myeloma cast nephropathy (MCN), which is a medical emergency that requires prompt diagnosis and intervention to prevent irreversible renal failure.

ETIOLOGY AND PATHOGENESIS OF MYELOMA

Myeloma is a B cell–derived malignancy of incompletely differentiated plasma cells that have two prominent features: increased production of monoclonal Ig, and bone destruction. Normally plasma cells derive from mature uncommitted B cells and after antigen stimulus undergo heavy chain class switching from μ (IgM) expression to α, δ, ε, or γ. Whole Ig production requires the intracellular assembly of two heavy chains and two LCs, kappa (κ) or lambda (λ), to derive whole IgG, IgA, IgD, and IgE immunoglobulin. Normally LCs are excreted in slight excess, with a κ:λ ratio of approximately 2:1. In myeloma a clone of cells secretes excessive quantities of a specific Ig and/or LC (the paraprotein or M protein). The genetic and somatic abnormalities underlying this malignant clone are complex and remain incompletely understood but have important implications for prognosis and treatment.[1] Both deregulation of cell cycling and impaired apoptosis account for their progressive and dysfunctional accumulation within the bone marrow, and occasionally other organs. Plasma cells express little surface Ig and are recognized by surface expression of CD38 and CD138; they normally reside only in the bone marrow. In myeloma, unrestrained plasma cell growth is supported by a complex milieu of autocrine and paracrine cytokines, especially interleukin (IL)–6. These cytokines are secreted from stromal cells, endothelial cells, and/or osteoclasts and maintain myeloma cell growth, survival, and migration; they also contribute to local organ dysfunction—for example, bone resorption, fracture, and anemia.[2]

ETIOLOGY AND PATHOGENESIS OF RENAL DISEASE

Free light chains (FLCs) circulate as monomers (predominantly κ, approximately 25 kD) and dimers (predominantly λ, approximately 50 kD) with a very short half-life (2 to 6 hours) because of free glomerular filtration, whereas the much larger whole Ig circulates intact for several weeks. The filtered FLC is reabsorbed in the proximal tubule cell (PTC) by receptor-mediated endocytosis after binding with the glycoprotein receptor cubilin (Fig. 65-1).[3] LCs in excess can induce an inhibitory effect on endocytosis *in vitro* and are associated with lysosomal overload and rupture, releasing enzymatic contents into the cytosol, manifesting histologically by evidence of crystallization, vacuolation, and desquamation of the PTC. Endocytosis of light chains induces the release of the proinflammatory cytokines IL-6, IL-8, and monocyte chemoattractant protein 1 (MCP-1) via the activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) in the PTC.[4] This mechanism suggests that LC overload induces factors promoting interstitial injury and fibrosis, as described in other proteinuric states. LC may also be cytotoxic to the PTC via direct DNA injury and the induction of apoptosis.[5] Less common manifestations of PTC injury include Fanconi syndrome, which is invariably associated with specific variant κ LCs and often with pathologic evidence of crystalline inclusions.[6]

Injury to the PTC allows escape or overflow of LCs to the distal nephron where they can interact with the Tamm-Horsfall protein (THP) secreted by the cells of the thick ascending loop of Henle (TAL). Variations in the specificity of the complementarity-determining region 3 (CDR3) of different LCs modify the affinity of the LC for binding with the specific single FLC-binding domain of THP, which could in part explain the variable nephrotoxicity (cast formation) of different LCs.[7] This specificity of the individual LC for THP was illustrated by the finding that the intraperitoneal installation of LC isolated from humans with specific renal LC-associated disease induces the same renal injury in animals.[8] Although renal injury occurs only in the presence of urinary LC, not all LCs are associated with injury, and neither the amount nor the type of urinary LC correlates with the severity of cast formation. Nevertheless, in general, the higher the urinary excretion of LC, the greater the risk of renal failure and reduced response to chemotherapy.[9-11] In addition to LC-specific factors, tubular solute composition and tubular flow rates modulate the risk for cast formation. In animals, urinary acidification, furosemide, increased urinary sodium increased urinary calcium concentration may affect the tendency to increased binding or aggregation of LC with THP, whereas colchicine may reduce this tendency in animals but not in humans.[12,13] The formation and passage of casts distally can occlude the tubule and allow intratubular obstruction, with rupture and even backflow of contents (Fig. 65-2).

EPIDEMIOLOGY

Most myeloma presents *de novo,* although a small number of cases evolve in patients with monoclonal gammopathy of undetermined significance (MGUS) each year. In patients with newly diagnosed myeloma, the prevalence of IgG, IgA, IgD, and FLC-only myeloma was 52%, 21%, 2%, and 16%, respectively.[9] IgM and IgE myeloma are extremely uncommon. Approximately 70% of patients with myeloma

also have a urinary M protein. At the time of diagnosis of myeloma, up to 50% of patients have evidence of impaired renal function judged by increased serum creatinine; approximately 25% present with serum creatinine exceeding 2 mg/dl (177 µmol/l).[9,10] In unselected series, 2% to 10% of patients present with severe renal failure necessitating dialysis; this figure is higher in series reported from renal units. In contrast to the general distribution of M-protein types in myeloma, LC and IgD myeloma are particularly associated with the risk of renal disease, being present in nearly 50% of patients with severe renal disease who require dialysis.[14]

Etiology of Renal Injury and Clinical Manifestations

	Cause	Manifestation
Pre-renal		
Volume depletion	Hypercalcemia Gastrointestinal losses (nausea and vomiting) Sepsis	Polyuria and polydipsia Hypotension Fever
Hemodynamic	Hemodynamic from NSAIDs	Oliguria, hyperkalemia
Other	Hyperviscosity (IgA, IgG3) Hyperuricemia	Mental state alterations Tumor lysis
Renal	Proximal tubular injury from light chains, uric acid, distal tubular injury from casts Glomerular disease (LCDD, amyloid)	Fanconi syndrome Tubular proteinuria Crystalluria Nephrotic proteinuria Hematuria, active sediment
Post-renal	Calculi	Colic

Table 65-1 Etiology of renal injury and clinical manifestations. *LCDD,* Light-chain deposition disease; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

CLINICAL PRESENTATION

Most patients present with constitutional symptoms (fatigue, weight loss) and skeletal pain, especially back pain. Renal impairment is common and has a variety of causes (see Table 65-1). In a smaller proportion of patients, renal failure is the presenting manifestation of myeloma, and the diagnosis of myeloma is made or suggested by the renal biopsy. In general these patients have more advanced

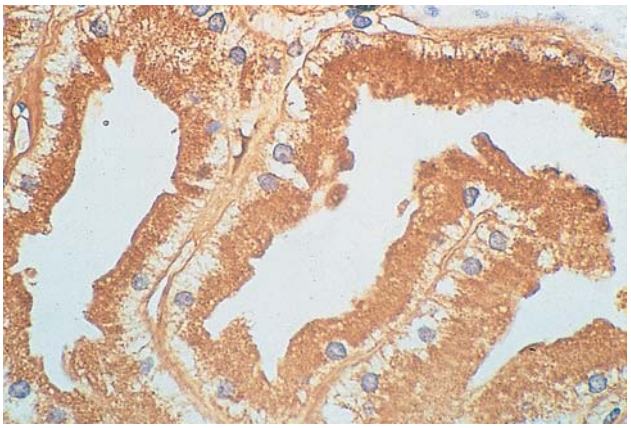

Figure 65-1 Uptake of light chains by proximal tubular cells. Renal biopsy from a patient excreting κ light chains. Immunoperoxidase staining showing κ light chains along the brush border and in the cytoplasm of PTC (brown stain).

Renal Injury Caused by Light Chains

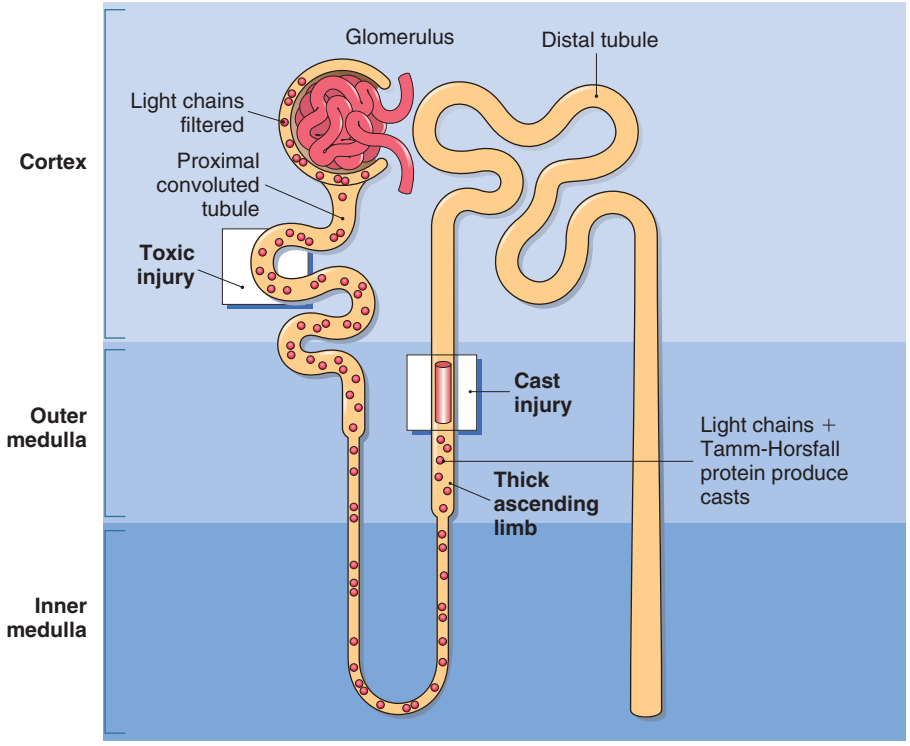

Figure 65-2 Renal injury caused by light chains. Sites *(shaded boxes)* where light chains injure the tubule. In the proximal tubule there is direct tubular cytotoxicity. In the distal tubule there is cast injury.

Differentiating Features of Myeloma Kidney and Other Monoclonal Immune Deposition Diseases (MIDDs)		
	Myeloma Kidney	**Other MIDDs**
Proteinuria	<3 g/l	>3 g/l
Hematuria	Rare	LCDD, occasional Amyloidosis, rare
Hypercalcemia	Common	Absent
Hypertension	Uncommon	LCDD, common Amyloidosis, uncommon
Cytopenias	Anemia very common Leukopenia and thrombocytopenia, occasional	Uncommon
Immunoparesis*	Very common	Uncommon
Lytic bone lesions	Very common	Absent
Renal impairment	Common	Common
Associated whole immunoglobulin	IgA, IgD, IgG	None
Type of light chain	Either	Amyloid λ > κ LCDD κ > λ
Serum light chain elevation	>500 mg/l	<500 mg/l

Table 65-2 Clinical features of myeloma kidney versus MIDDs. *LCDD,* Light-chain deposition disease. *Defined as a reduction in the nonparaprotein globulin fractions.

Renal Disease in Patients with Multiple Myeloma	
Histologic Finding	**Prevalence**
Myeloma kidney (myeloma cast nephropathy)	30%-50%
Interstitial nephritis or fibrosis without cast nephropathy	20%-30%
Amyloidosis	10%
Light-chain deposition disease	5%
Acute tubular necrosis	10%
Other (uric acid nephropathy, tubular crystals, hypercalcemia, FSGS)	5%

Table 65-3 Renal disease in patients with multiple myeloma. *FSGS,* Focal segmental glomerulosclerosis. *(From references 26, 66 to 71.)*

Histologic Features of Myeloma Kidney
Many eosinophilic, often fractured casts (medullary portion of the distal nephron predominantly)
Intratubular and interstitial macrophages and giant cells in response to casts
Interstitial inflammation, fibrosis, tubular atrophy, crystalline inclusions
Minimal glomerular abnormality
Minimal or no vascular changes

Box 65-1 Histologic features of myeloma cast nephropathy.

disease with high morbidity and mortality.[14] Renal findings are nonspecific, usually including normal size kidneys and bland urine. Urinary total protein excretion may be markedly increased because of the presence of LCs (Bence Jones protein), whereas urinary dipstick or albumin quantification may be misleading because they measure albumin only. This discrepancy between albumin and total protein measurements may alert clinicians to the diagnosis of myeloma. Normal or elevated ionized calcium, a decreased serum anion gap, lytic bone lesions on x-ray examination, hypogammaglobulinemia or reductions in levels of other immunoglobulin classes (immune paresis), an abnormal serum FLC ratio, and significant cytopenias or blood film changes (plasma cells and/or leukoerythroblastic film) are suggestive of myeloma. Clinical and laboratory findings that may distinguish MCN from other monoclonal immunoglobulin deposition diseases (MIDD) are listed in Table 65-2 and discussed in Chapter 27.

PATHOLOGY

Histologic examination of the kidney in myeloma has diagnostic and prognostic utility, although it is not always required, and the risk of complications after biopsy may be increased in patients with AKI who require dialysis. Biopsy is useful for the initial evaluation of AKI and to guide treatments designed to reverse AKI. Table 65-3 lists the likely findings and prevalence of renal injury noted at histologic or autopsy sampling. MCN is the commonest histologic finding, occurring in 30% to 50% of patients (Box 65-1 and Fig. 65-3, *A*). MCN is characterized by many distal tubular casts, which are strongly eosinophilic and consist of the monoclonal LC and laminated THP, which often appear fractured after fixation. Casts promote local inflammation with giant cell formation.[15,16] In 30% of patients, cast formation may not be prominent despite extensive tubulointerstitial injury (Fig. 65-3, *B* and *C*).[17] Glomeruli are usually spared unless there is associated LC deposition disease or amyloidosis (see Chapter 27).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The International Myeloma Working Group (2003) diagnostic criteria for symptomatic myeloma require (1) the detection and quantification of a monoclonal protein by serum electrophoresis (SEP) and characterization by immunofixation electrophoresis (IFE); (2) bone marrow (clonal) plasma cells or biopsy-proven plasmacytoma; and (3) the demonstration of any end-organ damage not otherwise explained by other pathology (including hypercalcemia, renal failure, anemia, and lytic bone disease).[18] The monoclonal M protein is the key abnormality required for diagnosis, and 97% of patients have an intact Ig and/or a free LC by SEP and IFE. The quantity of the M protein is estimated from the SEP and may be used for both diagnosis and to monitor response to therapy. Urinary LC (Bence Jones protein) is determined from a concentrated sample, but despite this, LC may still be below the level of detection by IFE. The specific quantitative FLC assay (which measures only LC not bound to whole Ig) for both urine and serum is significantly more sensitive than SEP and IFE alone and is an automated assay that allows rapid diagnosis.[19-21] An abnormal monoclonal FLC clone increases the specific LC fraction and may suppress the other LC, which alters the normal ratio of FLC (0.26 to 1.65 κ:λ) to reflect the oversecretion of the abnormal LC clone (i.e., <0.26 for λ FLC clone, >1.65 for κ clone). The normal serum levels of FLC are very low (7 to 13 mg/L), but in patients with impaired renal function, accumulation of both

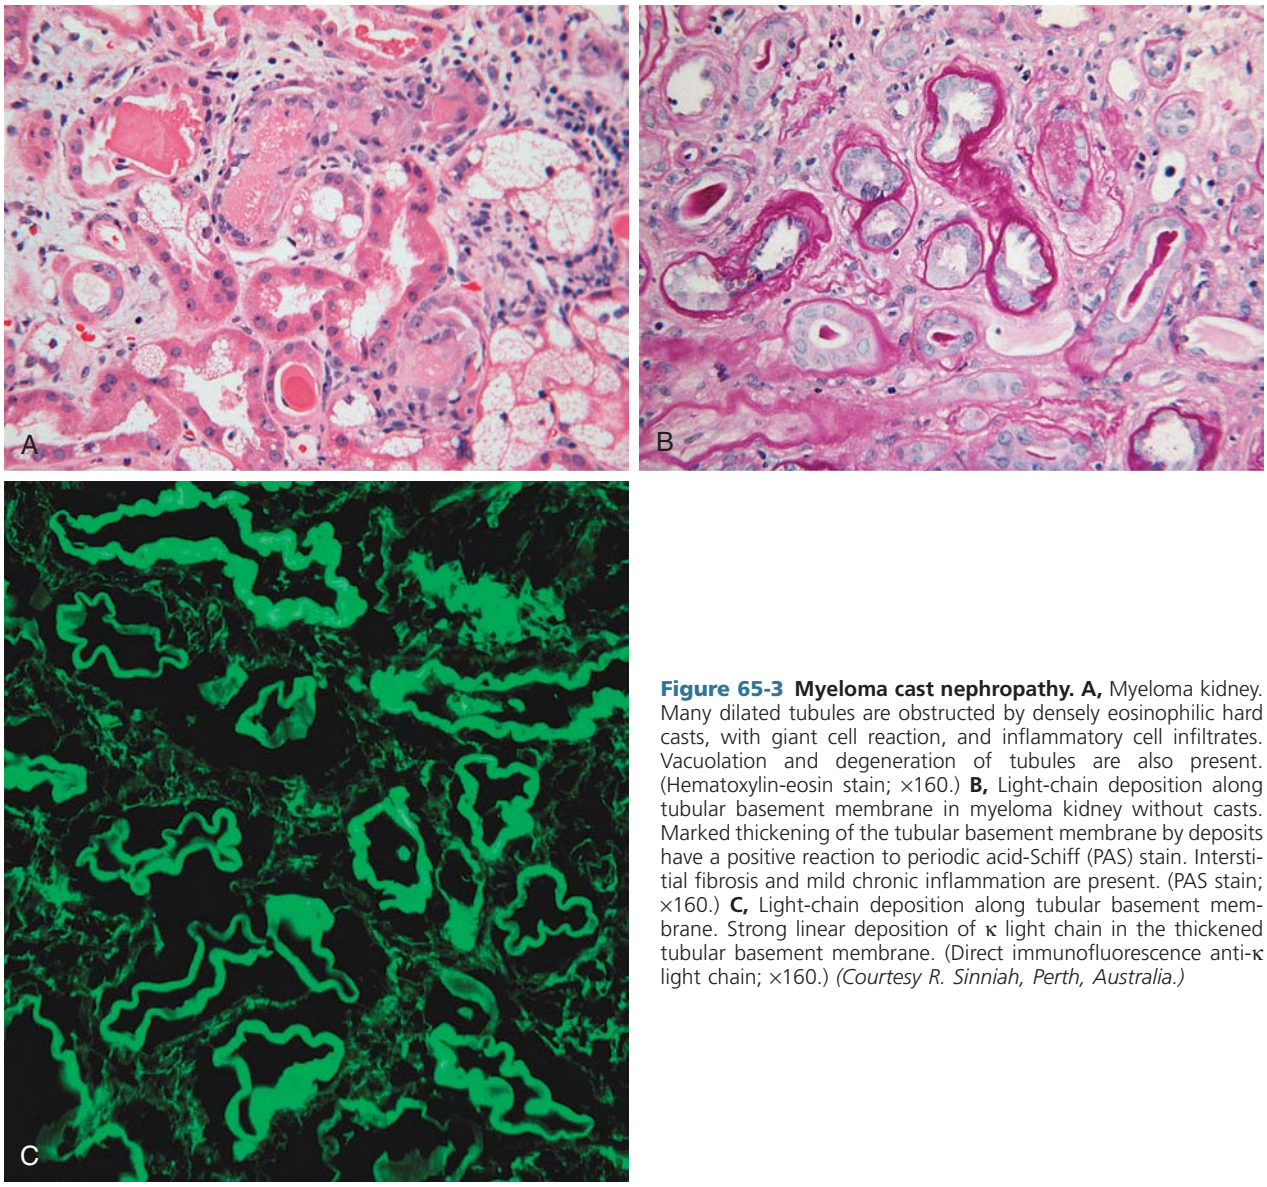

Figure 65-3 Myeloma cast nephropathy. A, Myeloma kidney. Many dilated tubules are obstructed by densely eosinophilic hard casts, with giant cell reaction, and inflammatory cell infiltrates. Vacuolation and degeneration of tubules are also present. (Hematoxylin-eosin stain; ×160.) **B,** Light-chain deposition along tubular basement membrane in myeloma kidney without casts. Marked thickening of the tubular basement membrane by deposits have a positive reaction to periodic acid-Schiff (PAS) stain. Interstitial fibrosis and mild chronic inflammation are present. (PAS stain; ×160.) **C,** Light-chain deposition along tubular basement membrane. Strong linear deposition of κ light chain in the thickened tubular basement membrane. (Direct immunofluorescence anti-κ light chain; ×160.) *(Courtesy R. Sinniah, Perth, Australia.)*

(κ and λ) FLCs occurs as a result of reduced excretion, and the ratio generally remains within the normal range. However, because λ FLCs tend to circulate as dimers, their clearance is reduced more than the monomeric κ FLCs, and this may alter the ratio. Therefore, an extended reference range of 0.37 to 3.1 is considered normal in the patient with renal failure, and use of this cutoff improves diagnostic sensitivity for myeloma to 99% with 100% specificity.[21] The absolute value of the serum monoclonal LC is of lesser importance in diagnosis, but in general, patients with renal failure without myeloma have polyclonal increases in FLC on the order of 10 to 20 times normal. In contrast, in biopsy-proven cast nephropathy the ratios are highly abnormal and the absolute increases in FLC are 100 to 200 times normal with typical values exceeding 500 mg/l (usually exceeding 1000 mg/l) at presentation (Fig. 65-4).[21] Measurement of serum FLC has significant advantages over SEP and IFE and is now incorporated into international clinical guidelines for the diagnosis and management of myeloma.[22]

Diagnostic difficulties can arise in elderly patients who are evaluated for newly diagnosed renal impairment and in whom routine SEP reveals an M protein. Approximately 3% of the population over 70 years of age will have a serum M protein, most consistent with MGUS. A diagnosis of MGUS is more likely if the serum level of the M protein is low (<3 g/dl), urinary LCs are absent or very low (<1 g/24 h), and the FLC ratio is normal with the absence of end-organ injury (no lytic lesions, <10% plasma cells on bone marrow aspirate).[23] This distinction is important because most patients with MGUS will die from an unrelated disease, and only 1% a year progress to myeloma.[24] The majority of renal disease in patients with MGUS is unrelated to the M protein,[25] although rare cases of focal segmental glomerulosclerosis (FSGS) have been associated with a dysproteinemia.[26] Evidence supportive of alternative causes of the renal disease (most commonly diabetes or vascular disease), along with a period of observation, may clarify the significance of the M protein, although renal and/or bone marrow biopsy may be required when diagnostic uncertainty persists.

NATURAL HISTORY

The majority of patients with renal impairment at presentation will show resolution of these predominantly functional changes with therapeutic measures that include withdrawal of nephrotoxins,

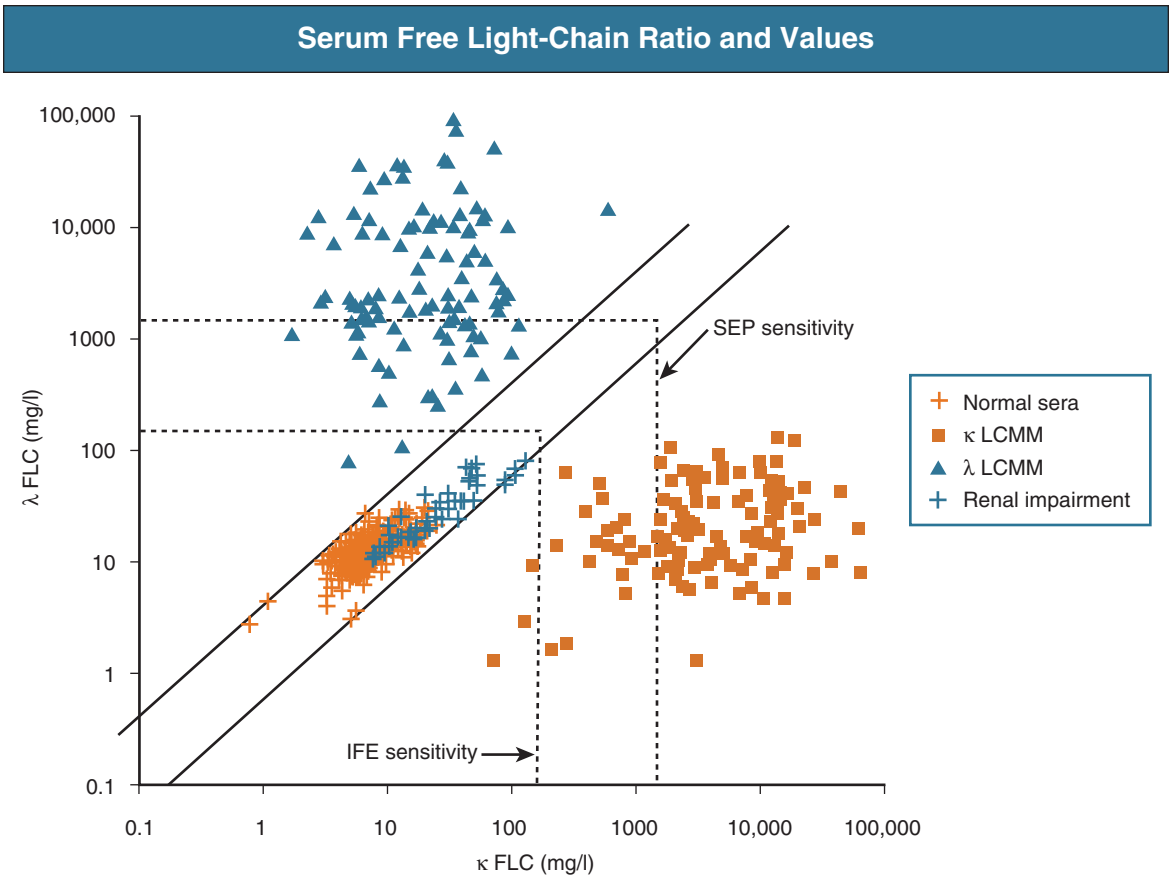

Figure 65-4 Serum free light-chain ratio and values in normal individuals, patients with renal impairment, and light-chain myeloma. *FLC,* Free light chain; *IFE,* immunofixation electrophoresis; *SEP,* serum protein electrophoresis; *LCMM,* light-chain multiple myeloma. *(Reprinted from reference 21.)*

rehydration, treatment of hypercalcemia, treatment of sepsis, and reduction in LC load with chemotherapy. Response to treatment with improvement in renal function is associated with improved clinical outcomes.[27] Reversibility occurs more frequently with lesser degrees of initial renal impairment, lower LC excretion, and hypercalcemia. Although renal function improves in the majority of patients, approximately 10% of patients with renal impairment at diagnosis may require dialysis. Patients requiring dialysis have reported rates of recovery of renal function as low as 5% to 15%, although recently these figures have increased up to 75% with the use of newer targeted LC-reduction strategies.[28-30] Sometimes this recovery occurs many months after presentation.

TREATMENT

There are three key issues in the management of MCN. The first is to suspect and diagnose myeloma in the differential diagnosis of AKI, and the inclusion of serum FLC measurement for routine evaluation of otherwise unexplained AKI in appropriate clinical circumstances is essential. This is because renal injury in myeloma is directly related to FLC excess, and the increased sensitivity and specificity of FLC measurement along with its rapid availability may implicate or refute myeloma as a likely diagnostic possibility days in advance of standard tests (SPE or IFE) or renal biopsy. Early diagnosis is crucial to allow implementation of the second strategy, which is to prevent or reverse oliguria by rapid identification and management of possible contributing factors to renal impairment, which are present in approximately 50% of patients. Hypercalcemia, sepsis, and nonsteroidal anti-inflammatory agents (NSAIDs) are the most common precipitants. Intravenous volume expansion is helpful to increase glomerular filtration, reduce single-nephron LC concentration, and increase tubular flow. The use of furosemide to promote diuresis should be minimized because it may favor cast formation by increasing distal urinary sodium concentration and urinary acidification. There is no clinical evidence of the superiority of volume expansion with sodium bicarbonate over sodium chloride, although prevention of urinary acidification is in theory desirable and in severe renal failure may be necessary for management of metabolic acidosis. The maintenance of a high fluid intake (3 l/day) with water after initial volume correction and restoration of urine output with intravenous crystalloid is recommended to maintain high urine flow rates. Hydration before the use of contrast agents for radiologic or other procedures is essential.[31,32]

The third key requirement is the rapid reduction of FLC in the serum by chemotherapy and, in patients with proven cast nephropathy, by enhanced dialysis (see later) or in some patients plasma exchange. The immediate commencement of high-dose dexamethasone 40 mg daily is recommended, because plasma cells are highly responsive to corticosteroids, which induce rapid apoptosis and lowering of LC concentration. The addition of newer chemotherapy strategies (see later) with high immediate LC-lowering effects in combination with corticosteroids is also critical to rapid response.[33-35] The routine addition of plasma exchange to conventional treatment did not improve either recovery from renal failure or patient survival.[36] The large volume of distribution of LCs (which freely cross cell membranes) is not well suited to plasma exchange; however, in some circumstances its use as an adjunct to chemotherapy may be

considered beneficial.[37] The use of a Polyflux dialysis membrane (HCO 1100, Gambro) with a high cutoff of molecular weight up to 50 kD, in conjunction with early chemotherapy, has been shown to reverse renal failure in association with the rapid reduction in circulating FLCs in patients with cast nephropathy.[29,38,39] The optimal use of this membrane is under clinical trial and may differ according to the type of LCs, response to chemotherapy, use of convective therapies, and extended duration of dialysis.[40] A suggested algorithm for management of multiple myeloma with AKI is shown in Figure 65-5.

Chemotherapy

Although myeloma is usually incurable, chemotherapy will induce clinical improvement and extended survival by control of the underlying disease in the majority of patients. The chemotherapy of myeloma is undergoing rapid evolution and has moved on from traditional chemotherapy with melphalan and prednisolone. The use of melphalan in patients with renal impairment (glomerular filtration rate [GFR] <30 ml/min) requires dose adjustment to avoid the risk of significant hematologic toxicity.[41] Bortezomib, a reversible proteasome inhibitor whose clearance is independent of renal function, has been successfully and safely used in patients with severe degrees of renal failure and myeloma without significant toxicity, and is recommended as the agent of choice for rapid reduction of LC in combination with dexamethasone and high-cutoff hemodialysis.[33,42,43] Bortezomib not only lowers the LC load by direct effects on plasma cells but may also protect renal proximal tubular cells by inhibiting activation of IL-6 and NF-κB induced by LC endocytosis.[44] Thalidomide and lenalidomide are increasingly used first-line treatment or as consolidation or maintenance therapy in conjunction

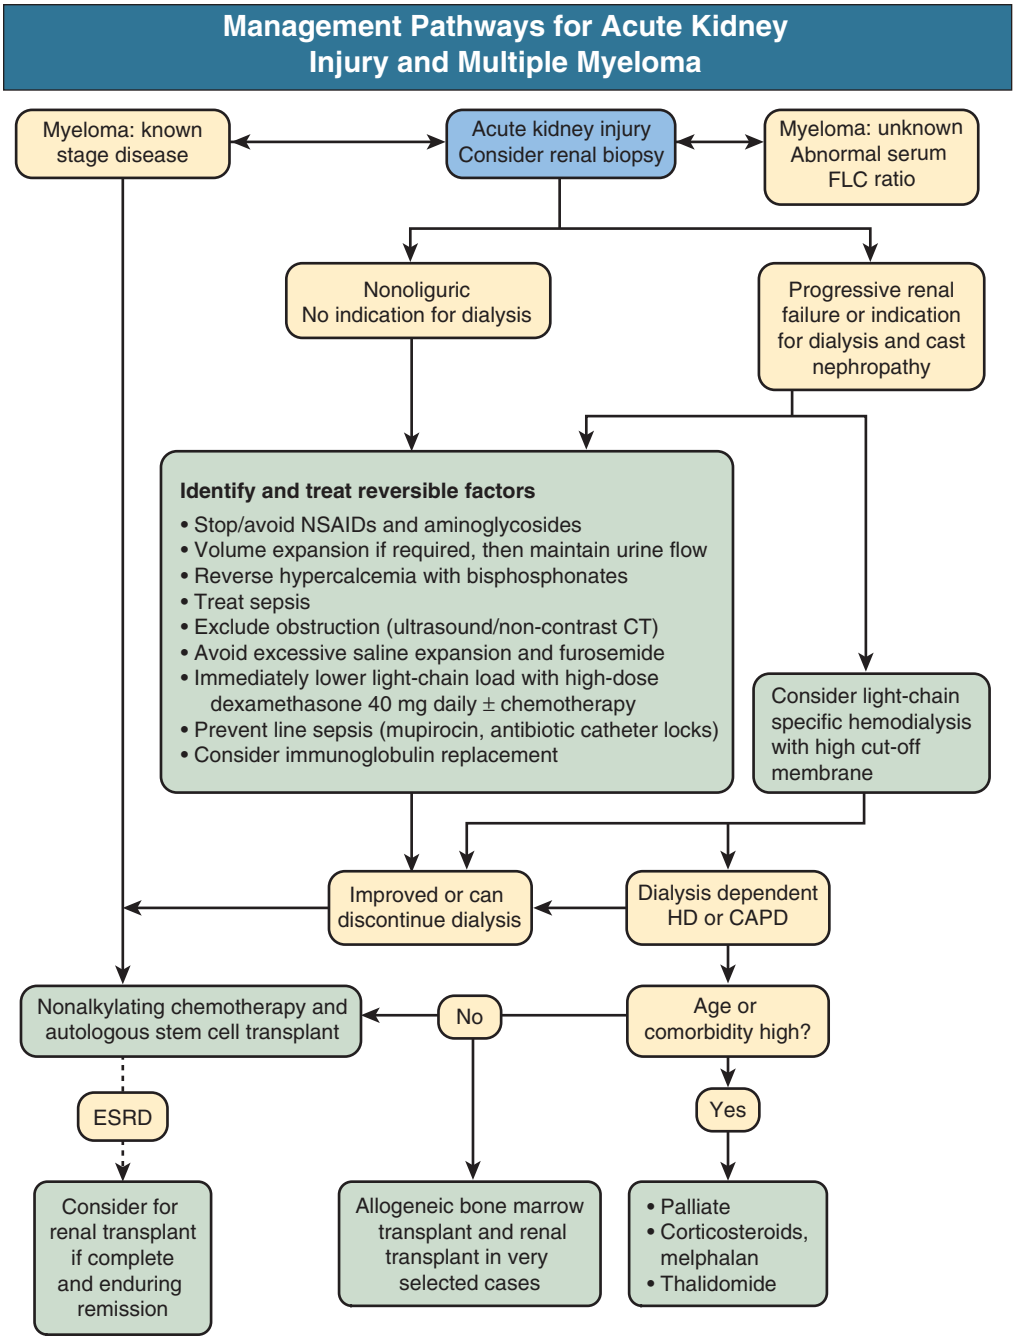

Figure 65-5 Management of multiple myeloma and acute kidney injury. *CAPD,* Continuous ambulatory peritoneal dialysis; *CT,* computed tomography; *ESRD,* end-stage renal disease; *FLC,* free light chain; *HD,* hemodialysis; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

with dexamethasone. Side effects of thalidomide include peripheral neuropathy, venous thrombosis, and teratogenicity; and although thalidomide has minimal renal excretion or removal by hemodialysis, some dose reduction may be prudent.[45,46] Lenalidomide may have reduced neurotoxicity; however, its use in patients with renal failure requires dose reduction, and myelosuppression may be more common in patients with reduced GFR.[47,48] Autologous stem cell transplantation (ASCT) significantly extends survival and is now the treatment of choice for eligible patients, usually those younger than 60 years with low comorbidity and chemotherapy-responsive disease.[49] Even patients with renal impairment and on dialysis may be suitable candidates for ASCT, although increased morbidity and mortality are recognized.[50,51] For the very elderly, chemotherapy selection is dependent on comorbidity, and melphalan-prednisolone or dexamethasone-thalidomide may be useful. Close multidisciplinary management and discussion with hematologists and oncologists is required to individualize decision making because of the continuous advances in this area.[52]

Infection and progression of disease remain the major impediments to survival, especially within the higher-risk ESRD group. Median survival in recent ESRD series with conventional therapies before ASCT was only 4 to 8 months; however, survival of up to 7 years has been reported in selected cases of ESRD managed with ASCT.[43,53]

Adjunctive Therapies

Patients with CKD or ESRD and multiple myeloma respond to erythropoiesis-stimulating agents, and these should be used along with other hematopoietic agents including granulocyte colony-stimulating factor (G-CSF) as required, although early in the disease frequent transfusion may be necessary.[54] Intravenous bisphosphonates rapidly correct hypercalcemia and are preferred to furosemide (which may aggravate tubular LC injury). In the longer term, bisphosphonates may reduce bone fracture.[55] However, there have been several reports of toxicity (acute tubular necrosis, proteinuria) with high doses and/or rapid infusion of pamidronate and zoledronic acid; reduced doses (pamidronate, 30 to 60 mg; zoledronic acid, 4 mg) and slower infusion rates are recommended.[56,57] Replacement of profound immunoglobulin deficiency with regular intravenous immunoglobulin (IVIG) has been proven to reduce infectious complications in stable treated myeloma patients but is not widely adopted (although recommended).[58] Caution is required to avoid further AKI resulting from the hyperosmolarity of some IVIG preparations, because renal impairment and diabetes represent known risk factors for this complication.[59]

Dialysis and Transplantation

When renal replacement therapy is required long term, both hemodialysis and peritoneal dialysis have been successfully used, and there are no data to indicate that outcome is influenced by dialysis modality. Choice of long-term therapy requires individual assessment of patient circumstances. The majority of studies support the use of dialysis, although survival is substantially reduced and early mortality (30%) is high in this group because of the severity of tumor burden and the high rates of sepsis.[60-62] Aggressive measures to reduce risk of systemic infection via antibiotic line locking and/or mupirocin at exit sites, and the use of IVIG replacement, should be routinely considered because there is often initial dependency on central venous catheters for dialysis, plasma exchange, and chemotherapy. The timing of placement of a permanent arteriovenous fistula (AVF) requires an individualized risk assessment because it may be several months before irreversibility of renal failure and a response to chemotherapy are proven. Renal transplantation has a high risk of disease recurrence in the allograft and patient mortality and, given the incurability of the disease, has rarely been appropriate.[63] Allogeneic bone marrow and renal allograft transplant have been reported, demonstrating the ability to induce allograft tolerance in haploidentical pairs.[64] This treatment is limited in availability and suitability for the majority of patients. The role of renal transplant after successful induction therapy and ASCT is unknown, but it may be suitable for younger patients when disease remission by standard criteria and normalization of the serum FLC ratio has been achieved. ASCT itself has been associated with recovery of renal function when the duration of dialysis is less than 6 months.[53,65]

CHAPTER 66

Thromboembolic Renovascular Disease

Barbara A. Greco, Jamie P. Dwyer, and Julia B. Lewis

Renal arterial and venous thromboembolic disease presents as a wide variety of clinical syndromes, ranging from vascular catastrophe with acute renal infarction to progressive decline in renal function as a result of chronic renal ischemia. Appropriate imaging allows accurate and timely identification of renal infarction, renal artery or venous thrombosis, and other renovascular abnormalities.

Thrombotic microangiopathies are discussed in Chapter 29, and renovascular hypertension and atherosclerotic ischemic renal disease are discussed in Chapter 39.

NORMAL ANATOMY

Renal Artery

The anatomic considerations that affect the clinical presentations and outcome of renal arterial thromboembolic events include the size of the vessel involved, from the main renal artery and the branch vessels to the arterioles and glomerular capillaries, and the condition of the collateral blood supply. In most individuals, the kidney has a single artery with a diameter of 3 to 7 mm. The main renal artery branches in either a double or a triple fork pattern or, less commonly, a ladder pattern.[1] The incidence of multiple renal arteries is about 30% with bilateral supernumerary arteries in 10%. The right renal artery usually passes posterior to the inferior vena cava (IVC), but rarely can be precaval.

The main collateral vessels to the kidney include the suprarenal, the lumbar, and the ureteral vessel complexes, which can maintain renal parenchymal viability in the face of main renal arterial occlusion. The collateral circulation to the kidney is depicted in Figure 66-1. In a study examining 301 aortograms, the adrenal arteries supplied collateral circulation to the kidney in 60% of cases, the lumbar in 55%, the ureteric in 15%, and the gonadal in 13%.[2] The factors determining the development and caliber of these vessels are poorly understood but include individual anatomy, state of the aorta, rate of progression of main renal artery narrowing, and condition of the intrarenal perforating arteries.

Renal Vein

Renal veins begin in the subcapsular region of the kidney. These stellate veins communicate with perirenal and cortical venous channels and empty into interlobular veins that drain into arcuate veins. The venae rectae drain the pyramids and join the arcuate veins. Arcuate veins leave the renal parenchyma through interlobar vessels, converging into four to six trunks near the hilum of the kidney (Fig. 66-2). Two or more renal veins have been described in up to 20% of people; this is more common on the right.[3] The main renal veins empty into the IVC; the left renal vein is three times longer than the right (7.5 cm vs. 2.5 cm). The left renal vein traverses behind the splenic vein and body of the pancreas before it crosses in front of the aorta near its termination in the IVC. Anatomic variation exists such that up to 2.3% of people have retroaortic renal veins and under 1% have circumaortic veins with branches extending both behind and in front of the aorta.[4] The left renal vein collects the flow from the left ureteral, gonadal, adrenal, and inferior phrenic veins. In Gerota's fascia, the perirenal venous network communicates with the retroperitoneal collateral veins from the lumbar, azygos, and tributaries of the portal system.[5,6]

THROMBOEMBOLIC RENOVASCULAR DISEASE

Thromboembolic renovascular disease results in disruption of normal renal blood flow, which may lead to either renal ischemia or overt infarction. The caliber and type of vessels involved (artery, arteriole, vein) as well as whether one or both kidneys are affected determine the clinical presentation (Box 66-1).

THROMBOEMBOLIC ISCHEMIC RENAL DISEASE

Ischemic renal disease caused by atherosclerotic renovascular disease (ASRVD) is discussed in Chapter 39. On occasion, thrombosis of the renal artery or branch vessels occurs acutely and without overt renal infarction, providing a clinical opportunity for renal salvage. The clinical settings in which this might occur include spontaneous thrombosis of atherosclerotic renal artery occlusive disease, spontaneous dissection of the aorta involving the origin of the renal artery, dissection of the renal artery itself, and as a consequence of aortic or renal artery interventions including endovascular stenting.

The clinical presentation of renal artery or branch vessel thrombosis without infarction often involves acceleration of hypertension because of renin release, worsening renal function, and even anuria if the entire functioning renal mass is involved. Patients may develop volume overload, pulmonary edema, and symptoms of uremia.

The clinical evaluation of the patient includes ruling out overt renal infarction and defining renal parenchymal viability despite main renal or branch vessel thrombosis. This can be achieved by demonstrating a nephrogram on delayed venous-phase imaging by conventional renal arteriography, computed tomographic angiography (CTA) or contrast-enhanced computed tomography (CT), magnetic resonance angiography (MRA) with gadolinium enhancement, or nuclear isotope scintigraphy. The diagnostic approach is complicated in the setting of reduced renal function because of the concern of nephrotoxicity from radiocontrast dye. In addition, the use of gadolinium with MRA is contraindicated if glomerular filtration rate (GFR) is below 30 ml/min because of the risk of nephrogenic systemic fibrosis.

Treatment involves assessment of the risks versus potential benefits of heroic revascularization procedures. The status of the contralateral kidney and overall residual renal function (RRF) should be weighed against the potential retrievable renal function from the

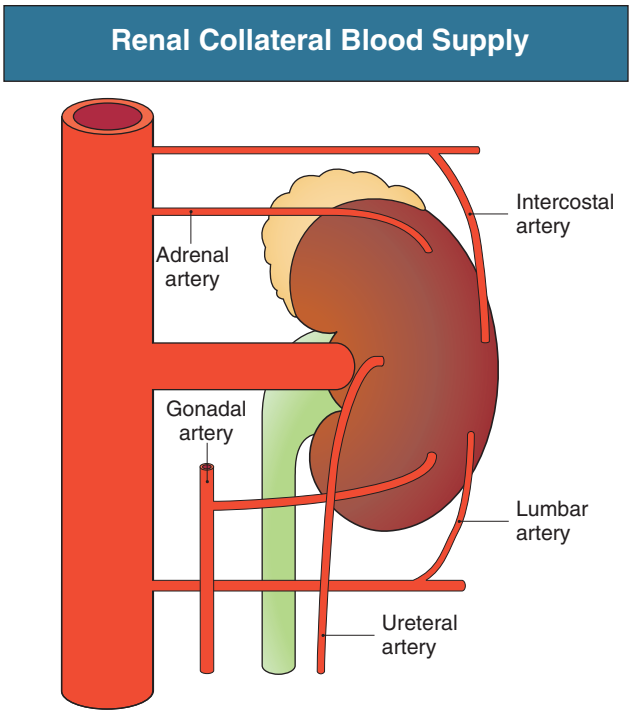

Figure 66-1 Renal collateral circulation. Diagrammatic representation of the potential collateral arterial vessels to the kidney.

underperfused kidney. The size and baseline function of the kidney before the thromboembolic event influence the potential benefits of renal revascularization. The cardiac and anesthesia risk from the intervention, such as surgical thrombectomy or bypass, has to be considered. Last, the intervention should be delayed until the clinical and renal status of the patient has recovered from any transient insults, such as acute kidney injury (AKI), decompensated congestive heart failure (CHF), myocardial infarction, and uncontrolled hypertension.

Renal artery revascularization can be achieved by endovascular thrombolysis, angioplasty, and stenting or by surgical approaches. This can be successful in restoring renal function even in patients with dialysis-dependent renal failure caused by occlusive renovascular disease.[7-9] Predictors of renal recovery are listed in Box 66-2 and include preserved renal size, evidence of a renal "blush" or nephrogram by imaging, recent decline in GFR, and recent baseline creatinine concentration below 3 mg/dl.[10] Figure 66-3 shows thrombosis of a renal artery within a stent placed 1.5 years previously for atherosclerotic renal artery stenosis in a patient with a single functioning kidney. The patient presented with anuric AKI. Percutaneous thrombolytic therapy and renal artery angioplasty restored renal perfusion and renal function.

RENAL INFARCTION

When abrupt interruption of renal blood flow occurs without adequate collateral blood supply, renal infarction may occur. Autopsy series suggest the incidence is between 0.5% and 1.5%. Renal infarction may involve the entire kidney or small areas of the cortex or medulla. Both arterial and venous thrombosis and renal artery embolism can cause renal infarction. The most common presenting symptoms of renal infarction include loin, flank, or abdominal pain with nausea and/or vomiting. Urinalysis often demonstrates microscopic hematuria and proteinuria. Transient or accelerated

Predictors of Recovery of Renal Function in Renal Artery Occlusion
Preserved renal size (>7-8 cm)
Recent baseline serum creatinine <3 mg/dl (284 μmol/l)
Recent rapid decline in glomerular filtration rate
Nephrogram visible on delayed or venous phase imaging
Distal reconstitution of occluded renal artery

Box 66-2 **Predictors of recovery of renal function in renal artery occlusion.**

hypertension may occur secondary to abrupt release of renin from the infarcted segment. Up to one quarter of cases are asymptomatic, identified only by enhancement or functional defects on renal imaging. Transient elevations in serum creatinine are not uncommon. When bilateral occlusion of both kidney arteries or infarction of a single functioning kidney occurs, the patient presents with oliguric or anuric AKI. Systemic signs of renal infarction include leukocytosis and fever. Tissue injury results in elevations of serum enzymes, most commonly lactate dehydrogenase, but transaminases, creatine kinase, and alkaline phosphatase may also be elevated.[12,13]

Diagnosis

Because the presenting symptoms are common to a number of disorders, a high clinical suspicion is required for the diagnosis of renal infarction. CT with intravenous contrast administration is the imaging modality of choice for demonstrating areas of the renal cortex that are not perfused. CT may demonstrate focal wedge-shaped areas of decreased attenuation or global infarction with or without a rim sign indicating intact collateral circulation to the renal cortex.[14] Perinephric stranding may be present as well. It is not uncommon to see simultaneous infarcts in the spleen or liver. Other potential imaging techniques include MRA with gadolinium (if GFR remains above 30 ml/min) or as time-of-flight or phase-contrast imaging, or nuclear scintigraphy with dimercaptosuccinic acid (DMSA) (Fig. 66-4). When the entire kidney is underperfused, it is often difficult to determine whether there may be salvageable renal parenchyma. Studies in experimental animals with acute renal artery occlusion have shown that the collateral circulation can maintain renal viability for up to 3 hours after occlusion.[15] In patients with underlying ASRVD, collateral vessels may be better developed and renal viability may be maintained for days to weeks. In these patients, urgent arteriography to identify the location of the arterial thrombosis or embolus may allow percutaneous or surgical revascularization.

Etiology

The most common causes of renal infarction are trauma, renal artery embolism from cardiac thrombus, and iatrogenic complications of endovascular procedures (Box 66-3). Spontaneous renal artery thrombosis or dissection is most often associated with atherosclerotic disease of the aortic or renal arteries, but other vascular causes include fibromuscular dysplasia, Takayasu arteritis, polyarteritis nodosa, Marfan syndrome, and Ehlers-Danlos syndrome with

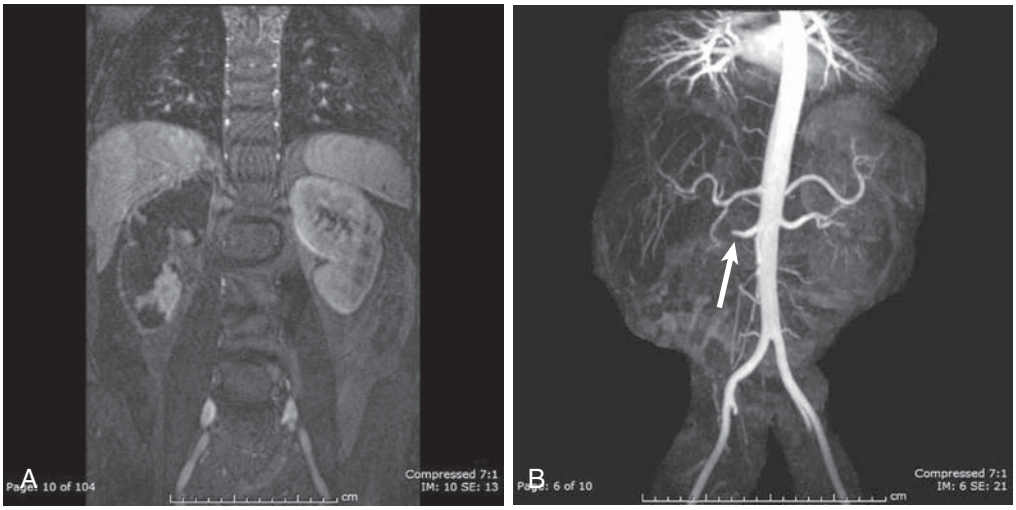

Figure 66-4 Renal infarction demonstrated by gadolinium-enhanced magnetic resonance imaging and magnetic resonance angiography (MRA) of the kidneys and renal arteries. Atrial fibrillation
Cardiac mural thrombi
Valvular heart disease
Paradoxical embolism
Tumor or fat embolism
Atheroemboli

Box 66-3 Causes of renal infarction. Bold refers to common causes.

associated dissection or aneurysms. Less common causes of infarction include hypercoagulable states, most commonly nephrotic and antiphospholipid antibody syndromes; inflammatory diseases of the retroperitoneum or aortorenal vasculature; and thrombotic microangiopathies (TMAs).

Thrombosis Caused by Trauma

Traumatic injuries to the renal arteries make up 1% to 4% of all nonpenetrating abdominal trauma. Classically, kidney trauma results from a deceleration injury, such as a fall from a great height with an upright landing on impact. This results in stretching of the renal arteries as the kidneys continue downward after the rest of the body has stopped. The subsequent stretching and recoiling of the renal arteries can result in acute thrombosis, which is typically bilateral. Direct blunt trauma to the loin or flank regions associated with motor vehicle accidents, street fights, and sports injuries can also result in renal artery thrombosis.

Evidence of lumbar vertebral injury should raise suspicion in the emergency department for renovascular trauma. Even when this injury is diagnosed early, the success rate for renal revascularization after trauma to the renal vessels remains low, between 0% and 29%.[16] The recently revised renal injury scale classification defines a class V renal injury as either main renal artery or vein laceration, avulsion, or thrombosis. In a series of 3580 traumatic renal injuries from a single institution, class V injuries had a renal salvage rate of only 4.3% and a high nephrectomy rate of 74%.[17]

Injuries to the renal pedicle that result in diminished perfusion to a single functioning kidney or to both kidneys require rapid intervention, and endovascular stabilization of renal blood flow may be helpful as a bridge to more definitive renal revascularization.

Thrombosis Caused by Hypercoagulable Disorders

Clotting disorders, such as protein C or protein S deficiency, antithrombin III deficiency, elevations in factor VIII, and rarely factor V Leiden mutations, can predispose to renal arterial thrombosis and infarction in addition to their association with renal vein thrombosis (RVT). Hypovolemia, polycythemia, and the use of oral contraceptive agents can increase the risk of thrombosis when these underlying disorders are present.

Antiphospholipid antibody syndrome is associated with both arterial and venous thrombotic events and can involve the renal circulation at any level. In patients younger than 50 years, the antiphospholipid syndrome can account for 15% to 20% of all deep venous thromboses and 30% of strokes. It is the most common cause of spontaneous arterial thrombosis. In one report of 16 cases of renal involvement with this syndrome, 15 of 16 patients had either arterial or venous thrombosis, 10 had intrarenal microangiopathy, one had suprarenal aortic occlusion, and one had main renal artery thrombosis.[18] Concomitant thromboses in the mesenteric and cerebral circulation have been reported.[19,20]

Renal Artery Embolism

The kidneys are frequently the target for emboli from thrombi originating in the heart. In one series, 1.4% of the general population had renal artery embolism at autopsy, of which only 2 of 205 cases (1%)

were diagnosed clinically.[21] The prevalences of left and right renal emboli are equal, and 12% of cases are bilateral.[22] Atrial fibrillation, cardiac thrombus after myocardial infarction, atrial myxoma or other cardiac tumors, endocarditis, paradoxical emboli, and aortic thrombus represent most of the conditions associated with renal embolism. Atrial fibrillation is the most common cause, with a rate of embolism four times higher than that of the general population; the highest risk is during the first year after the diagnosis of atrial fibrillation, when anticoagulation is subtherapeutic. When echocardiography is undertaken, cardiac thrombus is only rarely detected. Other causes of renal emboli include fiber or foam related to cardiac bypass procedures, calcium from valve annuli, and even "bullet emboli" in the setting of trauma. Aortic endovascular stenting has been associated with a 10% incidence of new renal infarcts, presumably of embolic origin.[23]

Paradoxical renal artery embolism may occur in patients with right-to-left cardiac shunts. The most common cardiac shunt is a result of atrial septal defects which are present in 9 to 35 cases per 10,000 of the population. The diagnosis of paradoxical embolism requires clinical, angiographic, or pathologic evidence of systemic embolism and the presence of venous thrombus along with an abnormal communication between the right and left circulations and a favorable pressure gradient (typically diagnosed by "bubble" echocardiography) for the passage of clot from the right to the left side of the heart.

The clinical presentations of renal artery embolism mirror those of renal infarction (Table 66-1).[22] Pain is present in more than 90% of cases confirmed by radiologic imaging techniques. It is unclear from the literature how many go undiagnosed because of lack of clinical symptoms. There is a 30-day mortality rate of 10% to 13% among patients experiencing renal embolism in the setting of atrial fibrillation.[24] Up to 40% of cases have at least transient reduction in renal function.

Although angiography is the gold standard for diagnosis of renal artery embolism, nuclear isotope scanning is also very sensitive (97%). Contrast-enhanced CT detects 80% of renal embolic events.[22] In other reports, CT or CTA has a sensitivity nearly matching that of renal angiography.

Clinical Presentation of Renal Embolism

Renal Embolism or Infarction	Atheroembolic Renal Disease
Clinical Signs and Symptoms	
Flank or loin pain (91%) Fever (49%) Nausea or vomiting (40%) Oliguria (16%) Transient hypertension (common)	Flank, abdominal, back pain (rare) Fever (common) Malaise, failure to thrive (common) Nonoliguria (common) Labile hypertension (common) Skin manifestations 60% Livedo reticularis Blue toes
Laboratory Abnormalities	
Elevated creatinine (53%) Elevated LDH (91%) Elevated CPK (rare) Leukocytosis (85%) Elevated transaminases (rare) Hematuria (72%)	Elevated creatinine (100%) Elevated ESR (97%) Elevated CPK or LDH 38% to 60% Leukocytosis (57%) Elevated amylase (57%) Eosinophilia (57%) Eosinophiluria (rare) Hematuria, transient proteinuria (common) Bland sediment (common) Hypocomplementemia 25%-70%
Diagnostic Testing	
Contrast-enhanced CT or MRI Nuclear imaging, DMSA Renal angiogram Time of flight noncontrast MRA	Tissue biopsy: skin, muscle, kidney

Aortic and Renal Artery Dissection

Aortic dissection can involve the origin of either renal artery, with the false lumen occluding the vessel and impairing renal perfusion. In this setting the predictors of renal salvage are the same as those for occlusion caused by atherosclerotic renal artery stenosis and include preserved renal size, collateral circulation permitting renal viability, and blush on imaging studies. In one report, despite renal atrophy, aortic stent graft placement allowed renal reperfusion and restoration of renal size and function.[25] Aortic dissection occurs most commonly in association with atheromatous aneurysmal vascular disease of the thoracic aorta, but it can occur in collagen disorders, such as Ehlers-Danlos type IV or Marfan syndrome, and with arteritis, such as Takayasu disease. Although MRA is nearly 100% sensitive for diagnosis of aortic dissection, CTA has a sensitivity of 93% and is more readily available, has a more rapid turnaround time, is less dependent on patient factors, and is usually the imaging modality of choice.

Dissection of the renal artery can occur after percutaneous renal angioplasty or stenting, spontaneously with ASRVD or fibromuscular dysplasia of the renal artery, or as a complication of renal artery aneurysms (Fig. 66-5). The pathogenesis is thought to be caused by penetration of blood into the arterial wall via an intimal tear or bleeding from the vasa vasorum. Risk factors for dissection include older age, hypertension, connective tissue disorders, pregnancy, bicuspid aortic valve, and coarctation of the aorta. A high index of suspicion and rapid imaging are critical to improve chances of patient and renal survival. Digital subtraction angiography is the most sensitive imaging modality because the lesion often starts in the midvessel or distal vessel and can involve branch or small polar arteries less well seen on MRA or CTA.[26] The optimal treatment of renal artery dissection is unclear. Revascularization using surgical or endovascular techniques may achieve retrieval or stability of renal function and improvement in renovascular hypertension depending on the degree of damage to the kidney beyond the dissection.

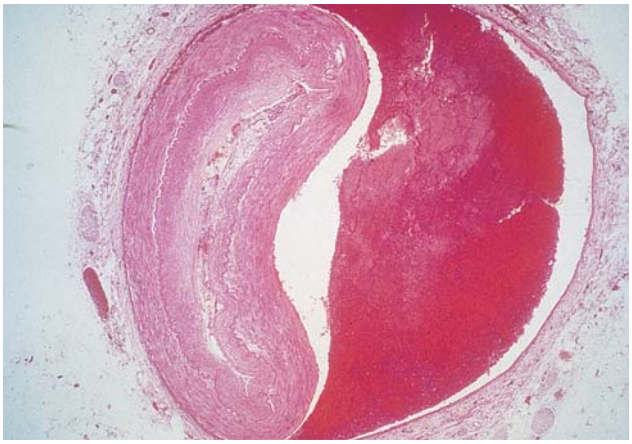

Figure 66-5 Cross section of a renal artery with dissection after renal angioplasty. Shown is the dissection with thrombus filling the false lumen. The kidney could not be salvaged.

Figure 66-6 Middle aortic syndrome. Angiogram showing typical smooth narrowing of the aorta. Bilateral stenosis of paired renal arteries is present. *(From reference 30.)*

Middle Aortic Syndrome

A rare entity, middle aortic syndrome is a diffuse narrowing of the aorta, considered a form of coarctation, causing renovascular hypertension (Fig. 66-6).[30] The cause is unknown, but associations with fibromuscular dysplasia, congenital anomalies, neurofibromatosis, Williams syndrome, and Takayasu arteritis have been reported. It can present as renal artery atresia, stenosis, or aortic thrombosis involving the renal arteries. Middle aortic syndrome usually presents as renovascular hypertension in infancy and can cause claudication of the lower extremities as well as mesenteric ischemia. Repair of middle aortic syndrome for treatment of hypertension and prevention of organ ischemia and before thrombosis is the goal. Angioplasty and stenting of stenotic segments, surgical bypass grafting, and autotransplantation of ischemic organs have been applied in the treatment of this disorder. A recently reported novel approach used tissue expanders to induce longitudinal growth of the aorta allowing for resection of the coarcted segment with end-to-end anastomosis of aortic segments of larger diameter.[27]

Thromboembolic Complication of Endovascular Interventions

Renal artery thrombosis, dissection, laceration, or embolism can occur secondary to vascular interventions, especially those involving placement of endovascular stents.[28] Occlusion of the vessel within the stent can occur many months to years after stent placement, particularly when in-stent restenosis is present. During the past decade, endovascular aortic stents have been used to treat infrarenal abdominal aortic aneurysms. When the stent crosses the orifice of the renal artery, renal perfusion is impaired, and there is a significant risk for renal artery thrombosis.[29] Renal artery stent placement may cause intimal dissection and thrombosis of the renal artery and even aortic dissection. Stent fracture or kinking can be associated with thrombosis of the lumen. Figure 66-7 demonstrates compression of a proximal renal artery stent with associated thrombotic occlusion of the vessel. Careful studies using filters to capture embolic material confirm that renal artery angioplasty with stenting of atherosclerotic renal arteries releases thousands of particles of various sizes in 70% to 100% of cases.[31] Preprocedure treatment with antiplatelet agents and intraprocedural use of embolic protection devices during renal stent implantation are under investigation as means of reducing the frequency of this underdiagnosed cause of renal infarction and chronic kidney disease (CKD).[32,33]

Renal Artery Aneurysms

Renal artery aneurysms are rare and associated most commonly with atheromatous, fibromuscular, and vasculitic disease (Fig. 66-8). They may be asymptomatic or cause renovascular hypertension, which is the presenting feature in 55% to 75% of cases. Thrombosis within an aneurysm can lead to distal thrombotic emboli and renal infarcts. Aneurysms with diameters of more than 1.5 cm have a higher risk of rupture. Elective repair of large renal aneurysms should be considered in women of childbearing age because of the risk of rupture during the third trimester of pregnancy and in patients with renovascular hypertension. Other complications of renal artery aneurysms include vessel dissection and arteriovenous fistula formation.

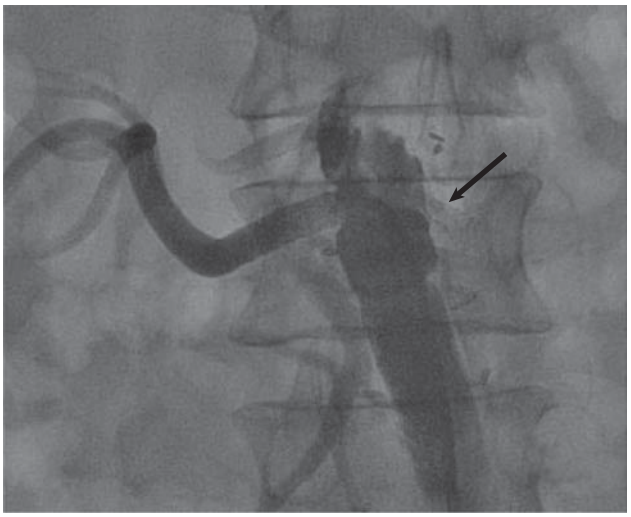

Figure 66-7 Thrombosis of renal artery complicating renal artery stenting. Right and left renal artery stents. The left renal stent *(arrow)* is triangular, indicating crimping of the proximal portion, which in this patient was associated with thrombosis of the renal artery, seen here as no contrast entering the vessel. The right renal stent is patent.

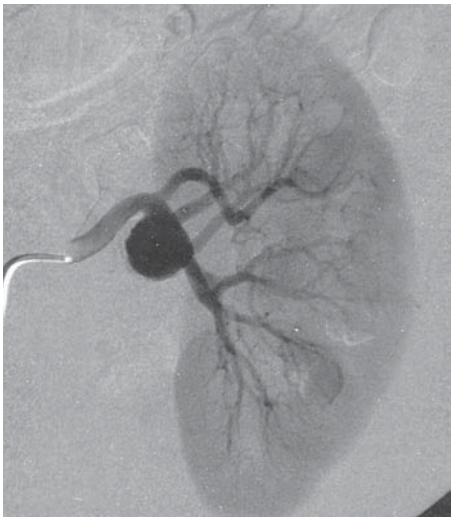

Figure 66-8 Renal artery aneurysm. Angiogram showing large renal artery aneurysm. The aneurysm is patent but is a risk factor for renal artery thrombosis.

Rare Causes of Renal Infarction

Rare causes of renal infarction include autoimmune diseases, such as Behçet syndrome, systemic lupus, and other autoimmune diseases; Henoch-Schönlein purpura (HSP); senile systemic amyloidosis; chronic Chagas disease; and drug abuse, such as intravenous injection or nasal insufflation of cocaine or even marijuana smoking. The exact mechanism involved in the pathogenesis of renal infarction in some of these conditions is unclear.

Treatment of Acute Renal Vascular Catastrophe

In the setting of renal infarction, a search for the cause of the renal vascular compromise should be undertaken to determine whether it is embolic or thrombotic. Treatment of the infarction itself is usually conservative and includes pain control and treatment of sometimes labile hypertension. If renal artery occlusion is caused by thrombosis associated with a hypercoagulable state or an embolism from a central source, systemic anticoagulation is indicated. Common sources include atrial fibrillation, atrial or mural thrombi, intracardiac mass, and valvular lesions; therefore echocardiography is indicated. Salvage of the kidney by acute thrombolytic therapy has also been attempted with limited success. There is no evidence that thrombolytic therapy can limit infarct size if it is administered in the acute setting.

Traumatic renal vascular occlusion often leads to renal infarction within 3 to 6 hours. Attempts at renal salvage under these circumstances are often unsuccessful unless the diagnosis is made immediately on presentation and immediate measures toward renal revascularization are undertaken. Renal angiography with intrarenal thrombolytic therapy and/or stenting can provide renal reperfusion in some cases even several days out from the thrombotic event.[34]

Thrombosis of atherosclerotic renal arteries, because of prior collateral development in most cases, often results in marked ischemia but not infarction of the kidney and allows consideration of optimal surgical and sometimes percutaneous endovascular revascularization to restore renal function.

ATHEROEMBOLIC RENAL DISEASE

Atheroembolic renal disease is common and may account for up to 10% of unexplained renal failure in the elderly. It most commonly occurs after arterial manipulation in arteriography, vascular surgery, angioplasty, and stent placement. In patients with extensive atherosclerosis with unstable plaques, spontaneous atheroemboli may occur, especially after the administration of oral or intravenous anticoagulants or thrombolytic agents. The incidence of atheroembolic disease after vascular interventions is unclear, but recent data suggest that it is common.[35] A study evaluated the frequency of renal perfusion defects in patients after endovascular stent repair of abdominal aortic aneurysms; 18% of the cases had identifiable renal perfusion defects, and the occurrence of these infarcts was significantly associated with atherosclerotic burden.[36] Atheroembolism may therefore be expected to occur in up to 30% of patients with extensive aortic atherosclerosis after endovascular intervention. Ipsilateral renal artery stenosis may be present in up to 80% of patients with renal cholesterol embolization. Conversely, cholesterol emboli were found in the kidneys of 36% of the patients undergoing surgical revascularization.[37] Thus, cholesterol embolization may contribute to the loss of renal function in patients with atherosclerotic ischemic renal disease.

Most patients are older than 50 years with generalized atherosclerosis and have a history of recent endovascular procedures or signs or symptoms of atherosclerotic vascular disease, such as claudication, abdominal pain, angina, myocardial infarction, transient ischemic attacks, retinal artery emboli, amaurosis fugax, stroke, abdominal aortic aneurysm, renovascular hypertension, or ischemic renal disease. Many have a history of risk factors for atherosclerosis, including hypertension, hypercholesterolemia, diabetes, and smoking.

Clinical Presentation

Acute or subacute renal impairment caused by renal microinfarctions developing as long as 6 months after the atheroembolic insult is the most common presentation leading to the diagnosis of cholesterol embolization. The clinical picture is multisystemic in nature and involves the kidneys in about 75% of patients. At autopsy, renal involvement is observed in 92% to 100%.

If a large shower of atheroemboli causes significant tubular damage, the AKI may have an oliguric phase characterized by a high fractional excretion of sodium. More often, the renal failure is nonoliguric and progressive because of ongoing embolization from a nidus of unstable ulcerative plaque. Some patients have only a moderate impairment in renal function, and others progress to end-stage renal disease (ESRD). Atheroembolic renal disease can also present as a more slowly progressive, often stair-stepping subacute renal impairment. Urinalysis findings are nonspecific but may include mild proteinuria, microhematuria, pyuria, and eosinophiluria. Renin release by ischemic zones in areas of embolization can lead to labile hypertension early in the course, sometimes associated with transient marked proteinuria. Fever, often low grade, is characteristic.

Although the kidneys are the organs most commonly involved, extrarenal cholesterol embolization will provide clues for diagnosis. Cutaneous findings in up to 60% of patients at initial presentation include blue or purple toes, mottled skin or livedo reticularis, petechiae, and purpura or necrotic ulceration in areas of skin embolization, such as the lower back, buttocks, lower abdomen, legs, feet, or digits (Fig. 66-9).

Other organs often involved include the spleen (in 55% of cases), pancreas (52%), gastrointestinal tract (31%), liver (17%), and brain (14%). This involvement can result in a number of clinical symptoms, including abdominal or muscle pain, nausea, vomiting, ileus, gastrointestinal bleeding, ischemic bowel, hepatitis, angina, and neurologic deficits. When retinal cholesterol embolization occurs, refractile yellow deposits known as Hollenhorst plaques may be seen at the bifurcation of retinal vessels on funduscopic examination (Fig. 66-10).

Figure 66-9 Livedo reticularis. The mottled skin changes associated with peripheral cholesterol embolization may be seen over the legs, buttocks, back, or flank and may be transient.

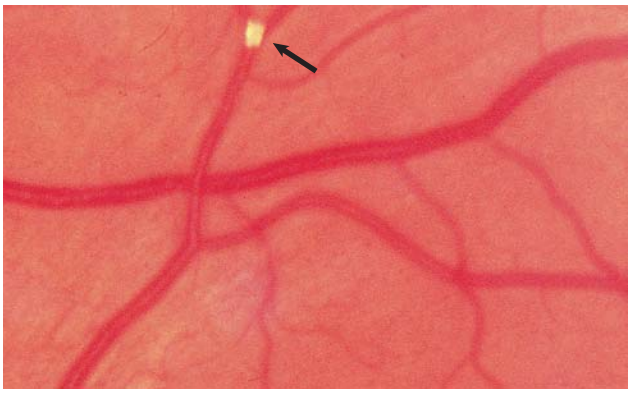

Figure 66-10 Hollenhorst bodies. Cholesterol embolus of a retinal arteriole *(arrow). (Courtesy Richard Mills, University of Washington, Seattle.)*

Diagnosis

The diagnosis of atheroembolic renal disease is suspected when subacute renal failure develops after a vascular intervention in the presence of livedo reticularis. Myriad laboratory abnormalities indicative of tissue injury are associated with cholesterol embolization, including elevated sedimentation rate (in 97% of cases), elevated serum amylase (60%), leukocytosis (57%), anemia (46%), hypocomplementemia (25% to 70%), and elevated lactate dehydrogenase and creatine kinase (38% to 60%). Eosinophilia, which may be transient, is seen in up to 57% of patients. The presence of eosinophilia should raise suspicion for atheroembolic renal disease in the appropriate clinical setting. Serum lactate is usually not elevated unless concomitant ischemic bowel is present. Definitive diagnosis is made by biopsy of an involved organ or system. A skin or muscle biopsy in an involved area may preclude the need for renal biopsy. In most circumstances, the diagnosis is made clinically.

Differential Diagnosis

Cholesterol embolization syndrome may mimic vasculitis, occult infection, neoplasm, or TMA. Contrast nephropathy with nonoliguric acute tubular necrosis (ATN) may also occur after angiography, angioplasty, or aortic vascular surgical procedures but is often more rapid as opposed to the subacute presentation of atheroemboli. Eosinophilia and eosinophiluria, rash, fever, and renal dysfunction may also be misdiagnosed as acute interstitial nephritis (AIN). Chronic cholesterol embolization syndrome may appear similar to hypertensive nephrosclerosis or ischemic renal disease. In the kidney transplant recipient, renal atheroembolism may mimic acute rejection or chronic allograft nephropathy (CAN).

Pathology and Pathophysiology

If clinical or other pathologic evidence has not secured the diagnosis, renal biopsy may be helpful. Diagnosis is based on the presence of birefringent, biconvex, elongated cholesterol crystals or biconcave clefts within the lumina of small vessels left behind in formalin-fixed tissue (Fig. 66-11). Because of the patchy nature of this disorder, open wedge renal biopsy guided by visualization of areas of ischemic infarction of the cortex has a higher likelihood of successful diagnosis than does percutaneous needle biopsy. The pathologist should be alerted by the clinician that cholesterol embolization is in the differential diagnosis before the biopsy specimen is processed. In frozen sections of tissue, the cholesterol material can be identified with polarized light microscopy. The pathologic findings may also include intimal thickening and concentric fibrosis of vessels, giant cell reaction to the cholesterol particles, vascular recanalization, endothelial proliferation, tubulointerstitial fibrosis with both eosinophil and mononuclear cell infiltrates, glomerular ischemia, and even focal segmental glomerulosclerosis (FSGS).[38] In the kidney, the most commonly affected vessels are the arcuate and interlobular arterioles, leading to patchy ischemic changes distal to these vessels.

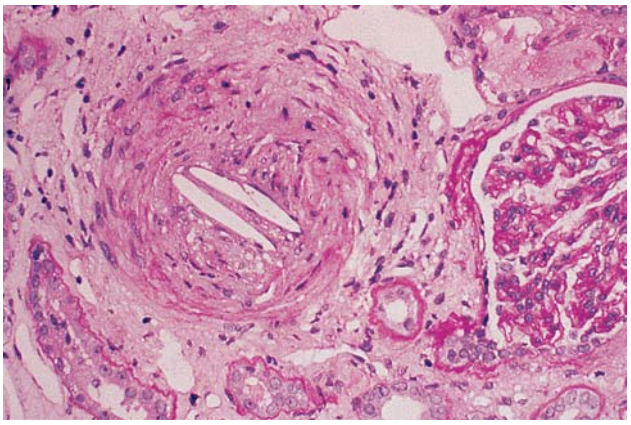

Figure 66-11 Cholesterol emboli in kidney biopsy specimen. Biconvex cholesterol clefts with giant cell reaction and recanalization of the lumen of a medium-sized renal vessel. (Periodic acid–Schiff stain.) *(Courtesy Dr. R. Horn, Vanderbilt University, Nashville, Tennessee.)*

Natural History

The natural history is determined by the extent of organ involvement and the degree of the embolization. In one series of cases, renal function declined rapidly in 29%, with a more slowly progressive course seen in 79%.[39] Among the latter group, the decline in renal function was thought to result from a combination of cholesterol embolization and ischemic renal disease. In another series, the peak serum creatinine concentration occurred within 8 weeks after an angiographic procedure.[40] Patients may also manifest acute or subacute renal impairment followed by partial recovery of renal function. Conversely, the outcome can be dismal, particularly when cerebral embolization occurs or when there is a large unstable atheromatous burden. Some patients with cholesterol embolization may develop ESRD. These patients have a mortality rate of 35% to 40% during 5 years, even when dialysis is offered.[40]

Treatment

There is no specific therapy for the cholesterol embolization syndrome. Therefore, its risk should be considered before angiographic and vascular surgical procedures are undertaken in patients with diffuse, extensive atherosclerotic disease. Because prevention is the most effective management strategy, patients with extensive aortic atherosclerosis should be considered for alternative approaches to cardiac catheterization, such as through the brachial artery. If vascular intervention is performed, signs of embolization should be sought both in the immediate postoperative period and for several months thereafter. When it is feasible, distal embolic protection devices should be used to trap embolic material for removal from the circulation to avoid end-organ damage by embolic debris.[41]

After the diagnosis of cholesterol embolization has been established, further endovascular interventions should be avoided. Poor outcomes have been reported in patients with cholesterol emboli who subsequently undergo coronary artery bypass surgery. When clinical factors dictate the need for aortic, renal, or peripheral arterial surgery, optimal timing and surgical approach are critical.

Conversely, there is a growing surgical experience with segmental aortic replacement to remove the source of emboli, particularly when atheroembolic disease occurs spontaneously. Transesophageal echocardiography is often used to identify mobile ulcerative plaque in the aorta to guide intervention.

Angiotensin-converting enzyme (ACE) inhibitors are effective in managing the labile hypertension seen early in the course of cholesterol embolization. Corticosteroids have been used with some success in patients with systemic cholesterol embolization and associated inflammatory symptoms.[42] There have also been several reports documenting improvement or stabilization of skin signs of cholesterol embolization after administration of statins,[43] which should be part of the treatment of the generalized atherosclerosis in these patients. Cholesterol embolization has also occurred after treatment with anticoagulants. Although direct causality between anticoagulants and cholesterol embolization has not been established, the proposed mechanism is that anticoagulants prevent thrombus organization over the ulcerative plaques. Therefore, anticoagulation should be avoided in the acute setting of cholesterol embolization unless a strong life-threatening indication for anticoagulation is present. This has implications for the delivery of renal replacement therapy, if indicated.

TRANSPLANT RENAL ARTERY STENOSIS AND THROMBOSIS

Epidemiology

Transplant renal artery stenosis is a common post-transplantation complication occurring most often in the period between 3 months and 2 years after transplantation. The highest reported incidence is 23% in a patient cohort screened angiographically, compared with reported incidences of 1.3% to 12% when other screening tests are used.[44] In many cases, anastomotic stenoses are not hemodynamically significant.[44] Renovascular complications, including renal artery stenosis and RVT, are more common in deceased donor than in living donor transplants and in allografts with multiple renal vessels.[45] The use of pediatric kidneys in adult recipients is associated with a higher rate of stenosis because of smaller donor vessel size, leading to greater turbulences and mismatch between donor and recipient vessels. As the transplant population ages, there has been increasing recognition of another subset of patients with pseudo–transplant renal artery stenosis, in which vascular disease proximal to the allograft artery, particularly involving the iliac vessel, results in renal ischemia.

Pathogenesis

The pathophysiologic basis for transplant renal artery stenosis is multifactorial and may include atheromatous disease in the donor artery, intimal scarring and hyperplasia in response to trauma to the vessel during harvesting, and anastomotic stenosis, which is most commonly associated with end-to-end anastomoses and may be related to suture technique. In end-to-side anastomoses, stenosis tends to develop in the postanastomotic site, suggesting that turbulence or other hemodynamic factors play a role. Immunologic causes of transplant renal artery stenosis have also been proposed on the basis of histologic similarities with chronic vascular rejection and association with prior acute rejection. Other proposed pathogenic mechanisms include calcineurin inhibitor (CNI) toxicity and cytomegalovirus (CMV) infection. Renal artery stenosis occurring many years after transplantation most often represents atherosclerotic disease in the renal artery.

Clinical Presentation

Patients typically present with new-onset hypertension or difficult-to-control blood pressure (BP) with or without graft dysfunction occurring 3 to 24 months after transplantation. Patients may also present with AKI. When the stenosis occurs in the iliac artery above the anastomosis of the transplanted renal artery (pseudo–transplant renal artery stenosis), the patient often presents with ipsilateral lower extremity claudication associated with hypertension and worsening renal function in the allograft.[46] Systolic bruits over the transplant are not diagnostic because they may represent turbulent flow in the main vessels in the absence of stenosis or biopsy-related arteriovenous fistulas. Risk factors for the development of renal artery stenosis include male gender, hyperlipidemia, and elevated serum creatinine at discharge from transplantation.

Diagnosis

Renal duplex sonography is the screening test of choice for transplant renal artery stenosis because the vessel is superficial and easy to interrogate. Peak systolic velocity of less than 180 cm/s can reliably rule out significant renal artery stenosis in the transplant vessel. The ratio of velocity in the renal and iliac vessels and the resistive index in the kidney have been shown to predict the hemodynamic response to percutaneous transluminal angioplasty. Phase-contrast MRA has an advantage over arteriography in viewing tortuous renal arteries and may provide information additional to Doppler ultrasound regarding the aorta and iliac vessels. However, with MRA, the surgical clip artifact may obscure the proximal renal artery, and it often cannot resolve peripheral renal vessels. High false-positive rates are associated with sharp anastomotic angles. CTA has the advantage over MRA from an imaging standpoint but requires a large amount of contrast material. The gold standard is selective renal angiography of the transplant and iliac artery. In situations in which the risk for contrast-induced nephrotoxicity is high, carbon dioxide angiography can be performed safely.

Treatment

Transplant renal artery stenosis causing renovascular hypertension or decline in kidney function may require intervention.[47] Angioplasty is the preferred initial approach to transplant renal artery stenosis, with initial success rates of up to 75% and patency for follow-up periods of up to 30 months. The average complication rate for angioplasty of the allograft artery is 10%. It is often unsuccessful when there is arterial kinking and is associated with a high complication rate in this setting. The reported rates of late restenosis are 10% to 33%, necessitating repeated procedures or stent placement at the site of restenosis or in the iliac artery when pseudo–transplant renal artery stenosis is caused by iliac atherosclerotic occlusive disease proximal to the takeoff of the transplant artery.[48]

Surgical revascularization is reserved for patients in whom angioplasty or stenting has been unsuccessful or complicated. Surgical renal revascularization is difficult and is associated with significant mortality in the transplantation setting. Extensive fibrosis develops around the allograft and often involves the renal vessels, making surgical access to the renal vessels risky. Complications include graft loss (in 15% to 30% of cases), ureteral injury (14%), and death (5%).

RENAL VEIN THROMBOSIS

Renal vein thrombosis is rare and primarily observed in children with severe dehydration (with an incidence in neonates of 0.26% to

0.7%) or in adults with nephrotic syndrome, renal tumors, or hypercoagulable states and after surgery or trauma to the renal vessels.[49] When it occurs in adults, the diagnosis is often never considered. Thrombosis of the longer left (7.5 cm) renal vein may also involve the ureteric, gonadal, adrenal, and phrenic branches that drain into the left vein, whereas on the right side, the adrenal and gonadal veins drain directly into the IVC. The renal veins also communicate with perirenal veins outside of the Gerota's fascia as part of the retroperitoneal collateral venous network: tributaries of the portal system, lumbar, azygos, and hemiazygos. Because of this network of venous complexes, occlusion of the left renal vein results in enlargement of the systemic collateral vessels and provides some protection against infarction.

Acute Versus Chronic Renal Vein Thrombosis

Experimentally, acute RVT is associated with immediate enlargement of the kidney with a marked increase in renal vein pressure, leading to a marked decrease in renal arterial flow. Complications include hemorrhagic infarction, kidney rupture, and retroperitoneal hemorrhage. In the dog, the kidney enlarges during the course of 1 week, then proceeds to atrophy as a result of progressive fibrosis. In contrast, slow, progressive ("chronic") thrombosis may allow collateral formation, resulting in minimal symptoms.

Clinical Presentation

Acute RVT is usually symptomatic and associated with loin, testicular, or flank pain and even the development of scrotal swelling or hydrocele; low-grade fever; and in the setting of a single kidney or renal transplant, symptoms of renal failure. Nausea and vomiting often accompany acute RVT, and symptoms might be confused with acute pyelonephritis. Leukocytosis can accompany acute thrombosis. Clinical signs include renal enlargement, which in infants manifests as a palpable abdominal mass. Hematuria is nearly universal and most often is microscopic. The high venous pressures result in a marked increase in proteinuria. Urinalysis sometimes reveals evidence of proximal tubule dysfunction, such as glycosuria. Oliguric renal failure occurs when RVT results in renal infarction of both kidneys or in patients with a single kidney. In some patients, RVT is diagnosed only after the patient has developed an acute pulmonary embolus and the source of the embolus is investigated or with worsening of renal function in the setting of proteinuric CKD.

Chronic RVT may be asymptomatic and is associated with extensive venous collaterals and minimal impairment of renal function and structure. Often, however, microhematuria, increase in proteinuria, and evidence of either reduced GFR or tubular dysfunction are present, particularly when indices of differential renal function are sought, such as with nuclear studies.

When RVT causes renal infarction, the distribution of the hypoperfused region tends to be medullary or subcortical. The renal impairment tends to be patchy and subtotal. These patients can develop severe hypertension acutely. The swollen kidney can rupture the capsule and result in massive retroperitoneal hemorrhage.

Etiology

The causes of RVT are listed in Box 66-4.

Neonatal Renal Vein Thrombosis

Renal vein thrombosis occurs in neonates in situations of dehydration and thrombophilia. The classic presentation triad includes a palpable abdominal mass, hematuria, and thrombocytopenia. Proteinuria, tubular dysfunction, reduced GFR, and hypertension may be associated. There is a greater predilection for development of RVT in male infants, with 67% of the reported cases occurring in boys.[50] Most cases are unilateral, with the left renal vein more commonly affected. Complications of neonatal RVT may include adrenal hemorrhage, renal atrophy, renal impairment, and hypertension. In neonates, the diagnosis is made by renal ultrasound and Doppler study of the renal veins. The strongest predictor of poor renal outcome is

Causes of Renal Vein Thrombosis

- **Malignancy**
  - **Direct invasion of tumor into the renal vein**
  - Retroperitoneal adenopathy, fibrosis, or tumor
  - Extension of inferior vena cava (IVC) obstruction
  - Hypercoagulable state with malignant disease
- **Nephrotic syndrome**
  - **Membranous nephropathy**
  - Lupus nephritis
- **Hypercoagulable states**
  - **Antiphospholipid antibody syndrome**
  - Factor V Leiden mutation
  - Antithrombin III deficiency
  - Protein S and C abnormalities
  - Heparin-induced thrombocytopenia
  - Birth control pills
  - Polycythemia
  - Others
- **Surgical or procedure complication**
  - **After aortic aneurysm repair or rupture**
  - After pyeloplasty
  - After partial nephrectomy
  - After anterior spinal fusion
  - After IVC filter or PICC
  - After embolization of gastric varices
- **Trauma**
- **Pregnancy complication**
- **After renal transplantation**
  - **Technical complication**
  - Acute cellular or vascular rejection
  - OKT3 and calcineurin inhibitor therapy
  - Sticky platelet syndrome
  - **Hypercoagulable state**
- **Infections**
  - **Acute pyelonephritis**
  - Pyogenic spondylitis
- **Inflammatory disorders**
  - **Pancreatitis**
  - Inflammatory bowel disease
  - Inflammatory aortic aneurysm
  - Behçet disease
  - Budd-Chiari syndrome
- **Neonatal**
  - **Dehydration**
  - Congenital

marked decrease in perfusion detected on initial Doppler interrogation.[51] The optimal treatment approach to neonatal RVT is controversial. Fibrinolytic therapy may be associated with bleeding complications, including adrenal hemorrhage, and is usually not successful in restoring renal function unless it is undertaken within 24 hours of the thrombotic event.[52]

Nephrotic Syndrome

Patients with nephrotic syndrome have increased risk of venous thromboembolism; deep venous thrombosis is most commonly diagnosed (see Chapter 15).[53] The prevalence of RVT in nephrotic syndrome is unclear because it is largely undiagnosed; studies report frequencies from 5% to 62%.[49] Numerous abnormalities promoting a prothrombotic state occur secondary to heavy proteinuria. It is interesting to note that RVT appears to be more common in membranous nephropathy (MN) and lupus nephritis (LN), but RVT can complicate any cause of proteinuric renal disease. In this setting, RVT can lead to an increase in baseline proteinuria and present with AKI superimposed on chronic renal impairment.

After Renal Transplantation

Renal vein thrombosis after transplantation is rare and occurs in less than 0.5% to 4% of transplants, usually within the first week after transplantation.[54] It usually leads to graft infarction, but rupture of the allograft can also occur. Causes include technical issues related to the anastomosis, compression of the renal vein by fluid collections, volume depletion, acute rejection, and hemostatic and hypercoagulable states. Factor V Leiden mutation, which occurs in 2% to 5% of the population, is a risk factor for transplant RVT and should be sought when it occurs. Another syndrome known as *sticky platelet syndrome* can result in post-transplant RVT. There are some data supporting the protective effects of low-dose aspirin in this population. Immunosuppression with cyclosporine and OKT3 may increase the risk of RVT. Renal salvage is possible with early diagnosis, surgical exploration, and thrombectomy.[55]

Pregnancy

Pregnancy and the postpartum state are hypercoagulable states. There have been reports of spontaneous RVT in the postpartum period associated with renal infarction. RVT complicating pregnancy should be suspected when clinical clues such as flank pain and hematuria are present.

Malignant Disease

Malignant disease accounts for the greatest number of cases of RVT.[56] RVT can result from invasion of tumor of renal origin into the renal vein. About half of renal cell carcinomas are associated with RVT at autopsy. In addition, neoplasia originating in the renal vein or IVC, such as leiomyosarcoma or cavernous hemangioma, can cause RVT. Extrinsic compression of the renal vein by a tumor or retroperitoneal fibrosis may also cause this syndrome.

Diagnosis

Diagnosis of RVT requires imaging. Conventional ultrasound may demonstrate alterations in size and echogenicity. Renal duplex sonography may show increases in resistive indices, and ultrasound can directly visualize the filling defect, but this may depend on the angle of the vein, the body habitus of the patient, and the operator's experience. In neonates, renal Doppler ultrasound is the diagnostic study of choice. Sonographic findings in neonatal RVT include renal enlargement, loss of corticomedullary differentiation, and linear echogenicities radiating from the renal hilum as a result of interlobular and interlobar venous clot. Later scans may show linear, punctuate, or lace-like calcifications in these regions, representing calcified thrombi. Up to 80% of neonates with RVT have clot extending into the IVC. In patients with renal transplant RVT, the duplex waveform pattern demonstrates reversal of diastolic flow, which is not pathognomonic or specific for RVT. Imaging of the renal vein with MRA or other imaging modalities are needed to confirm transplant RVT. In adults, both CT and magnetic resonance (MR) venography have much greater sensitivity than renal vein duplex studies for the diagnosis of RVT. CT venography requires a significant contrast load, making MR venography preferable in patients with allergy to contrast agents or those at risk for contrast-associated nephrotoxicity. Figure 66-12 is a CT venogram demonstrating unilateral RVT.

Treatment

Treatment is controversial and depends on the setting, acuteness, and renal consequences. If there is no contraindication, most patients are treated with systemic anticoagulation acutely. In adults with acute RVT that is compromising renal function, catheter-directed thrombolytic therapy with urokinase or tissue plasminogen activator with or without percutaneous mechanical thrombectomy can be successful in regaining patency of the vessel and restoring renal function.[57] There are reports of successful thrombolytic therapy in pregnancy-associated RVT. The long-term benefit of this approach is unclear, and it is less successful when the thrombotic process begins in the small intrarenal venules rather than in the major veins, as is often the case when primary renal disease or a hypercoagulable state initiates the process. In neonatal RVT, which often results in renal nonfunction, thrombolytic therapy and anticoagulation have been used with variable results. In two recent reports of neonatal RVT, supportive care was recommended for unilateral RVT without extension into the IVC, whereas thrombolytics were used for bilateral cases with impending renal failure.

Surgical interventions include nephrectomy, thrombectomy, and retroperitoneal surgery for non–renal-associated abnormalities, such as tumor, retroperitoneal fibrosis, aortic aneurysm, and acute pancreatitis. Surgery tends to be reserved for situations in which the RVT results in hemorrhage from renal capsular rupture or for long-term consequences of RVT, such as hypertension or infection of a nonfunctioning kidney resulting from previous RVT.

A conservative approach may be favored when left RVT occurs because of the extensive collateral venous supply on that side,

ultimately allowing venous drainage and improvement in renal function. Systemic anticoagulation is indicated acutely to prevent extension of thrombus into the IVC and for prevention of pulmonary emboli. Anticoagulation should be continued indefinitely in patients with persistent hypercoagulable state after RVT. In addition, eventual recanalization of the venous system can result in delayed improvement in renal function as measured by nuclear medicine studies.

SECTION XII

Geriatric Nephrology

CHAPTER 67

Geriatric Nephrology

Mitchell H. Rosner, Edgar V. Lerma, and Sundararaman Swaminathan

Aging is associated with a decline in kidney function, which can manifest as early as the fourth decade of life and accelerates between the fifth and sixth decades. These changes affect glomerular and tubular function, systemic hemodynamics, and body homeostasis. This chapter focuses on the management of the population older than 65 to 70 years.

AGING-ASSOCIATED STRUCTURAL CHANGES

Anatomic Changes

The human kidney reaches a maximum size of approximately 400 g (12 cm in length) in the fourth decade of life. A natural decline of approximately 10% in renal mass per decade then follows. This natural decline is associated with cortical thinning and decrease in the number of functional nephrons.

Glomerular Changes

Structural glomerular changes with age include basement membrane thickening as well as development of focal and segmental or, rarely, global, glomerulosclerosis, which increases to 10% to 30%, and in some studies even exceeding 70% of glomeruli by the eighth decade (Figs. 67-1 and 67-2).[1] Preserved glomeruli often show an increase in overall tuft cross-sectional area, consistent with glomerular hypertrophy.[2] In aging mice and rats a strong relationship has been demonstrated between the glomerular hypertrophy and glomerulosclerosis, consistent with the hypothesis that glomerular hypertrophy may actually predispose to the development of glomerulosclerosis.[3] Neither kidney function nor chronic kidney disease (CKD) risk factors can explain the strong association between age and glomerulosclerosis in healthy adults.[4]

Tubular and Interstitial Changes

Tubulointerstitial injury associated with aging is most pronounced in the outer medulla, with tubular dilation and atrophy, mononuclear cell infiltration, and interstitial fibrosis. Some tubules (especially in the distal tubule and collecting duct) may develop small diverticuli; it has been suggested that these diverticuli play a role in the development of upper urinary tract infections (UTIs; pyelonephritis) by harboring bacteria, thereby predisposing to recurrent infection.[5]

Vascular Changes

Arterioles often develop hyalinosis with aging. Thickening of the arterioles with an increase in the medial thickness/lumen diameter ratio is common with aging but is observed almost exclusively in hypertensive individuals.[5] The arcuate arteries become more angulated and irregular with aging, and there is increased tortuosity and spiraling of the interlobar vessels. These changes occur independently of hypertension but are augmented in its presence. With aging, some afferent arterioles, particularly of juxtamedullary glomeruli, develop vascular shunts to the efferent arterioles, thereby bypassing glomeruli, leading to "aglomerular arterioles."[6]

AGING-ASSOCIATED CHANGES IN RENAL FUNCTION

Glomerular Filtration Rate

Inulin clearance studies document a progressive fall in glomerular filtration rate (GFR) after the age of 40 years, with a relatively greater decline in men (Fig. 67-3).[7] However, the fall in GFR is not inevitable; in as many as one third of patients who remain normotensive, there is no decrease in creatinine clearance with age.[5]

In addition to the decrease in GFR with aging, there may be a reduction in renal "reserve." Whereas some studies suggest that aging humans show a normal increase in GFR after amino acid infusion, others have shown a marked reduction in increases in renal plasma flow (RPF) and GFR in response to concurrent infusion of amino acids and dopamine in healthy elderly individuals.[8,9]

Renal Plasma Flow

Renal plasma flow also decreases from a mean of 650 ml/min in the fourth decade to 290 ml/min by the ninth decade, with increasing renal vascular resistance (Fig. 67-4).[5] The fall in RPF with age is greater in men than in women and in those who are hypertensive.[10] Because RPF decreases relatively more than GFR, filtration fraction (defined as GFR/RPF) increases with age. Studies using a xenon washout technique demonstrated that there is a true reduction in renal blood flow when it is factored for renal mass.[11] The decrease in renal blood flow especially involves the cortex, and blood flow to the medulla is relatively preserved.

Proteinuria

The prevalence of both microalbuminuria (urinary albumin levels of 30 to 300 mg/day) and albuminuria increases progressively after the age of 40 years. The increased prevalence is most marked in diabetic and hypertensive patients but is also observed in patients lacking these risk factors (Fig. 67-5).[12]

ASSESSMENT OF RENAL FUNCTION IN THE ELDERLY

Serum creatinine is a less reliable indicator of renal function in the aging population. After the age of 60 years, there is a progressive decrease in urinary creatinine excretion, which largely reflects muscle mass decreases with aging (Fig. 67-6).[13] For example, serum creatinine did not change between young patients and older patients

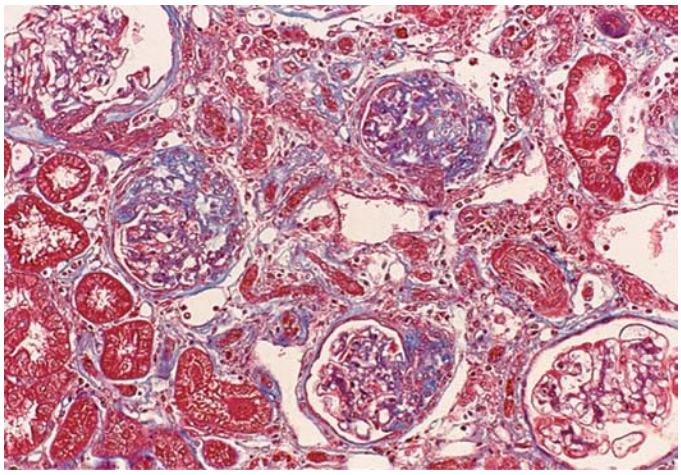

Figure 67-1 Glomerulosclerosis and tubulointerstitial fibrosis in an aging rat. Similar changes, consisting of focal segmental glomerulosclerosis, tubular atrophy, and interstitial fibrosis, occur in humans. (Trichrome stain; original magnification ×400.)

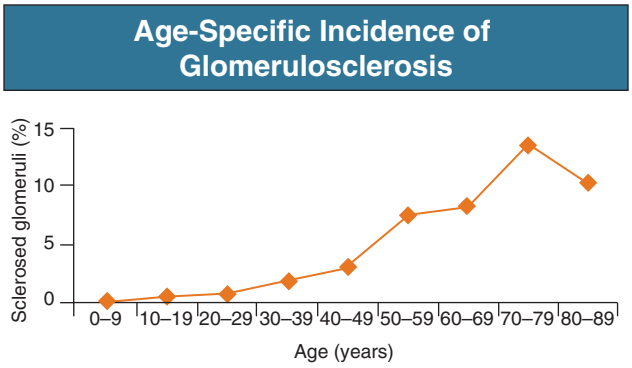

Figure 67-2 Glomerulosclerosis increases with aging. *(Modified from reference 1.)*

despite a reduction in creatinine clearances from 140 ml/min/1.73 m^2 at mean age 30 years to 97 at mean age 80 years.[14]

There is no consensus on the optimal approach to estimation of GFR in elderly people. Whereas the MDRD (Modification of Diet in Renal Disease) study equation and the Cockcroft-Gault formula for estimating GFR use age in their calculations (see Chapter 3), neither has been validated in people older than 70 years, and both underestimate true GFR in those older than 65 years with standard techniques such as isotope clearance. Although the MDRD equation may be more accurate than the Cockcroft-Gault formula,[15] serum cystatin C, which is independent of muscle mass, may be superior to both and is an independent risk factor for mortality in the elderly.[16] A new GFR-estimating equation was derived from 610 patients who were older than 70 years using iohexol clearance as the gold standard. This Berlin Initiative Study (BIS) equation worked particularly well in classifying patients with CKD stage 2 to 4 kidney function.[17] More data are needed to determine which estimated GFR equation performs the best in the elderly patient.

PREVALENCE OF CHRONIC KIDNEY DISEASE IN THE ELDERLY

According to the United States Renal Data System's 2010 and 2011 Annual Data Report as well as the National Health and Nutrition

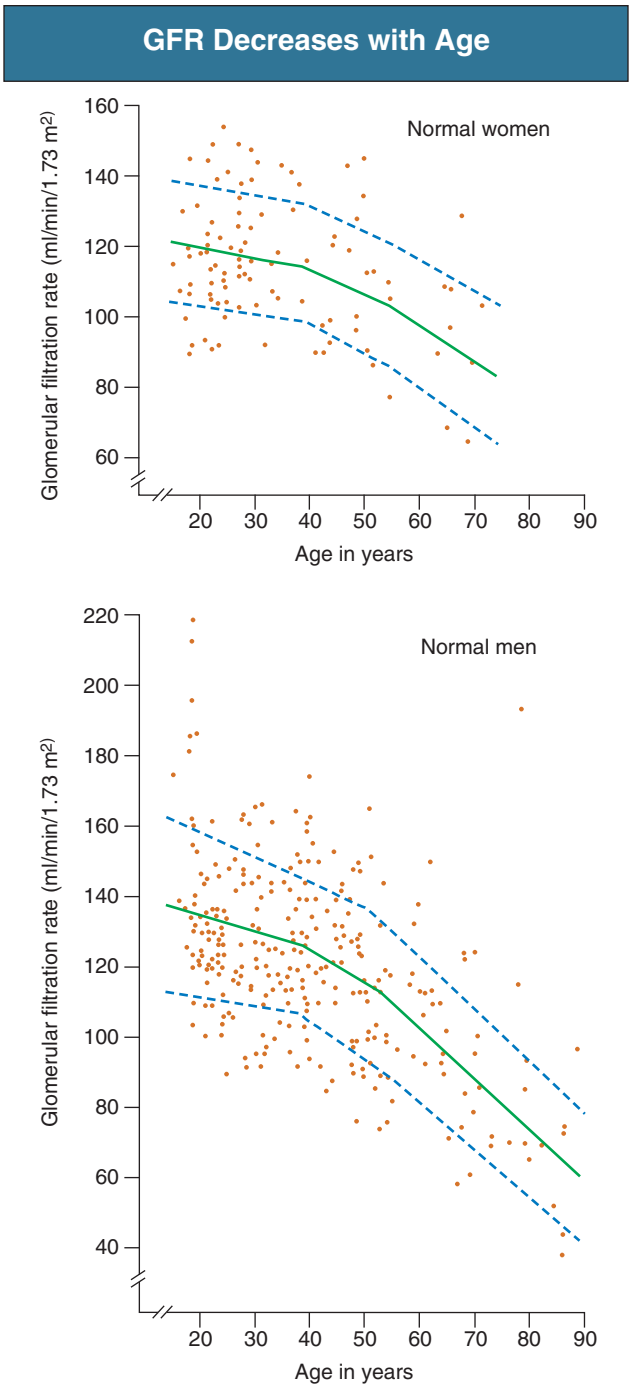

Figure 67-3 Glomerular filtration rate (GFR) decreases with age. GFR (inulin clearance) begins to fall at age 40 years, and the rate of decline is more rapid in men than in women. *(Modified from reference 7.)*

Examination Survey (NHANES) study, the incidence of CKD is increasing most rapidly in people aged 65 years and older, in whom the incidence of recognized CKD more than doubled between 2000 and 2008 (Figs. 67-7 and 67-8).[18] CKD has been associated with an overall increase in all-cause cardiovascular mortality (see Chapters 79 and 82). Nevertheless, reductions of estimated GFR (eGFR) to 50 to 59 ml/min/1.73 m^2 do not increase mortality risk among patients age 65 years or older compared with patients with eGFR of more than 60 ml/min (Fig. 67-9).[19] These observations have led to the debate regarding whether the decrease in GFR that occurs with aging should really be considered unhealthy[20] and whether the term

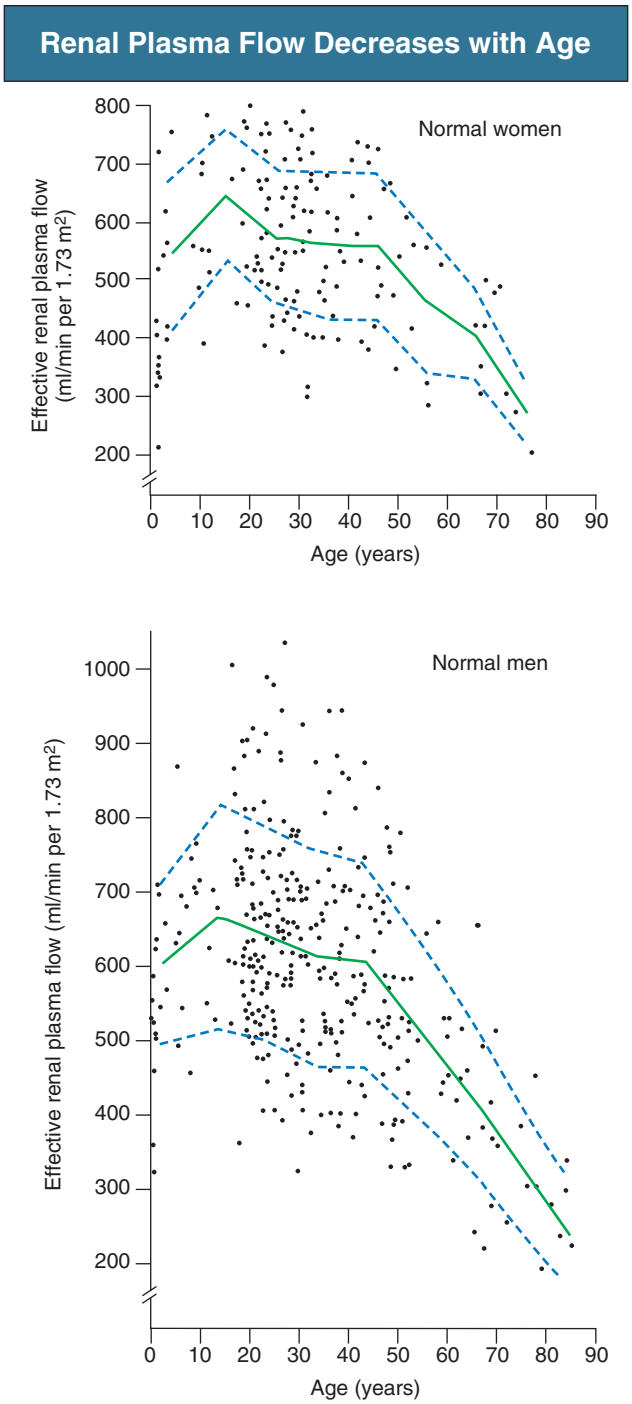

Figure 67-4 Renal plasma flow (RPF) decreases with age. RPF (*p*-aminohippurate clearance) begins to fall rapidly after the age of 50 years, and the rate of decline is more rapid in men than in women. *(Modified from reference 7.)*

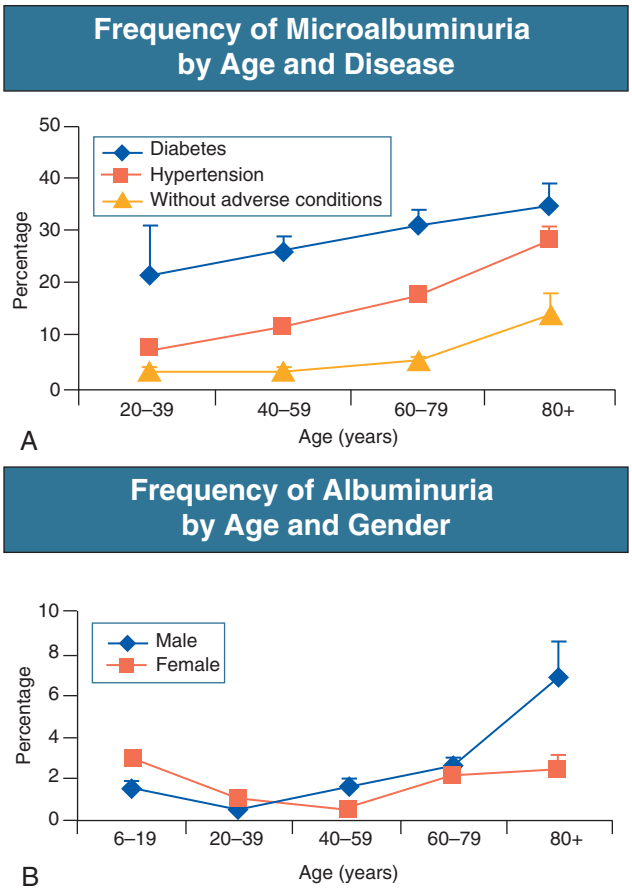

Figure 67-5 Increased proteinuria with aging. A, Microalbuminuria increases with age, with the greatest prevalence in diabetes, followed by hypertension and then the absence of either condition. **B,** Albuminuria increases with age, and the prevalence is greater in men than in women. *(Modified from reference 12.)*

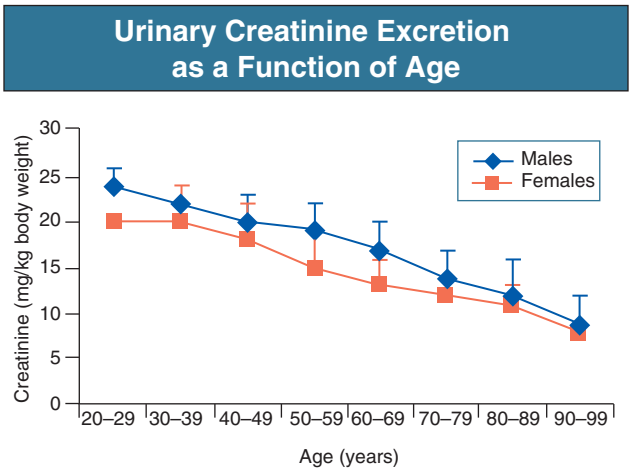

Figure 67-6 Urinary creatinine excretion (factored for body weight) decreases with age. *(Modified from reference 13.)*

"chronic kidney disease" in such cases should be replaced with "age-related reduced kidney function".[21]

RISK FACTORS FOR CHRONIC KIDNEY DISEASE IN THE ELDERLY

The variability in the severity of aging-related renal disease in humans and experimental animals has suggested that there may be specific risk factors for its development. In experimental animal models, aging-related histologic changes vary according to the genetic strain, gender, body mass index, and diet. In animal models, aging-related changes can be retarded with protein or calorie restriction or blockade of the renin-angiotensin system (RAS).[22] According to a multistage community-based survey, age, annual income, use of oral analgesics, metabolic syndrome, hyperuricemia, and hemoglobin were risk factors for CKD in both elderly and nonelderly

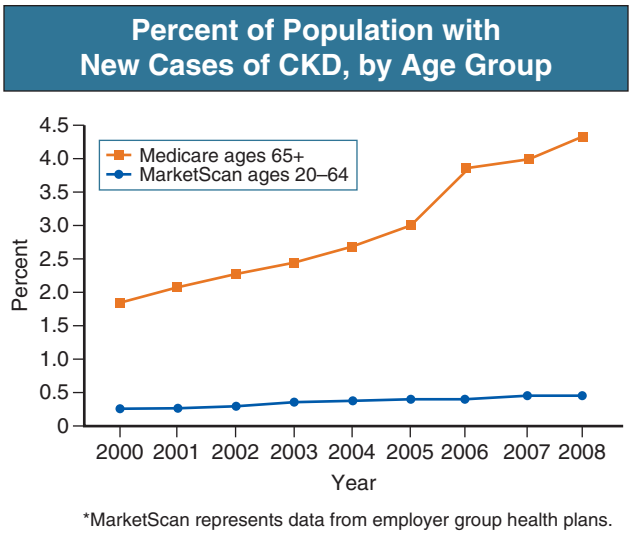

Figure 67-7 New cases of chronic kidney disease (CKD) over time stratified by age group. Medicare is a U.S. national social insurance program. MarketScan is an online health research database. *(Modified from reference 18.)*

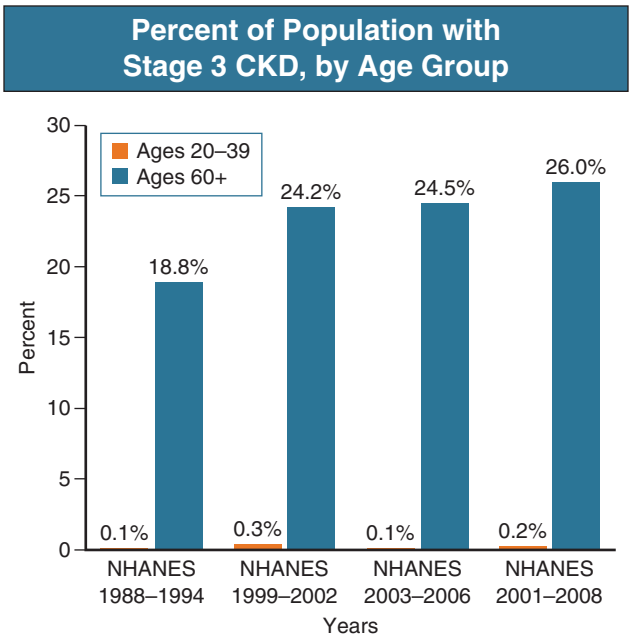

Figure 67-8 Prevalence of stage 3 chronic kidney disease (CKD) by age group over time. *NHANES,* National Health and Nutrition Examination Survey. *(Modified from reference 18.)*

patients.[23] In elderly patients, previous medical history of diabetes mellitus, CKD, stroke, and analgesic use were positively correlated with CKD.[23] In another prospective study, increased levels of physical activity correlated with a lower risk for rapid GFR decline (defined as loss greater than 3 mL/min/1.73 m^2 per year in GFR, as estimated by longitudinal measurements of cystatin C levels) in a general population of older adults.[24]

PATHOGENESIS OF AGE-RELATED CHRONIC KIDNEY DISEASE

A variety of mechanisms have been proposed for aging-related renal changes (Box 67-1).

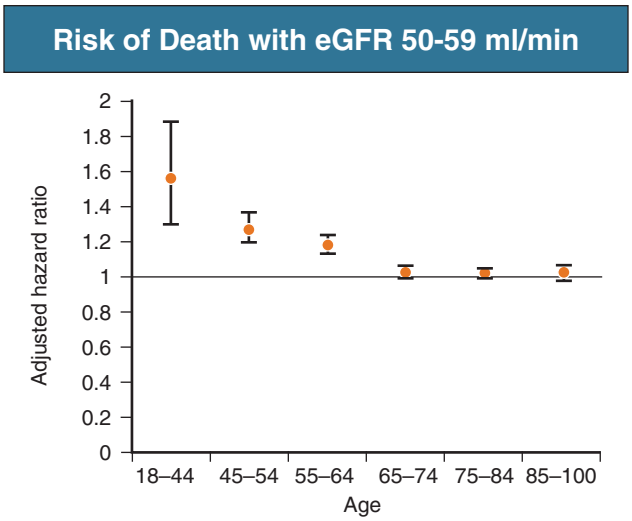

Figure 67-9 Adjusted hazard for death associated with an eGFR of 50 to 59 ml/min/1.73 m^2. *(Modified from reference 19.)*

Proposed Mechanisms for Aging-Associated Kidney Disease

- Decreased Klotho
- Oxidative stress
- Senescence (with telomere shortening and loss of mitochondria)
- Glomerular hypertension and hyperfiltration
- Intrarenal activation of the renin angiotensin system
- Decreased renalase
- Hemodynamic
  - Glomerular hypertension and hyperfiltration
  - Intra-renal activation of renin angiotensin system
  - Endothelial dysfunction (loss of nitric oxide)
  - Renal ischemia
  - Decreased renalase
- Metabolic
  - Accumulation of advanced glycation end products
  - Chronic effects of uric acid
- Cellular dysfunction
  - Oxidative stress
  - Decreased Klotho
  - Senescence (with telomere shortening and loss of mitochondria)
- Inflammation
  - Renal transformation growth factor β (TGF-β) expression
- Endothelial dysfunction (loss of nitric oxide)
- Renal ischemia
- Renal transforming growth factor β (TGF-β) expression
- Accumulation of advanced glycation end products (AGEs)
- Chronic effects of uric acid

Box 67-1 Mechanisms for aging-related kidney changes.

The kidney is the only known source of the anti-aging hormone Klotho. Mice with Klotho deficiency recapitulate features of systemic and renal aging. Klotho is synthesized by the distal nephron and is secreted as a circulating hormone.[25] Klotho is a multipotent protein and serves as a cofactor for the phosphaturic hormone fibroblast growth factor 23 (FGF-23), regulates oxidative stress, and

antagonizes transforming growth factor β (TGF-β) signaling. The mechanisms whereby Klotho regulates the aging process are being elucidated in animal models.

Additional mechanisms of renal aging may involve telomere shortening of chromosomal DNA, loss of mitochondria, and accelerated apoptosis. Increased numbers of apoptotic tubular and interstitial cells have been shown in the aging rat.[26] This process may involve oxidative stress.[27]

Aging-associated renal disease may also be mediated by activation of the RAS, which may lower renal Klotho expression. In turn, in animal models, angiotensin type I recpetor (ATI) blockade upregulates Klotho,[28] and *in vivo* Klotho gene delivery attenuated angiotensin II (Ang II)–induced renal damage.[29] Treatment of rats with angiotensin-converting enzyme (ACE) inhibitors reduces aging-associated oxidative stress and preserves mitochondria in renal proximal tubules in association with upregulation of cellular antioxidant enzymes.[30] Targeted disruption of the gene encoding for the ATIA receptor also results in marked prolongation of life span in mice.[31] The longevity in these mice was associated with a decrease in cardiac and vascular injury possibly through attenuation of oxidative stress and overexpression of prosurvival genes (also in the kidney).

A loss of nephrons results in hyperfiltration with increased glomerular hydrostatic pressure and glomerular hypertrophy, which are known risk factors for glomerular scarring.[32] Depending on the animal strain, glomerular hydrostatic pressures may be either elevated or normal with aging.[22] It is thus likely that glomerular hypertension, when it occurs with a decrease in nephron mass, is a contributor to, rather than an initiator of, the aging-associated decline in renal function.

With aging, the elastic arteries dilate and stiffen, resulting in higher pulse wave velocity with increased pressure transmission to the microvasculature.[33] Measures of large-artery stiffness are closely related to markers of renal microvascular injury, including albuminuria.[34] Aging-associated intimal hyperplasia of the interlobular arteries and disease of the afferent arteriole may also alter renal autoregulation, resulting in injury to the glomeruli.[35] Higher systemic pulse pressure, seen in aging individuals, has been associated with an accelerated decline in GFR.[36]

Endothelial function also declines with aging, particularly in men. It is associated with a progressive reduction in nitric oxide production by endothelial cells and is reflected clinically by a reduction in brachial artery reactivity.[37] Loss of normal endothelial vasodilators may account for the increased renal vasoconstrictive response observed in aging rats to agents such as Ang II and endothelin 1 and may also contribute to the development of renal microvascular disease. Endothelial dysfunction can also inhibit renal angiogenesis, resulting in progressive capillary loss and ischemia. Indeed, mice lacking endothelial nitric oxide synthase show a marked acceleration of aging-associated renal disease.

Aging is also associated with more pronounced renal hypoxia, and ambient partial pressure of oxygen (P_{O_2}) is about 20 mm Hg lower in both the renal cortex and the medulla in otherwise healthy aged individuals compared with young patients.[38] The reduced ability of the aged kidney to generate vasodilators may also contribute to renal hypoxia.[39]

Advanced glycation end products (AGEs), although typically associated with diabetes, are also present in the diet and can accumulate in aging. The content of AGEs in the diet correlates with serum AGE levels, oxidant stress, organ dysfunction, and life span in animal models.[40] Calorie restriction may extend life span in animal models in part by reducing AGE levels.[40,41] Chronic administration of aminoguanidine (an inhibitor of AGE synthesis) also reduces glomerulosclerosis in the aging rat.

FLUID AND ELECTROLYTES IN AGING

Sodium Balance and Hypertension

Aging is associated with both impaired excretion of a salt load[42] and defective conservation in the setting of sodium restriction.[43] Proximal sodium reabsorption is increased in aging, whereas distal sodium reabsorption may be reduced.[44] Studies in rats suggest that pressure natriuresis is impaired in aging.[22] Because the diet of most individuals in developed countries contains excess sodium (8 to 10 g of salt daily), there is a tendency in the elderly population for total body sodium excess.

The relative defect in sodium excretion and increased total body sodium may be predisposing factors for the development of hypertension. Blood pressure increases with age. After the age of 60 years, most people are hypertensive (Fig. 67-10).[45] Salt sensitivity occurs in more than 85% of aging people, and sodium restriction will result in

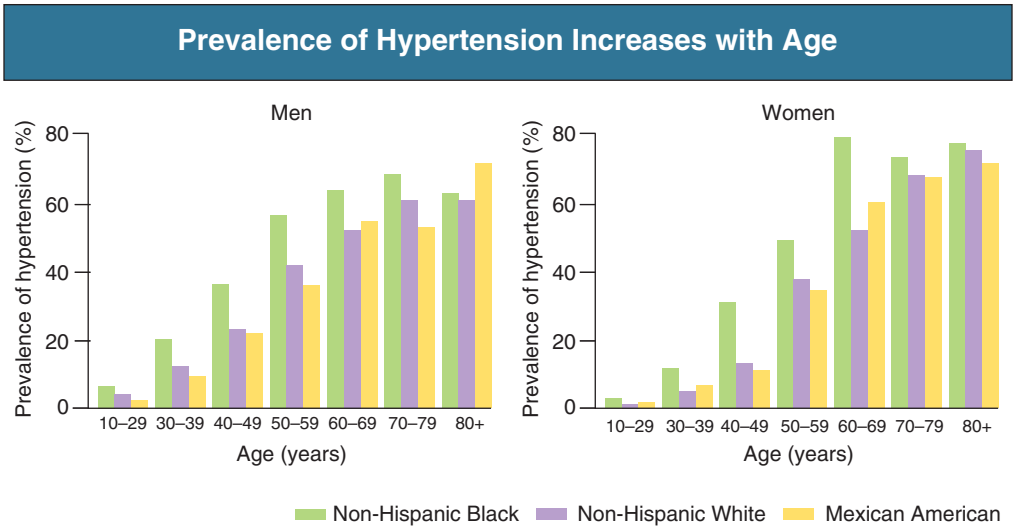

Figure 67-10 Prevalence of hypertension based on age, gender, and race. *(Modified from reference 45.)*

a significant fall (>10 mm Hg) in mean arterial pressure.[46] Populations that ingest low-sodium diets, such as the Yanomamö Indians of southern Venezuela, do not show an increase in blood pressure with age.[47] Loss of vascular compliance as a result of collagen deposition in the larger arterial vessels may also contribute to aging-associated hypertension, as may endothelial dysfunction, perhaps mediated by oxidative stress. Aging-associated renal and vascular changes may explain why correction of secondary forms of hypertension (such as primary aldosteronism, Cushing syndrome, renovascular hypertension, and hypothyroidism) is less effective at curing hypertension in older patients. In one study, diastolic blood pressure fell to below 90 mm Hg in 24 of 25 patients younger than 40 years after treatment of the mechanism responsible for the secondary hypertension but in only 38 of 61 patients older than 40 years.[48]

During hypovolemia, an inappropriate excretion of sodium is observed in the elderly that can exacerbate hypotension and increase the risk for acute kidney injury (AKI).[49]

Osmoregulation and Water Handling

The most common electrolyte abnormalities in the elderly are the dysnatremias; this results from impaired water handling with aging. Hyponatremia has been found in up to 11% of the ambulatory geriatric population and 5.3% of hospitalized elderly patients.[50] Hypernatremia is found in about 1% of patients older than 60 years admitted to the hospital.[50] Both concentration and dilution of the urine are affected by aging and account for part of the susceptibility to dysnatremias.

In the elderly, the maximal urinary osmolality and thirst response to hyperosmolality are reduced, which may predispose to dehydration and hypernatremia.[51] The impairment in urine concentrating ability results from a defect in the concentrating gradient in the medullary region and can lead to nocturia.[52] Compounding the risk for hypernatremia is that the ill elderly patient may not have ready access to water.

The elderly also have an impaired ability to dilute the urine and thus have a decreased ability to excrete a water load, leading to an increased predisposition to hyponatremia that is often compounded by the use of medications such as thiazide diuretics and selective serotonin reuptake inhibitors.[53]

Other Tubular Defects and Electrolyte Problems

Potassium excretion is impaired in the elderly, and the transtubular potassium gradient is decreased.[54] Hyperkalemia occurs more frequently in elderly patients treated with drugs that interfere with potassium excretion (such as potassium-sparing diuretics). Other factors contributing to the predisposition for hyperkalemia in the elderly include decreased GFR, lower basal levels of aldosterone, and tubulointerstitial scarring impairing the Na^+,K^+-ATPase transporters. Hypokalemia is also common because of renal or extrarenal losses.

Most elderly individuals can maintain acid-base balance under normal conditions. However, during conditions of stress when acid production is increased (sepsis or AKI), an inability to excrete an additional acid load may be uncovered. This is supported by a study demonstrating that elderly patients could not increase net acid excretion to the same level as younger adults in response to a protein meal.[55]

Hypercalcemia occurs in 1% to 3% of elderly patients. Causes include malignant tumors, hyperparathyroidism, immobilization, and use of thiazide diuretics. Hypocalcemia is less common and is observed mainly in patients with advanced CKD (in association with vitamin D deficiency and hyperphosphatemia), chronic malabsorption, and severe malnutrition. Aging is associated with increased parathyroid hormone levels (which correlate inversely with GFR) and a decrease in serum calcitriol and phosphate.

Hypomagnesemia is reported in 7% to 10% of elderly patients admitted to the hospital; most commonly, this is the result of malnutrition or laxative or diuretic use. Hypermagnesemia is less common and is found primarily in patients with CKD or who are taking large doses of magnesium-containing antacids. Gout (as well as an elevation in serum uric acid levels) is also more common in the aging population.

ENDOCRINE FUNCTION AND RENAL HORMONES

Erythropoietin (EPO) levels increase with age, probably related to a compensatory response to subclinical blood loss, increased erythrocyte turnover, and increased EPO resistance.[56] Nevertheless, EPO levels are significantly lower in the anemic elderly patient compared with the anemic younger individual, suggesting a blunted response to low hemoglobin.[57]

Elderly women with GFR below 60 ml/min have lower calcium absorption and lower 1,25-hydroxyvitamin D levels, probably because of diminished conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by the aging kidney.[58]

The kidney removes about 50% of insulin in the peripheral circulation by filtration and proximal tubular uptake and degradation. The decline of renal function in the elderly leads to a decrease in insulin clearance. This is in part offset by diminished glucose tolerance, which may relate to the increasing frequency of obesity observed in aging individuals.

CLINICAL MANIFESTATIONS

General Considerations

Aging is associated with declines in renal function that ultimately limit the ability to defend against destabilizing events. Moderate fluid loss (e.g., episode of diarrhea) and moderate fluid loading (e.g., inappropriate perioperative intravenous fluids) may be poorly tolerated and lead to hypovolemia and fluid overload, respectively. Hypovolemia in those taking multiple medications including ACE inhibitors may lead to AKI. Overzealous administration of water as 5% dextrose or 0.45% saline may result in hyponatremia especially in patients taking selective serotonin reuptake inhibitors, which may increase levels of antidiuretic hormone. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) in the elderly is associated with increased risk for hyponatremia, hyperkalemia, hypertension, and impaired renal function.

Glomerular Diseases

Elderly patients may have treatable kidney diseases identifiable on renal biopsy.[59] In a study of 235 biopsy specimens in patients older than 80 years, 67% of the patients had treatable lesions.[60] The pathologic spectrum of glomerular disease seen in elderly people is similar to that seen in the general population, although the prevalence of various pathologies differs. For example, diabetic kidney disease is seen with increasing frequency in the aging population. Among patients with the nephrotic syndrome who are older than 60 years, membranous nephropathy is the most common diagnosis (32.1% of

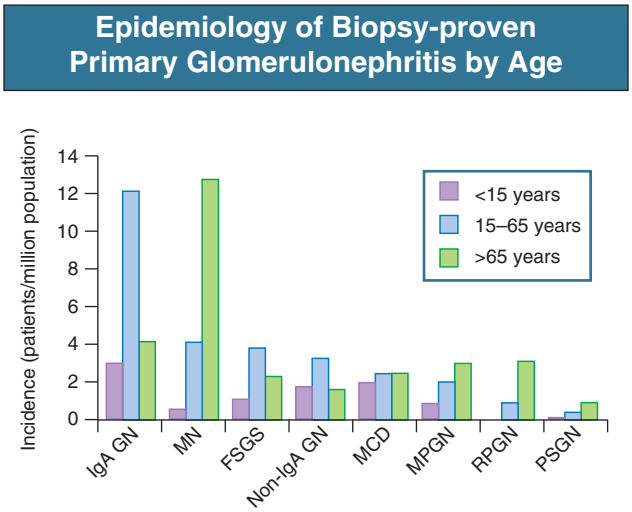

Figure 67-11 Epidemiology of biopsy-proven primary glomerulonephritis by age. Children presenting with nephrotic syndrome are often treated empirically for MCD; thus, MCD as a diagnosis is likely underrepresented in data derived from biopsy registries. *FSGS,* Focal segmental glomerulosclerosis; *IgA GN,* IgA nephropathy; *MDC,* minmal change disease; *MGN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *non-IgA GN,* other mesangial proliferative glomerulonephritis; *PSGN,* poststreptococcal glomerulonephritis; *RPGN,* rapidly progressive glomerulonephritis. *(Modified from reference 61.)*

patients), followed by amyloidosis (typically light chain derived) and minimal change disease (Fig. 67-11).[60,61] Other important causes of AKI from glomerular disease in the elderly include rapidly progressive glomerulonephritis (GN) resulting from pauci-immune (antineutrophil cytoplasmic antibody (ANCA)–associated) GN (accounting for about 30% of elderly patients with AKI who undergo kidney biopsy).[59] In contrast, certain glomerular disorders are uncommon in elderly people, such as lupus nephritis, minimal change nephropathy, and IgA nephropathy. Only 2% of patients with systemic lupus present after the age of 60 years.[60,61] Antinuclear antibody tests performed in elderly patients are more likely to yield false-positive results.

Because of age-related declines in kidney function as well as the presence of significant comorbid medical conditions, elderly patients have a much greater risk for developing serious toxicities from immunosuppressive therapies.[62] Retrospective series examining the course of ANCA-associated GN in the elderly reveal a poorer prognosis with high rates of end-stage renal disease (ESRD), death, and treatment-related complications.[63]

Renovascular and Atheroembolic Disease

There is an increased frequency of renovascular and atheroembolic disease with aging. In several case series, AKI resulting from atheroembolic disease accounted for 4% to 7% of cases.[59] Atherosclerotic renal artery stenosis (ARAS) is estimated to be present in about 7% of patients older than age 65 years and is a major cause of secondary hypertension, ischemic nephropathy, and CKD in the elderly.[64] In elderly people with hypertension and elevated serum creatinine, especially with a history of vascular disease, a screening test for renovascular disease, such as by magnetic resonance angiography or renal artery duplex scanning, should be considered (see Chapter 39). Percutaneous transluminal renal angioplasty and renal artery stenting are of variable value in the elderly because many have significant arteriosclerosis, which may limit the benefits of intervention.[64] Thus, an individualized approach to therapy is warranted.

Acute Kidney Injury

Polypharmacy associated with aging greatly increases susceptibility to the development of AKI.[65] Whereas the causes of AKI in the elderly patient encompass the same spectrum of pre-renal, renal, and post-renal causes that are seen in other age groups, the elderly patient has a higher relative risk for developing AKI from obstructive uropathy and sepsis. Decision making regarding whether to provide active intervention such as with continuous renal replacement therapy in elderly patients with AKI and multisystem organ failure will be influenced by comorbidity and likely outcomes.

Urinary Tract Infections

There is an increased risk for asymptomatic bacteriuria and symptomatic UTIs with aging (see Chapter 53). In men, this may relate to the increased risk of prostatic hypertrophy and urinary calculi with age. In postmenopausal women, the risk is increased by the prevalence of incontinence, cystoceles, and postvoid residual urine. Chronic use of indwelling catheters in elderly patients is also associated with increased bacterial colonization rates; treatment of these UTIs should generally be based on the presence of symptoms or signs (fever, elevated white blood cell count, or dysuria). Exceptions include high-risk patients, such as those with frequent or recurrent UTIs or structural defects of the urinary tract; patients scheduled to undergo urologic surgery, particularly transurethral resection of prostate; neutropenic patients; and renal transplant recipients. Atypical presentations of UTI are common in the elderly and include presentation with lethargy, delirium, and anorexia. The treatment of catheter-associated infections is discussed in Chapter 53.

Obstructive Uropathy

Obstructive uropathy (see Chapter 60) is common in elderly men, usually a result of benign prostatic hypertrophy, prostate cancer, or urethral stricture. The incidence of obstructive uropathy in women is about one third to one half that in men, and the condition is primarily caused by malignant neoplasms of the genitourinary tract. Lower urinary tract obstruction should be excluded by measuring the postvoid residual bladder volume, either by a bedside ultrasound bladder scan or by temporary placement of a urethral catheter. Ultrasound is the most appropriate imaging study for diagnosis of upper urinary tract obstruction (see Chapter 60).

Urinary Incontinence

The lower urinary tract also undergoes significant changes with aging. Decreased bladder contractility occurs secondary to weakening and thinning of the detrusor smooth muscle. This leads to a dysfunctional pattern, eventually culminating in involuntary detrusor contractions. Bladder capacity decreases, whereas postvoid residual bladder volume increases by about 50 to 100 ml. Elderly people also have a higher frequency of nocturia, in part because of the decrease in renal concentrating capacity and perhaps also associated with disordered sleep and the increasing use of diuretics in this population.

Transient urinary incontinence is very common in the elderly and has multiple potentially treatable causes, which are best recalled by a mnemonic, DIAPPERS (Box 67-2).[66] In men, the most common cause is overflow incontinence from prostatic obstruction, whereas in women a prolapsed uterus with cystocele is frequently the cause. In the absence of an easily reversible cause, nonsurgical therapeutic options for urinary incontinence include behavioral therapy and biofeedback, pelvic floor exercises, pharmacologic therapy (e.g.,

Transient Causes of Urinary Incontinence (DIAPPERS)	
D	Delirium or confusional state
I	Infection—urinary (symptomatic)
A	Atrophic urethritis, vaginitis
P	Pharmaceuticals (e.g., diuretics)
P	Psychological, especially depression
E	Endocrine (hypercalcemia, hypokalemia, glycosuria)
R	Restricted mobility
S	Stool impaction

Box 67-2 Transient causes of urinary incontinence in the elderly (DIAPPERS). *(Modified from reference 66.)*

α-adrenergic antagonists to reduce prostatic hypertrophy), and, if it is unavoidable, long-term catheterization. Surgery may be required for large cystoceles, vaginal vault prolapse, and postprostatectomy stress incontinence.[66]

Hematuria

Benign causes of hematuria include benign prostate diseases, UTI, and cystic renal diseases. Malignant neoplasms of the urinary tract are more common in older patients. This change in epidemiology with advancing age requires that the diagnostic workup for hematuria include cystoscopy and urinary tract imaging. Bladder carcinoma is rarely observed before the age of 40 years; it increases progressively after the fourth decade. Renal cell carcinomas (RCCs) are most commonly observed in the seventh decade. RCC is more aggressive in the elderly, and treatment decisions can be difficult, especially in the setting of significant CKD where nephrectomy may lead to dialysis dependence.[67] Other causes of hematuria may need to be considered, as discussed in Chapter 61.

Nephrotoxicity and Drug Dosage

Elderly patients are prone to increased nephrotoxicity because they are often administered medicines on the assumption that a normal or nearly normal serum creatinine concentration is consistent with normal renal function. Thus, the dosage may be inappropriate; it is critical not to rely solely on serum creatinine values for determination of dosages, and eGFR should be used in this regard. Elderly patients with CKD may take multiple medications, often prescribed by multiple physicians. This creates a great risk for drug-drug interactions that can be exacerbated when renal clearance is impaired.

End-Stage Renal Disease and Renal Replacement Therapy

The mean age for a patient to initiate renal replacement therapy is currently over 60 years in the United States and in Europe. The mean age of ESRD patients requiring dialysis in most developing countries is much lower, 32 to 42 years, than that in the developed world. Recently in the United States there has been a decline in the incidence of ESRD in patients older than 65 years, with a continued high incidence in those older than 75 years (Fig. 67-12).[68] Despite the frequency of CKD among elderly patients, ESRD as an outcome is far less common than cardiovascular morbidity or mortality.[69] For example, older patients with CKD stage 3 are more likely to die and less likely to reach ESRD than are their younger counterparts.[69]

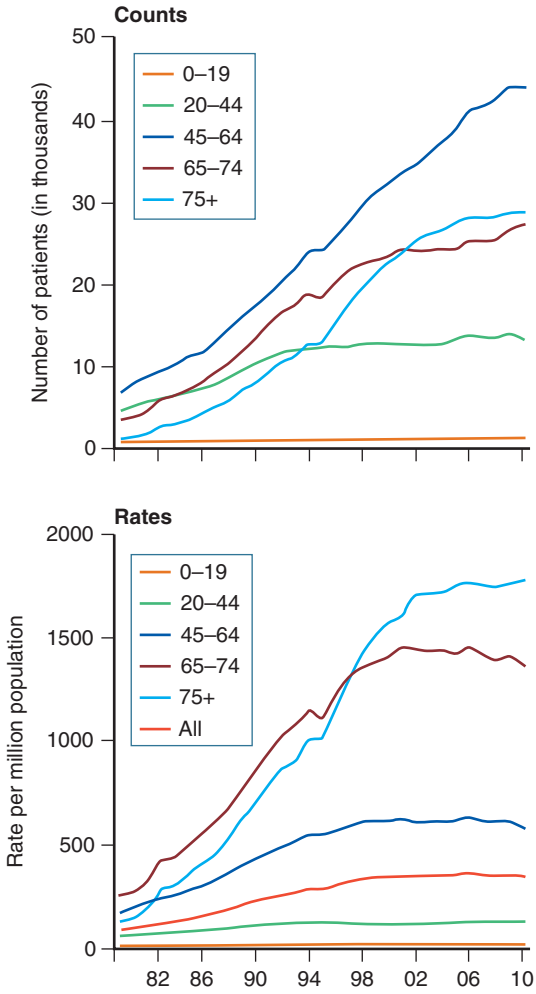

Figure 67-12 Incidence and prevalence of end-stage renal disease (ESRD) in the United States by age. Patients older than 65 years have a higher incidence and prevalence of ESRD; factored for gender and race. *(Modified from reference 68.)*

The decision to offer renal replacement therapy should not be based solely on the age of the individual. It is important to recognize that such a decision involving an elderly patient is more complex and fraught with more challenges than in younger patients and requires a multidisciplinary approach that involves family members. Nonmedical barriers may be particularly important in the elderly—for example, limited transportation, family support, and cost. Whereas the IDEAL (Initiating Dialysis Early and Late) study demonstrated no particular benefit with early initiation of renal replacement therapy,[70] another study raised the issue of potential harm of early initiation of RRT, particularly in the elderly.[71] Nursing home patients who began dialysis experienced sharp and sustained declines in their ability to perform basic daily activities.[72] A year after beginning dialysis, 58% of the patients had died, and only 13% still functioned at the same level as they had before beginning dialysis. Thus, although dialysis may be life extending, it does not lead to improvements in functional status in this patient group. Of note, the period before and after the initiation of dialysis is a time of high risk, with elderly patients having a high risk for worsening disability that is often permanent, as well as death.[73]

As with younger patients, vascular access remains the Achilles heel of hemodialysis. As with other populations, the survival of arteriovenous fistulas in elderly patients is significantly greater than that of arteriovenous grafts.[74] In fact, successful use of an arteriovenous fistula in the elderly has results similar to those in younger people, with prolonged patencies and low incidence of infections and thromboses. Similarly, use of tunneled hemodialysis catheters is also associated with increased mortality in elderly patients on hemodialysis.[74] Unfortunately, many elderly hemodialysis patients have severe widespread atherosclerosis affecting vascular beds, and catheter-based hemodialysis may be the only viable option.

Limitations of hemodialysis in the elderly may include their sensitivity to fluid shifts and the presence of significant cardiac dysfunction; hence peritoneal dialysis (PD) may theoretically offer some advantage by offering a slow, sustained degree of ultrafiltration that leads to greater hemodynamic stability. Unfortunately, inherent functional limitations and lack of social support may provide impediments to broader use of PD in the elderly.[75] Studies have demonstrated similar outcomes in elderly patients undergoing hemodialysis versus PD.[75]

Transplantation should be considered in the management of elderly patients with ESRD because studies have shown that selected elderly recipients benefit from renal transplantation by a significant reduction in mortality compared with wait-listed ESRD patients.[76] This survival benefit is most striking for patients with ESRD caused by diabetes or hypertension, but it becomes less apparent the longer the patient waits before transplantation.[76] Even when expanded-criteria donor (ECD) kidneys are used, a 25% mortality reduction has been shown in those who undergo transplantation, as compared with those who are wait-listed.[77] Overall graft survival for the elderly transplant patient is similar to that in younger patients.[78] It has been argued that lower doses of immunosuppression are sufficient in elderly renal transplant recipients.[78] However, the Eurotransplant Senior Program, allocating kidneys from donors 65 years or older to recipients 65 years or older regardless of human leukocyte antigen (HLA) matching, found 5% to 10% increased rejection rates in this "old to old" group compared with two better HLA-matched groups, the "old to any" and the "any to old," within the Eurotransplant Kidney Allocation System.[79] In a subanalysis of the Efficacy Limiting Toxicity Elimination (ELiTE)–Symphony study, a large prospective, randomized trial comparing immunosuppressive regimens in renal transplant patients, equal rates of rejection in elderly (60 years or older) versus younger (younger than 60 years) recipients were demonstrated.[80] Furthermore, this subanalysis suggested that older recipients who receive a marginal kidney from an older or expanded-criteria donor may fare worse than younger recipients, with an increased likelihood of death, delayed graft function, graft loss, treatment failure, and reduced graft function.

For those who decide not to pursue renal replacement therapy, maximum conservative management and palliative care, which focus on symptomatic therapy, are options. This concept underscores the importance of individualizing patient goals with a focus on quality of life. For those with severe functional or cognitive impairment or for whom complications of dialysis have negatively affected their quality of life, dialysis discontinuation is an important consideration. Hospice services remain underused for ESRD patients but may provide an important support mechanism for patients and their families who wish to discontinue dialysis.

Renal Disease and Cancer

CHAPTER 68

Onconephrology: Renal Disease in Cancer Patients

Ala Abudayyeh and Abdulla Salahudeen

Renal disease is an important complicating feature of cancer, and also of its treatments and complications. Renal syndromes such as the syndrome of inappropriate antidiuretic hormone (SIADH) and tumor lysis syndrome (TLS) are commonly associated with cancer. However, cancer is also associated with other electrolyte abnormalities and renal syndromes (Box 68-1). The frequency of kidney complications in patients with cancer, and especially those undergoing treatment, is leading oncologists to include a nephrologist as part of a team approach for cancer therapy.[1] In this chapter we review the major renal syndromes associated with cancer or its treatment.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is the most common reason why nephrologists are consulted with regard to hospitalized cancer patients and includes pre-renal, intrarenal, and post-renal AKI (see also Chapter 69). In a recent survey, the rate of AKI in patients admitted to a comprehensive cancer center was 12%, nearly threefold higher than in most noncancer settings, and AKI was also associated with poorer clinical outcomes.[2,3] AKI developed in 55% of these cancer patients after they had been in the hospital for at least 48 hours (Fig. 68-1). The significant risk factors for AKI in these patients were diabetes, hyponatremia, and the use of intravenous radiocontrast, chemotherapy, and antibiotics.[2] Identifying cancer patients who are likely to develop AKI in the hospital may allow kidney injury prevention (KIP) strategies to avert AKI and improve clinical outcomes.[2]

Pre-renal Acute Kidney Injury

Nearly one third of AKI in cancer patients is pre-renal resulting from reduced renal perfusion caused by volume depletion from chemotherapy-induced nausea, vomiting, and diarrhea. In addition, chemotherapy-associated hypoalbuminemia contributes to the reduction in effective plasma volume, adding further to the reduction in renal perfusion. Extracellular volume depletion as a result of third spacing as in malignant ascites or pleural effusion, or insensible losses from neutropenic fever can also lead to pre-renal AKI. Similarly, renal fluid loss may occur as a consequence of hypercalcemia-associated nephrogenic diabetes insipidus, which can be compounded by the renal vasoconstrictive effect of hypercalcemia (see Chapter 10).[4] In patients with pre-renal dysfunction, use of nephrotoxic agents such as intravenous radiocontrast, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, and various antibiotics and antiviral and antifungal agents may result in enhanced nephrotoxicity leading to intrarenal AKI.

Intrarenal Acute Kidney Injury

Intrarenal AKI is one of the commonest forms of renal injury in cancer patients, often preceded by pre-renal AKI. The cause is often multifactorial (see Chapter 69). Several chemotherapeutic agents as well as other medications commonly used in cancer patients can cause intrarenal AKI. AKI in this setting is referred to as toxic acute tubular necrosis (ATN), which tends to be nonoliguric and milder in severity (Table 68-1). In contrast, cancer patients with sepsis and septic shock sustain ischemic ATN, which is often oligoanuric and severe. Most of these patients with septic shock and ischemic ATN would have received chemotherapy with or without hematopoietic stem cell transplantation (HSCT) and are often neutropenic. Renal recovery is slow in ischemic ATN and often incomplete.[5] Nevertheless, the presence of cancer alone should not preclude patients from being considered for dialysis. It is our practice to provide dialysis for at least 48 hours to critically ill cancer patients with advanced renal failure so that a proper evaluation can be made for the role of continuing dialysis. The majority of cancer patients in septic shock receive large volume resuscitation, blood products, and vasopressors while oligoanuric and therefore require continuous renal replacement therapy (CRRT).[2,5] The occurrence of AKI remains an important obstacle for the effective use of chemotherapeutic agents. Conversely, high and repetitive doses of chemotherapy, concurrent with other nephrotoxic agents, render the patient vulnerable to AKI.

Post-renal Acute Kidney Injury

In patients with genitourinary cancers, obstruction of the urinary tract is a likely cause for acute (post-renal) AKI or chronic kidney disease (CKD). Cancers commonly associated with urinary tract obstructions are cancers of the bladder, prostate, cervix, and ovary. Among these, patients who have undergone pelvic irradiation or urogenital surgery with urinary diversion are more likely to have urinary obstruction. The obstruction seen in patients with cervical and ovarian cancers can be a result of metastatic spread involving the ureters or can be caused by ureteral or bladder compression from lymphadenopathy (Fig. 68-2). In HSCT recipients with BK infection, ureteral obstruction is not an uncommon cause of renal impairment. Although ultrasound (US) examination of kidney and bladder is the screening test for obstruction in these patients, occasionally the US findings may be negative if the obstruction is of short duration or when renal encasement by retroperitoneal cancer has occurred. In patients in whom the index of suspicion for obstruction is high, repeat US examination, nephrostogram, or both may become necessary.

MYELOMA AND AMYLOIDOSIS

Myeloma and amyloidosis are discussed in detail in Chapters 65 and 27, respectively. Renal involvement occurs in about 50% of patients with multiple myeloma, but the degree of renal involvement varies depending on the type of myeloma.[6,7] Myeloma with light-chain overproduction is commonly associated with renal involvement, with as many as 50% of patients requiring dialysis.[8] The type of light

Kidney Disease Associated with Common Cancers and Cancer Treatments

Leukemia

Common: AKI from sepsis, volume depletion, drug toxicity

Rare: Infiltrative disease, glomerulonephritis, AKI from TLS

Myeloma

Common: Myeloma kidney, AKI from volume depletion

Rare: Amyloidosis, LCDD, Fanconi syndrome, AKI from hypercalcemia, MPGN type I

Lymphoma

Common: AKI from TLS and volume depletion

Rare: Obstructive uropathy, infiltrative disease, minimal change disease (Hodgkin), MPGN type 1 (non-Hodgkin lymphoma)

Renal Cell Carcinoma

Common: Anti-VEGF toxicity

Rare: Obstructive uropathy, membranous nephropathy

Lung and Head and Neck Cancer

Common: Platinum toxicity

Rare: SIADH, membranous GN

Genitourinary and Gynecologic Cancers

Common: Obstructive uropathy

Rare: Platinum toxicity

Kidney Disease in Commonly Used Cancer Treatments

Common: AKI, tubulopathy, and CKD from chemotherapeutic agents (e.g., cisplatin, ifosfamide, methotrexate); complications of conditioning regimen and HSCT, and from toxicities of targeted anticancer therapies (including proteinuria, TMA, and hypertension)

Rare: Radiation nephritis, TMA, glomerulonephritis

Obstructive Uropathy

Common: Genitourinary and gynecologic cancers

Rare: Lymphoma

Box 68-1 Kidney disease associated with common cancers and cancer treatments. *AKI,* Acute kidney injury; *CKD,* chronic kidney disease; *GN,* glomerulonephritis; *HSCT,* hematopoietic stem cell transplantation; *LCDD,* light-chain deposition disease; *MPGN,* membranoproliferative glomerulonephritis; *SIADH,* syndrome of inappropriate antidiuretic hormone; *TLS,* tumor lysis syndrome; *TMA,* thrombotic microangiopathy; *VEGF,* vascular endothelial growth factor.

Timing of AKI Following Admission to a Cancer Center

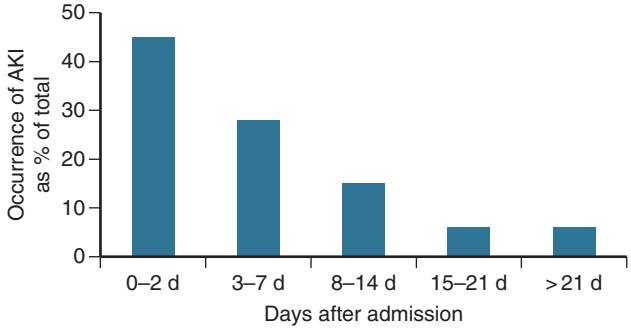

Figure 68-1 Timing of acute kidney injury (AKI) after admission to a cancer center. In 55% of patients, AKI developed after 48 hours after admission, suggesting an opportunity to undertake proactive measures to potentially prevent AKI. *(Modified from reference 2.)*

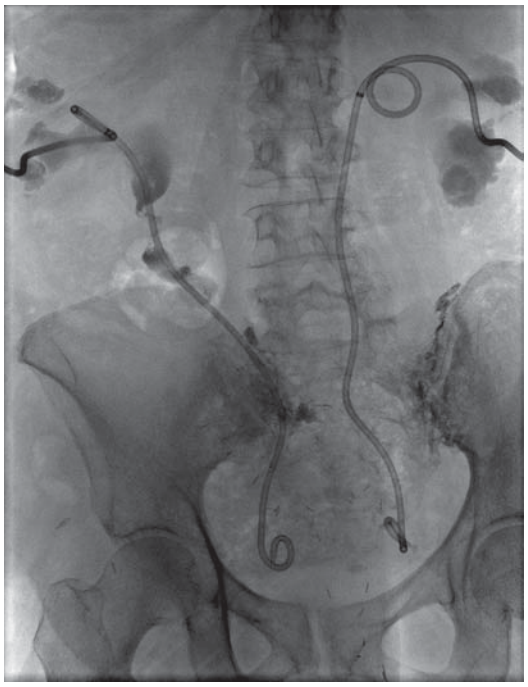

Figure 68-2 Nephrostogram showing bilateral obstructive uropathy (dilated pelvicalyceal system) in a patient with advanced rectal cancer treated with chemotherapy, radiation, and surgery. Bilateral nephroureteral catheters are in place for urine drainage. *(From the University of Texas MD Anderson Cancer Center, 2013.)*

chain is also important; cast nephropathy and renal amyloidosis are common with lambda light chains, whereas severe proximal tubular injury causing Fanconi-like syndrome and light-chain deposition disease are common with kappa light chains. Treatment of myeloma with dexamethasone, thalidomide or related compounds such as lenalidomide, or proteasome inhibitors such as bortezomib, followed by myeloablative HSCT, has substantially improved the survival of myeloma patients.[9] Although renal involvement of myeloma is associated with poorer clinical outcomes, kidney biopsies are not routinely performed in cancer centers. However, prompt institution of chemotherapy often leads to rapid renal recovery, occasionally obviating the need for dialysis. Reduction in serum light-chain levels with a combination of chemotherapy and plasma exchange or high-cutoff dialysis has also been shown to correlate with renal recovery, but currently there are no data to suggest that adding extracorporeal removal of light chains to myeloma therapy provides any added advantage.[8] The presence of renal failure or being on dialysis is no longer a contraindication to HSCT for myeloma.[10] Nevertheless, these patients require dose reduction of lenalidomide and melphalan to avoid major systemic toxicities. Unlike the initial reports that suggested that recovery of renal function after HSCT occurs in a sizable proportion of patients on dialysis because of myeloma, this seems to be the exception rather than the rule in clinical practice.[11,12]

Primary systemic (AL) amyloidosis in patients with light-chain disease is another infrequent manifestation of myeloma. When amyloidosis does complicate myeloma, it carries a grave prognosis. Large kidneys, gross proteinuria, and characteristic renal deposition of amyloid are hallmarks of renal amyloidosis and, based on autopsy studies, it occurs in about 5% to 10% of patients with myeloma.[13] The

Commonly Used Treatments in Cancer Patients that May Cause Renal Toxicity		
Tubular Injury	**Glomerular Injury**	**Renal Vascular Injury**
Acute Tubular Injury	**FSGS**	**Thrombotic Microangiopathy**
Platinums, zoledronate, ifosfamide, mithramycin, pentostatin, imatinib, diaziquone, pemetrexed	Interferon (IFN), pamidronate, zoledronate	Bevacizumab (anti-VEGF monoclonal antibody)
Tubular Syndromes	**Minimal Change Disease**	**Tyrosine Kinase Inhibitors**
Renal Tubular Acidosis	IFN, pamidronate	Sorafenib, sunitinib, imatinib
Ifosfamide, amphotericin, calcineurin inhibitors	**Proteinuria**	**Other Agents**
Fanconi-like Syndrome	Sorafenib, sunitinib, vatalanib, axitinib	Gemcitabine, mitomycin C, interferon-α (IFN-α)
Cisplatin, ifosfamide, azacitidine, diaziquone, imatinib, pemetrexed		
Salt Wasting		
Cisplatin, azacitidine		
Magnesium Wasting		
Cetuximab, cisplatin, panitumumab		
Nephrogenic Diabetes Insipidus		
Cisplatin, ifosfamide, pemetrexed		
Acute Interstitial Nephritis		
Sorafenib, sunitinib		
Crystal Nephropathy		
Methotrexate, acyclovir		
SIADH		
Cyclophosphamide, vincristine		

Table 68-1 Commonly used treatments in cancer patients that may cause renal toxicity. *FSGS,* Focal segmental glomerulosclerosis; *SIADH,* syndrome of inappropriate antidiuretic hormone.

treatment of AL amyloidosis with chemotherapy followed by HSCT has been shown to improve patient survival and reduce proteinuria.[14]

ANTI–VASCULAR ENDOTHELIAL GROWTH FACTOR THERAPY

The discovery that vascular endothelial growth factor (VEGF) is an important mediator of tumor growth and angiogenesis led to the development of drugs targeting VEGF and VEGF receptors (VEGFRs) for cancer therapy.[15] However, VEGF is also an essential growth factor to maintain glomerular endothelial health. VEGF is secreted by podocytes and traverses the basement membrane where it binds to VEGFRs on endothelial cells and maintains glomerular endothelial cell integrity and filtration barrier function (Fig. 68-3). Anti-VEGF drugs such as the monoclonal antibody bevacizumab, as well as drugs that inhibit tyrosine kinase such as sunitinib, block VEGF function. This leads to dysfunction of the glomerular endothelial cells and disruption of the filtration barrier, resulting in proteinuria, thrombotic microangiopathy (TMA), hypertension, and renal failure.[16,17] Mild and asymptomatic proteinuria is common, and heavy proteinuria occurs in less than 10% of treated patients.[18] Hypertension or aggravation of preexisting hypertension is common. The reported incidence varies from 17% to 80%.[19,20] The onset of hypertension reflects the efficacy of VEGF blockade, perhaps explaining why bevacizumab-induced hypertension correlates with clinical outcome in patients with advanced colorectal cancer.[21] Hypertension is managed with the use of standard antihypertensive medications, although the use of ACE inhibitors or ARBs is preferable in patients with proteinuria.[20] The occurrence of renal side effects with anti-VEGF therapy often necessitates a reduction in dose and possibly discontinuation of the drug.

TUMOR LYSIS SYNDROME

Patients with high-grade lymphoma, acute leukemia, and other rapidly proliferating tumors are prone to TLS, especially with the initiation of chemotherapy (see Chapters 69 and 71). Among these, patients with Burkitt lymphoma who are treated with rituximab are particularly at risk. Volume depletion, hypotension, large primary or metastatic tumor load, preexisting CKD, and concurrent exposure to potential nephrotoxic agents are common risk factors associated with TLS-induced AKI. Cell lysis leads to hyperuricemia, hyperkalemia, hyperphosphatemia, and acidosis causing AKI, primarily from the deposition of uric acid crystals in the tubules. Recent studies suggest that hyperuricemia may also play a role in TLS-associated AKI independent of crystals, possibly because of the effect of uric acid to stimulate inflammation and endothelial dysfunction.[23] Tissue deposition of calcium phosphate crystals may also occur, including in the myocardium, where it may have a role in causing severe arrhythmias. A proactive approach is adopted especially in patients with high risk for TLS, which involves hydration to maintain a high urine output (>100 ml/h) and the use of allopurinol or recombinant uricase (rasburicase) to block the increase in serum uric acid levels. Rasburicase degrades uric acid to water-soluble allantoin. Whether rasburicase, which is costly but more effective at lowering uric acid levels, is superior to allopurinol in the prevention of TLS-associated AKI is uncertain.[24] Dialysis should be considered early in

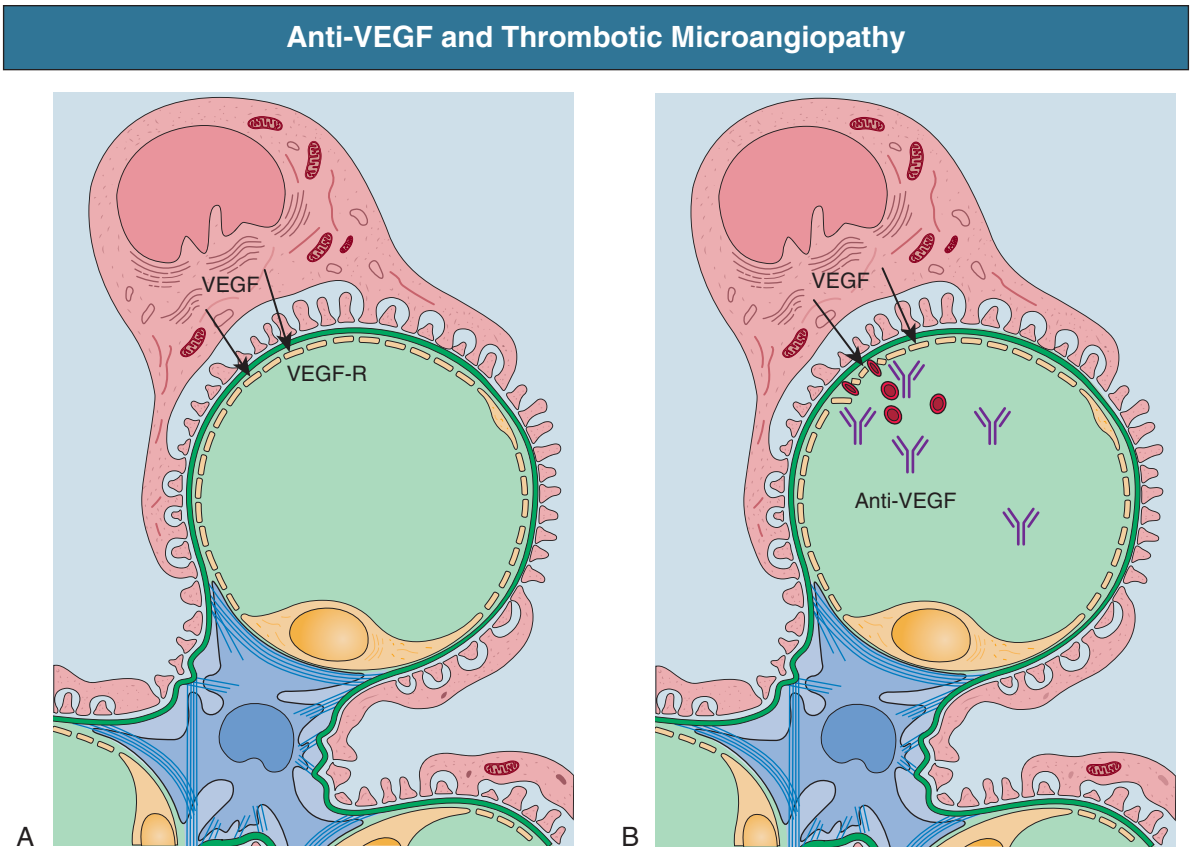

Figure 68-3 Anti–vascular endothelial growth factor (VEGF) and thrombotic microangiopathy. A, Under normal circumstances, VEGF is produced constitutively by the podocyte and crosses the glomerular basement membrane *(arrows)* to bind VEGF receptors (VEGF-Rs) on the endothelial cells, where it maintains endothelial health and integrity. **B,** When anti-VEGF antibody is administered, the antibody binds to the VEGF and blocks its binding to the endothelial cell, resulting in endothelial cell injury and thrombotic microangiopathy. Key: Platelets (red circular disks in **B**).

patients with TLS who develop signs of progressive renal failure (rising serum creatinine, e.g., over 1.5 mg/dl [130 µmol]) because even mild renal dysfunction can limit the kidneys' ability to eliminate the rapidly accumulating high levels of potassium and other tumor lysis products that occur in massive TLS. Furthermore, accumulation of tumor lysis products in turn can aggravate renal injury.[25] Patients at risk for TLS need close laboratory monitoring, and in patients with severe TLS and especially those with reduced urine output and kidney function, continuous dialysis or CRRT may be required to control hyperkalemia and persistent hyperphosphatemia (Fig. 68-4).[26] In many patients dialysis can be discontinued after 2 to 3 days provided good urine output and sufficient renal function are present.

CANCER-RELATED GLOMERULONEPHRITIS

Although the presence of cancer-related glomerulonephritis (GN) seldom changes the oncologist's approach to the underlying cancer management, this relatively rare entity is of considerable interest to nephrologists because it may provide insights into the pathophysiology of primary GN. Rarely proteinuria or nephrotic syndrome can be the presenting feature of cancer. Membranous nephropathy (MN) is the most common glomerular pathology associated with solid tumors; in the largest series of 240 patients with kidney biopsy–proven MN, a cancer diagnosis was noted in 10%, but a cancer diagnosis in many was made after the diagnosis of MN.[27] Common cancers associated with MN are lung, gastric, colon, and renal carcinomas, but several other solid tumors can also be associated—for example, prostate and breast cancers (Table 68-2).[28] In Hodgkin disease, the most common lesion is minimal change disease (MCD; see Chapter 17), possibly related to tumor-related T cell dysfunction. Chronic lymphocytic leukemia is commonly associated with membranoproliferative glomerulonephritis (MPGN; see Chapter 21), especially in the presence of cryoglobulinemia. HSCT is associated with MN, and, rarely, an MCD lesion can be a manifestation of chronic graft-versus-host disease (GVHD).[29] Use of interferon-α (IFN-α) anti-VEGF therapies, and bisphosphonates in cancer therapy have also been associated with various glomerular diseases and TMA.[28]

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Among the types of HSCT, the myeloablative allogeneic HSCT, which requires administering higher doses of irradiation, chemotherapy, or a combination, carries the highest risk for development of AKI—as high as 70%—and occurrence of AKI in any form of HSCT is associated with poor clinical outcomes including survival.[30] The causes of AKI in HSCT are multifactorial, and in addition to usual and anytime causes of AKI such as volume depletion, intravenous contrast, sepsis, and drug toxicity, HSCT can be associated with a few specific syndromes that tend to occur during certain time intervals after HSCT (Table 68-3). A rare but early form of AKI may occur within hours after HSCT and is caused by hemolysis-related

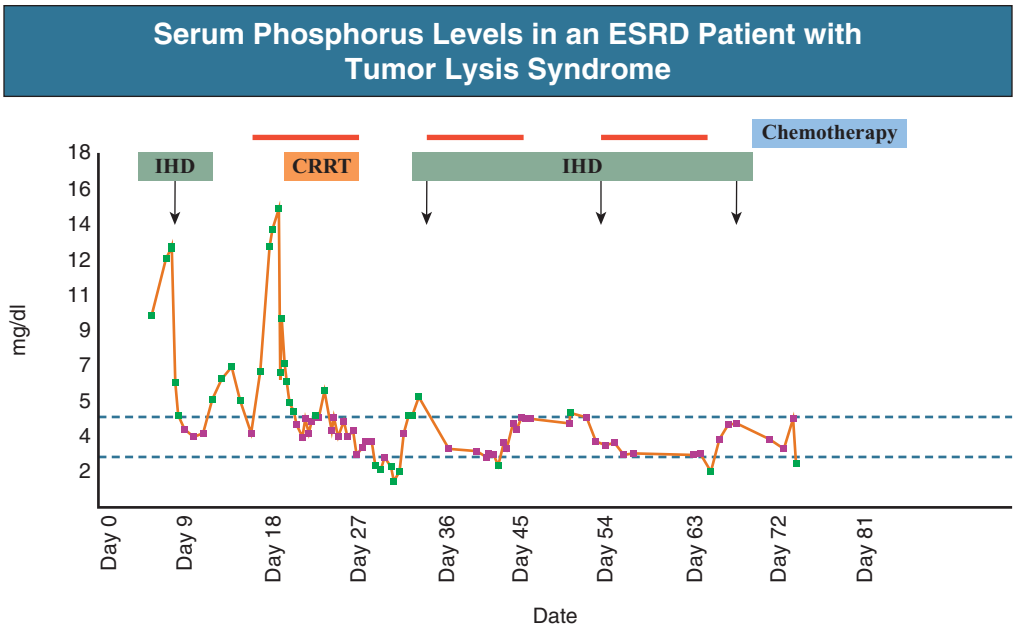

Figure 68-4 Serum phosphorus levels in an ESRD patient with tumor lysis syndrome. Shown is the effect of continuous renal replacement therapy (CRRT) or intermittent hemodialysis (IHD) *(arrows)*.

pigment nephropathy from the stem cell preservative dimethyl sulfoxide. Within days after HSCT, the rare "engraftment syndrome," consisting of fever, skin rash, and pulmonary edema, which has been ascribed to marked cytokine release related to neutrophil recovery, can lead to multiorgan failure including AKI. Within weeks to months, several syndromes may occur that can cause AKI, including veno-occlusive disease (VOD) of the liver, GVHD, TMA, and BK virus nephropathy.[31] VOD is a serious and potentially fatal complication of myeloablative HSCT that is fortunately on the decline as a result of less intensive conditioning regimens.[32] Features of VOD such as fluid retention, low urinary sodium excretion, and abnormal liver functions suggest that it is a form of hepatorenal syndrome. Severe VOD may result in multiorgan failure including AKI necessitating dialysis and is associated with a very high mortality.[25] Defibrotide is an oligonucleotide with antithrombotic and fibrinolytic activity that carries minimal hemorrhagic risk and has been shown to improve VOD outcomes, but the drug is currently awaiting U.S. Food and Drug Administration (FDA) approval.[33] Late-onset AKI (20 to 99 days) after hematopoietic cell transplantation (HCT) is usually caused by TMA as a result of renal endothelial and mesangial cell (mesangiolysis) injury secondary to irradiation used for conditioning before HSCT or as a complication of GVHD. TMA resembles hemolytic uremic syndrome in that thrombocytopenia, schistocytosis, anemia, and elevated lactate dehydrogenase (LDH) are present. Later in the course (after 3 months), use of nephrotoxic agents such as calcineurin inhibitors is common as a long-term cause of progressive renal dysfunction, especially when their doses are escalated to prevent or manage GVHD in patients who have undergone allogeneic transplants. Patients who have undergone HSCT show a decline in their estimated glomerular filtration rate (eGFR) by at least 25 mL/min/1.73 m^2, irrespective of age,[34] but patients seldom develop end-stage renal disease (ESRD) as a complication of HSCT. BK virus infection occurs in up to 70% of HSCT recipients, more often in the unrelated cord blood transplants conditioned with myeloablative regimens.[35] BK cystitis, which usually affects the bladder but may involve the kidneys and ureters, occurs early in the course of HSCT and can persist. Treatment options are limited; cidofovir is sometimes used but is marginally effective and also is associated with its own nephrotoxicity. Infection of the ureters may cause ulcerations, resulting in hematuria, ureteral stenosis, and obstruction. Temporary placement of a percutaneous nephrostomy catheter relieves obstruction and significantly improves kidney function.[36]

ELECTROLYTE ABNORMALITIES

Although electrolyte abnormalities are common in cancer patients, factitious laboratory findings are also not infrequent and should be kept in mind to avoid unnecessary admission, investigation, and potentially harmful treatment. Paraproteins, especially IgM, may cause assay interferences with several tests, mostly because of physical interferences with reagents, reactions, or both.[37] Pseudohyperkalemia may occur in patients with acute leukemia, chronic lymphocytic leukemia, and chronic myeloproliferative disorders, mostly because of cells releasing potassium during storage. When factitious values are suspected, careful collection and prompt analysis of repeat samples (often including comparison of plasma and serum drawn values) are required.

Hyponatremia is the most common true electrolyte abnormality and affects nearly 50% of hospitalized cancer patients.[38] Hyponatremia is frequently caused by SIADH and can be associated with both euvolemia and increased extracellular volume. SIADH was originally described in small cell lung cancer, but it may occur with non–small cell lung cancer, head and neck cancers, and a number of hematologic cancers.[39,40] Pain and pain medications such as morphine and its derivatives, antidepressants, and several chemotherapeutic agents may also cause hyponatremia either by increasing arginine vasopressin (AVP) secretion or by enhancing its effect at the renal tubule. Fluid restriction to correct hyponatremia is difficult in cancer patients, especially in patients receiving chemotherapy or HSCT, because these procedures are associated with high fluid intake. Oral sodium chloride and loop diuretics are only partly effective, whereas

use of V_2 receptor antagonists such as tolvaptan is very effective in correcting hyponatremia.[41] Although SIADH is common in cancer patients, in one third of patients hyponatremia may result from volume depletion. Hypovolemic hyponatremia should be correctly identified from the history, physical examination, and urinary sodium excretion (see Chapter 71). In these patients normal saline repletion promptly corrects the hyponatremia.

Causes of Acute Kidney Injury (AKI) and Other Renal Disease in Relation to the Timing of Hematopoietic Stem Cell Transplantation (HSCT)	
Peri-HSCT	Tumor lysis syndrome from conditioning regimen (rare) Systemic toxicity from conditioning regimen—for example, volume depletion (common) Dimethyl sulfoxide (DMSO)–induced hemolysis, acidosis, and pigment nephropathy (rare)
Days to weeks after HSCT	Pre-renal AKI from volume depletion, AKI from neutropenic sepsis and drug toxicity (common) AKI related to engraftment syndrome (rare)
Weeks to months after HSCT	AKI from sepsis, volume depletion, drug and radiocontrast toxicity (common) AKI from veno-occlusive disease of the liver, graft-versus-host disease (GVHD), thrombotic microangiopathy, and BK virus nephropathy (rare)
Months to years after HSCT	CKD from previous AKI, from continuous use of calcineurin inhibitors especially with GVHD, and from preexisting cancer—for example, myeloma (common)

Table 68-3 Causes of AKI and other renal disease in relation to the timing of HSCT.

Hypernatremia is much less frequent in hospitalized cancer patients compared with hyponatremia (3% vs. 47%), but it is associated with higher mortality and longer hospital stays.[42] Most hypernatremia occurs in the hospital and is observed primarily in critically ill patients with leukemia and HSCT who are receiving loop diuretics. Treatment of hypernatremia is discussed in Chapter 8.

Other electrolyte abnormalities that are common in cancer patients, especially those who are receiving chemotherapy, include hypokalemia, hypomagnesemia, and hypophosphatemia. Vomiting and diarrhea and poor nutrition from chemotherapy can account for many of these abnormalities. However, severe abnormalities are usually caused by drug-induced tubular injury resulting from an acquired form of Fanconi syndrome. Ifosfamide and cisplatin are the commonest agents, but κ light-chain myeloma can also be associated with acquired Fanconi syndrome. Cetuximab, which is often used for the treatment of colorectal cancer, can cause hypomagnesemia that occasionally can be severe. Under normal circumstances, epidermal growth factor (EGF) binds its receptor (EGFR) and stimulates magnesium reabsorption in the distal convoluted tubular cell. Cetuximab is an EGFR antibody that competes with EGF for its receptor, thereby inhibiting normal reabsorption of luminal magnesium and causing renal wasting.

When it comes to electrolyte replacement, the general principles of replacing present deficit and ongoing loss also apply in cancer patients. Patients with Fanconi-like syndrome and severe cetuximab-induced hypomagnesemia may require large amounts of parenterally administered electrolytes to correct their deficit and ongoing losses. The electrolyte requirement subsides with time, but extensive replacement may be required over weeks to months. Renal tubular acidosis (see Chapter 12) resulting from tubular bicarbonate loss is also common in patients with κ light-chain myeloma and in cancer patients treated with antineoplastic, antifungal, or calcineurin-inhibitor drugs and generally responds to oral alkali therapy.

Hypercalcemia is common in cancer patients with advanced cancer with bone metastasis and heralds a poor prognosis. Hypercalcemia is frequently associated with multiple myeloma and can

Management of Cancer-related Hypercalcemia

1. General measures: intravenous fluids followed by loop diuretics.
2. Administer calcitonin, corticosteroids, or both for acute and short-term calcium control.
3. If patient is severely symptomatic and with reduced urine output and impaired renal function, consider dialysis with low-calcium dialysate.
4. Start bisphosphonates for longer-term hypercalcemia control (adjust for renal dysfunction).
5. Treat cancer.
6. For bone resorption–associated hypercalcemia: Humanized anti-RANKL antibody (denosumab) may be more effective than bisphosphonates (under evaluation).
7. For PTHrP-related hypercalcemia: Humanized monoclonal antibody against human PTHrP may be more effective than bisphosphonates (under evaluation).

Box 68-2 Management of cancer-related hypercalcemia. *RANKL,* Receptor activator of nuclear factor κB ligand; *PTHrP,* parathyroid hormone–related protein.

be the presenting feature. Several mechanisms may underlie the tumoral hypercalcemia, such as elevated parathyroid hormone–related peptide (PTHrP) levels arising from the tumor cells as in lung cancer, ectopic vitamin D in certain lymphomas, or tumor resorption of bones as in advanced cancer (see also Chapter 10). Treatment of hypercalcemia often begins with vigorous administration of intravenous fluids (Box 68-2). Although corticosteroids and calcitonin are still useful, persistent hypercalcemia requires bisphosphonate therapy for longer-term control. Rarely dialysis with low-calcium dialysis bath can be used to reduce severe hypercalcemia in symptomatic patients, especially in the presence of renal impairment or inadequate urine output. Use of bisphosphonates, especially zoledronate and pamidronate, can be complicated by AKI and collapsing FSGS, respectively, but ibandronate, another drug in this class, is not known to be associated with renal toxicity.[43]

CANCER THERAPY IN CHRONIC KIDNEY DISEASE AND END-STAGE RENAL DISEASE PATIENTS

Patients with CKD or ESRD have a higher risk for developing cancers, especially renal cell carcinomas (see Chapter 89). Because of the renal failure, treating these patients with chemotherapeutic agents also poses several unique challenges. Pharmacokinetic modeling of chemotherapeutic agents in cancer patients on dialysis suggests that these agents in general tend to be overdosed.[44] Careful dosage and timing of dialysis are critical because overdosage can aggravate systemic toxicities with fatal consequences, whereas underdosage can lead to ineffective cancer treatment (see Chapter 77). Common risk factors for chemotherapy-induced nephrotoxicity include volume depletion, hypoalbuminemia (reduced effective plasma volume), metabolic derangements (hyperuricemia and hypercalcemia), older age, presence of diabetes and other comorbid conditions, underlying AKI or CKD, presence of sepsis, and concomitant use of other potential nephrotoxins. Therefore, optimizing the renal status of the CKD patient before chemotherapy—applying the KIP strategy—such as correcting volume status, adjusting the chemotherapeutic doses of certain drugs according to renal function, removing potential nephrotoxic agents, and taking precautionary measures against tumor lysis can reduce the chance for AKI and in turn chemotoxicity. Moreover, administration of certain chemotherapeutic agents such as platinum compounds requires dose adjustments and timing with dialysis. Other commonly used agents for cancer treatment that need consideration for dose adjustment for glomerular filtration rate and dialysis are melphalan, methotrexate, pemetrexed, capecitabine, hydroxyurea, fludarabine, etoposide, irinotecan, and lenalidomide.[45,46] When tumor lysis occurs in ESRD patients, it can be particularly challenging because of the lack of kidney function to eliminate the products of tumor lysis, and the institution of 2 to 3 days of CRRT or even continuous hemodialysis may become necessary (see Fig. 68-4). Moreover, in CKD-ESRD patients undergoing active cancer treatment, erythropoietin (EPO) should be used judiciously because several controlled trials have shown that higher doses can be associated with poorer cancer outcomes,[47] possibly as a result of stimulation of cancer growth by EPO itself. Use of EPO in this population should follow FDA guidelines and should be managed in consultation with the oncologist.

SECTION XIV

Acute Kidney Injury

CHAPTER 69

Pathophysiology and Etiology of Acute Kidney Injury

J. Ashley Jefferson, Joshua M. Thurman, and Robert W. Schrier

DEFINITION

Acute kidney injury (AKI) is a clinical syndrome denoted by an abrupt decline in glomerular filtration rate (GFR) sufficient to decrease the elimination of nitrogenous waste products (urea and creatinine) and other uremic toxins. This has traditionally been referred to as *acute renal failure* (ARF), but in recent years an effort has been made to implement the term *acute kidney injury* instead, and to develop a standardized definition of AKI. One proposed definition of AKI, for example, is a decline in kidney function over 48 hours as demonstrated by an increase in serum creatinine of greater than 0.3 mg/dl, an increase in serum creatinine of more than 50%, or the development of oliguria.[1] Staging criteria have also been developed based on the magnitude of the rise in serum creatinine and changes in the volume of urine output over 1 week,[1] and studies have validated that these staging criteria are of prognostic value (see Table 71-1).

ETIOLOGIC OVERVIEW

Although AKI is defined by a reduced GFR, the underlying cause of the renal impairment is most frequently a result of tubular and vascular factors. AKI can have a broad range of causes, and the differential diagnosis must be considered in a systematic fashion to avoid missing multiple factors that may be contributing to the condition. The traditional paradigm divides AKI into pre-renal, renal, and post-renal causes. Pre-renal uremia may be caused by hypovolemia or a decreased effective arterial volume. Post-renal obstructive renal failure is usually diagnosed by urinary tract dilation on renal ultrasound. Intrinsic renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply; glomerular, tubular, and interstitial disease; Fig. 69-1). Major extrarenal artery or venous occlusion must also be considered in the differential diagnosis (see Chapter 66). Similarly, disorders of the small intrarenal vasculature can result in AKI (e.g., vasculitis, thrombotic microangiopathy [TMA], malignant hypertension, eclampsia, postpartum states, disseminated intravascular coagulation [DIC], scleroderma; see Chapters 25, 29, 37, 44, and 64). All forms of acute glomerulonephritis (GN) can present as AKI, as can acute inflammation and space-occupying processes of the renal interstitium (e.g., drug-induced, infectious, and autoimmune disorders, leukemia, lymphoma, sarcoidosis).

In the hospital setting, pre-renal uremia and acute tubular necrosis (ATN) account for the majority of AKI cases,[2,3] often in the setting of AKI superimposed on chronic kidney disease (CKD), so-called "acute-on-chronic renal failure" (Fig. 69-2). The term *tubular necrosis* is a misnomer because the alterations are not limited to the tubular structures and true cellular necrosis in human ATN is often minimal. However, the term *acute tubular necrosis* is commonly used in the clinical setting. To make things even more confusing, the terms *acute tubular necrosis, acute renal failure,* and *acute kidney injury* are frequently used interchangeably in the literature. The term *acute tubular necrosis* should be reserved for cases of AKI in which a renal biopsy (if performed) shows the characteristic changes of tubular cell injury, and for patients with findings of tubular injury (such as renal tubular epithelial cells in the urine sediment) in an appropriate clinical setting (Fig. 69-3).

There are also significant geographic differences in the causes of AKI; the spectrum of causes in tropical countries is described in Chapter 70.

PATHOPHYSIOLOGY AND ETIOLOGY OF PRE-RENAL ACUTE KIDNEY INJURY

Impaired renal perfusion with a resultant fall in glomerular capillary filtration pressure is a common cause of AKI. In this setting, tubular function is typically normal, renal reabsorption of sodium and water is increased, and consequently urine chemistries reveal a low urine sodium (<20 mmol/l) and a concentrated urine (urine osmolality >500 mOsm/kg) as long as no loop diuretic has been administered.

A marked reduction in renal perfusion may overwhelm autoregulation and precipitate an acute fall in GFR. With lesser degrees of renal hypoperfusion, glomerular filtration pressures and GFR are maintained by afferent arteriolar vasodilation (mediated by vasodilatory eicosanoids) and efferent arteriolar vasoconstriction (mediated by angiotensin II). In this setting, AKI may be precipitated by agents that impair afferent arteriolar dilation (nonsteroidal anti-inflammatory drugs [NSAIDs]) or efferent vasoconstriction (angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers [ARBs]).

Pre-renal AKI is commonly secondary to extracellular fluid volume depletion resulting from gastrointestinal losses (diarrhea, vomiting, prolonged nasogastric drainage), renal losses (diuretics, osmotic diuresis in hyperglycemia), dermal losses (burns, extensive sweating), or possibly sequestration of fluid, so-called third spacing (e.g., acute pancreatitis, muscle trauma). Renal perfusion may be impaired even in the setting of normal or even increased extracellular fluid. For example, renal perfusion may be reduced by a decreased cardiac output (heart failure) or by systemic arterial vasodilation with redistribution of cardiac output to extrarenal vascular beds (e.g., sepsis, liver cirrhosis). The presence of AKI in the setting of severe heart failure has been termed the *cardiorenal syndrome* and is often exacerbated by the use of ACE inhibitors and diuretics.

An unusual cause of pre-renal AKI is the hyperoncotic state. Infusion of large quantities of osmotically active substances such as mannitol, dextran, or protein can increase the glomerular oncotic

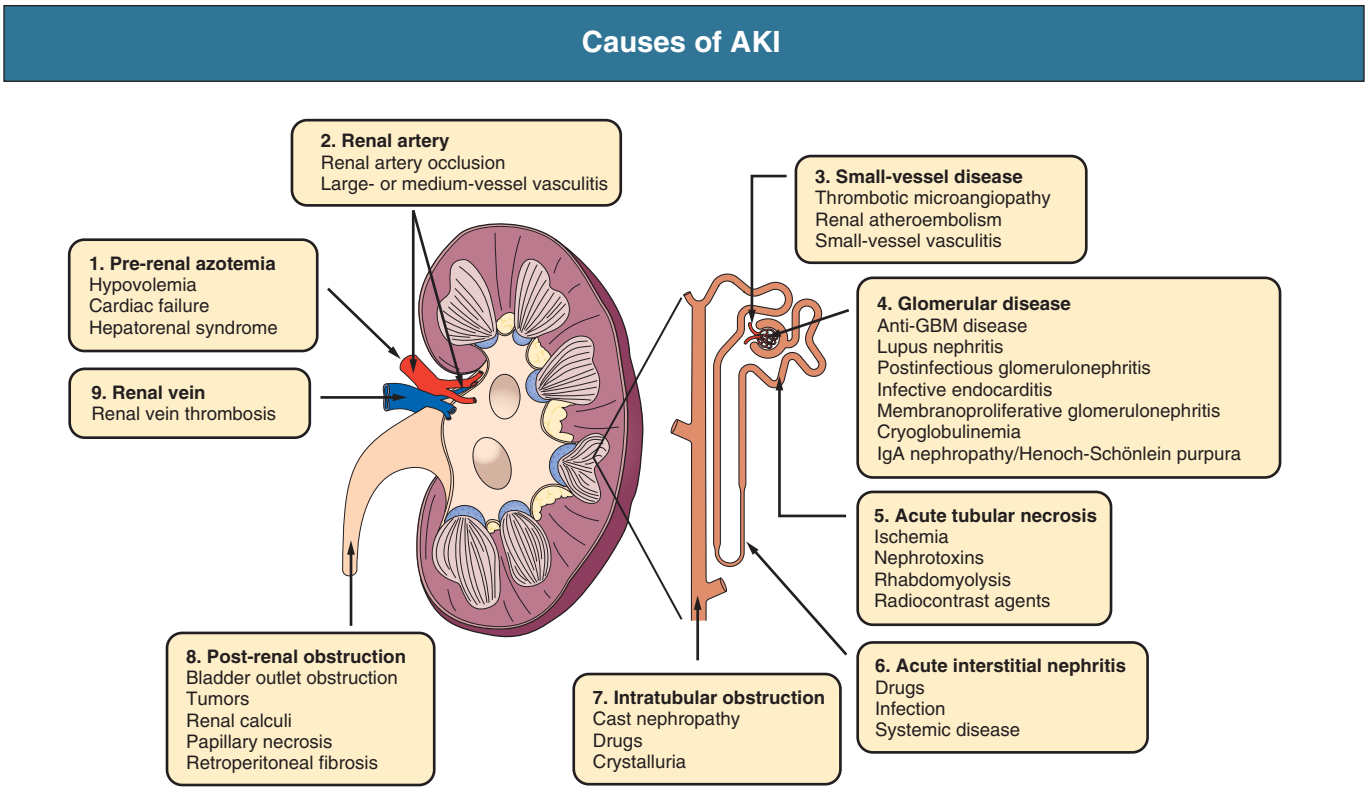

Figure 69-1 Causes of acute kidney injury (AKI). AKI is classified into pre-renal, renal, and post-renal causes. Renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply; glomerular, tubular, and interstitial disease). *GBM,* Glomerular basement membrane.

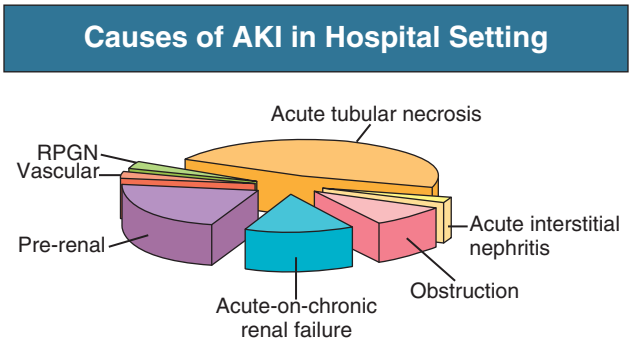

Figure 69-2 Causes of acute kidney injury (AKI) in the hospital setting. Madrid Acute Renal Failure Study (1996). *RPGN,* Rapidly progressive glomerulonephritis.

pressure enough to exceed the glomerular capillary hydrostatic pressure, which stops glomerular filtration, leading to an anuric form of AKI.

Pre-renal AKI can be corrected if the extrarenal factors causing the renal hypoperfusion are rapidly reversed. Failure to restore renal blood flow (RBF) during the functional pre-renal stage will ultimately lead to ischemic ATN and tubular cell injury.

PATHOPHYSIOLOGY AND ETIOLOGY OF POST-RENAL ACUTE KIDNEY INJURY

In any patient presenting with AKI, an obstructive cause must be excluded because prompt intervention can result in improvement or complete recovery of renal function (see Chapter 60). Post-renal forms of AKI are divided into intratubular and extrarenal. Tubular precipitation of insoluble crystals (phosphate, oxalate, uric acid, methotrexate, acyclovir, sulfonamides, indinavir, triamterene) or protein (hemoglobin, myoglobin, paraprotein) can increase intratubular pressure. If sufficiently high, this opposes glomerular filtration pressure and can decrease GFR. Similarly, obstruction of the extrarenal collecting system at any level (renal pelvis, ureters, bladder, or urethra) can lead to post-renal AKI. Obstructive uropathy is common in older men with prostatic disease and in patients with a single kidney or intra-abdominal, particularly pelvic, cancer. Severe ureteral obstruction is also seen with retroperitoneal fibrosis. Most causes of obstructive uropathy are amenable to therapy, and the prognosis is generally good, depending on the underlying disease. Obstructive uropathy is further discussed in Chapter 60.

PATHOPHYSIOLOGY OF ACUTE TUBULAR NECROSIS

Acute tubular necrosis commonly occurs in high-risk settings, which include vascular and cardiac surgery, severe burns, pancreatitis, sepsis, and chronic liver disease. ATN is responsible for most cases of hospital-acquired AKI and is usually a result of ischemic or nephrotoxic injury. In the intensive care unit, two thirds of cases of AKI are a result of the combination of impaired renal perfusion, sepsis, and nephrotoxic agents.[4]

The importance of combined injurious mechanisms is also emphasized by experimental data. In animal studies, severe and prolonged hypotension (<50 mm Hg for 2 to 3 hours in the rat) does not cause ATN. Similarly, in animal models, very high doses of single nephrotoxic agents are required to induce AKI. These features may

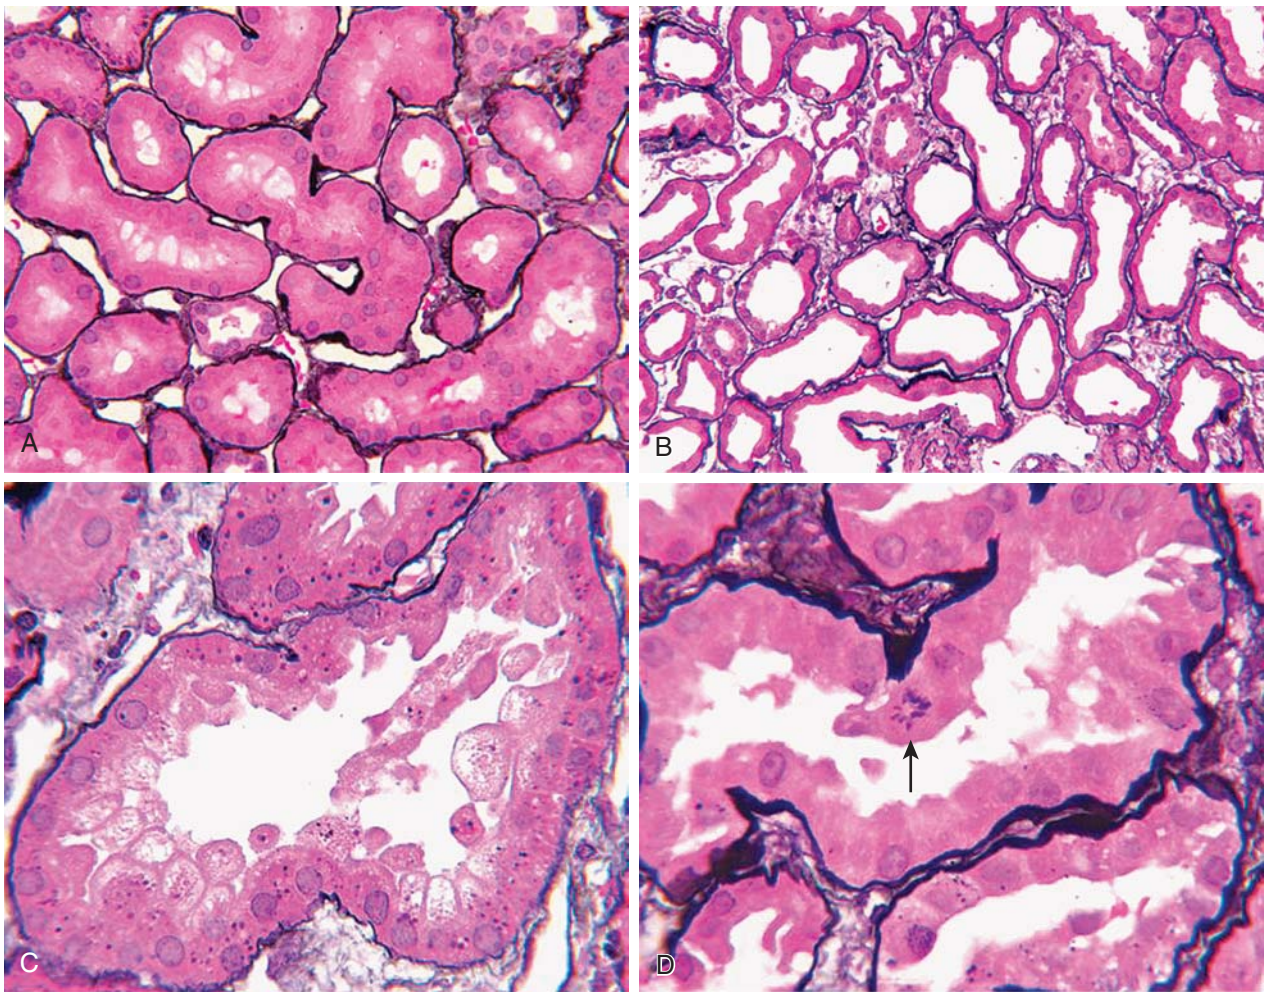

Figure 69-3 Renal pathology in acute tubular necrosis (ATN). A, Normal cortical renal tubules. **B** and **C,** ATN. Note the flattened epithelium, bare basement membranes, and intraluminal cellular debris. **D,** Recovering ATN showing a tubular epithelial cell mitotic figure *(arrow). (Courtesy Erika Bracamonte, MD, University of Arizona.)*

reflect an inherent resistance to tubular injury in animal models, but also illustrate the fact that a single insult alone is rarely sufficient to induce ATN. Fever may exacerbate ATN by increasing the renal tubular metabolic rate, thereby increasing adenosine triphosphate (ATP) consumption. In an experimental model (renal artery occlusion in the rat), renal ischemia for 40 minutes resulted in minimal renal injury at 32° C but marked renal injury at 39.4° C.

The typical course of uncomplicated ATN is recovery over 2 to 3 weeks; however, superimposed renal insults often alter this pattern. For example, episodes of hypotension induced by hemodialysis may lead to additional ischemic lesions, potentially prolonging renal functional recovery, and patients with AKI often have multiple comorbidities.

Histology

The typical features of ATN on renal biopsy include vacuolization and loss of brush border in proximal tubular cells. Sloughing of tubular cells into the lumen leads to cast obstruction, manifested by tubular dilation. Interstitial edema can produce widely spaced tubules, and a mild leukocyte infiltration may be present (see Fig. 69-3).

Despite the term *acute tubular "necrosis,"* frankly necrotic cells are not a common finding on renal biopsy, and histologic evidence of injury frequently involves only 10% to 15% of the tubules despite marked functional impairment. This implies that factors other than just tubular cell injury (such as vasoconstriction and tubular obstruction) are important in the loss of GFR.

TUBULAR INJURY IN ACUTE TUBULAR NECROSIS

The tubular damage is usually caused by a combination of ischemic injury resulting in depletion of cellular ATP and direct tubular epithelial cell injury by nephrotoxins. Most accept that the S_3 segment of the proximal tubule and the medullary thick ascending limb (mTAL) are particularly vulnerable to hypoxic injury (Fig. 69-4). There are several reasons for this vulnerability.[31]

Blood Supply

The blood flow to the kidney is not uniform, and most of it is directed to the renal cortex, where the cortical tissue partial oxygen pressure (P_{O_2}) is 50 to 100 mm Hg, for glomerular filtration. By contrast, the outer medulla and medullary rays are watershed areas receiving their blood supply from vasa recta. Countercurrent oxygen exchange occurs, leading to a progressive fall in P_{O_2} from cortex to medulla,

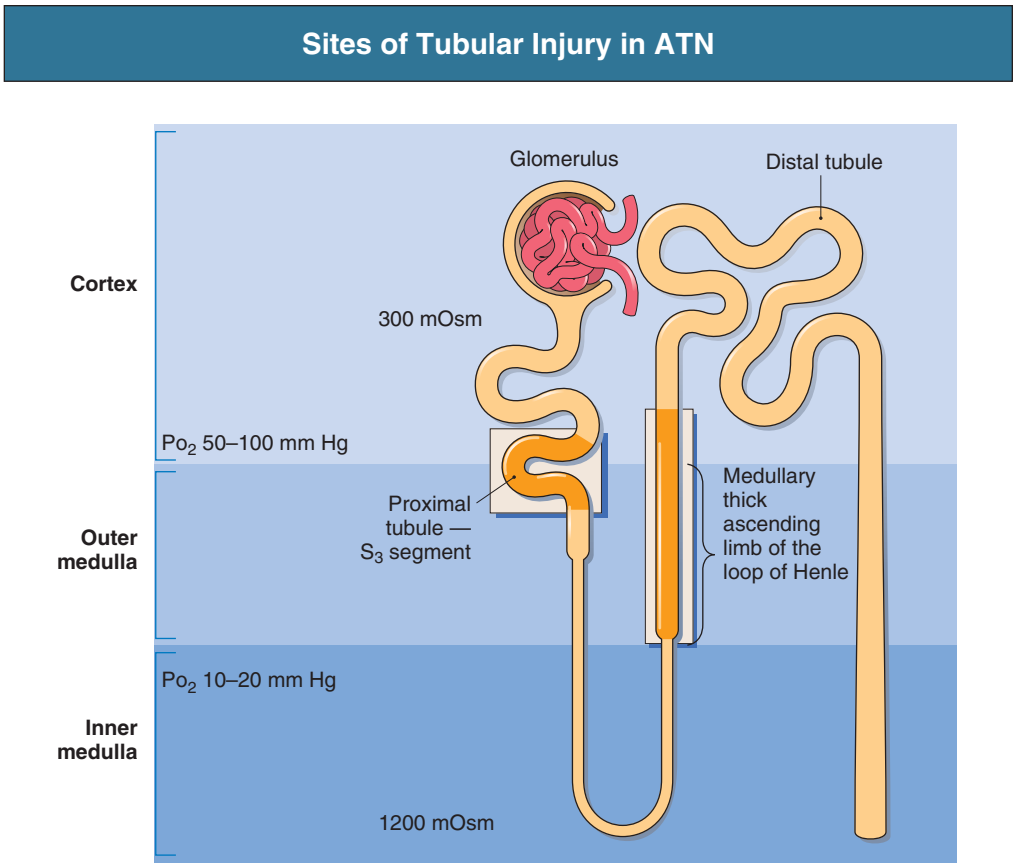

Figure 69-4 Sites of tubular injury in acute tubular necrosis (ATN). The S_3 segment of the proximal tubule and the medullary thick ascending limb are particularly vulnerable to ischemic injury because of the combination of borderline oxygen supply and high metabolic demands.

which results in medullary cells living on the "brink of hypoxia" (medullary P_{O_2} as low as 10 to 15 mm Hg). The S_3 segments of proximal tubule cells and distal mTALs are thus exposed to borderline chronic oxygen deprivation.

High Tubular Energy Requirements

The cells of the S_3 region and mTAL have high metabolic activity, principally because of sodium reabsorption driven by basolateral membrane Na^+-K^+-ATPase. Indeed, blocking sodium reabsorption in the mTAL with loop diuretics raises the medullary tissue P_{O_2} from about 15 to 35 mm Hg. Of note, the reduction of GFR in the setting of AKI may be renoprotective by diminishing sodium filtration and hence limiting ATP-dependent sodium reabsorption.

Glycolytic Ability of Tubular Cells

Proximal tubular cells have minimal glycolytic machinery and rely almost solely on oxidative phosphorylation for the generation of ATP. In contrast, mTAL cells have a large glycolytic capacity and are more resistant to hypoxic or ischemic insults.

Hemodynamic Factors in the Development of Acute Tubular Necrosis

Impaired Renal Autoregulation

Autoregulation normally occurs between systolic blood pressures of 80 and 150 mm Hg; within this range, RBF, glomerular pressures, and GFR are maintained. Below 80 mm Hg, this autoregulation fails, and ischemic injury may result. In certain conditions, such as aging or chronic renal disease, autoregulation is abnormal, and ischemic injury may occur more easily with reductions in perfusion pressure. In addition, experimental studies demonstrate impaired autoregulation in ischemic ATN. In settings of low renal perfusion (e.g., volume depletion, left ventricular failure, edematous states, renal artery stenosis), GFR may be dependent on autoregulation mediated by vasodilatory prostaglandins acting on the afferent arteriole and angiotensin II–mediated efferent arteriolar vasoconstriction to maintain glomerular pressure. Any interference with these mechanisms (e.g., administration of ACE inhibitors or acute inhibition of cyclooxygenase-1 [COX-1] or COX-2 by NSAIDs) may produce a precipitous fall in GFR.

Intrarenal Vasoconstriction

In established ATN, RBF is decreased by 30% to 50%. Indeed in AKI, rather than the normal autoregulatory renal vasodilation that occurs in response to decreased perfusion pressure, there is evidence of renal vasoconstriction. A number of vasoconstrictors have been implicated in this response, including angiotensin II, endothelin-1, adenosine, thromboxane A_2, prostaglandin H_2, leukotrienes C_4 and D_4, and sympathetic nerve stimulation (Fig. 69-5). Tubuloglomerular feedback (TGF) also contributes to this vasoconstriction. Some of these vascular abnormalities may be mediated by increased cytosolic calcium content in afferent arterioles as a result of ischemia. Disruption of the actin cytoskeleton in vascular smooth muscle cells may also impair autoregulation.

Tubuloglomerular Feedback

The role of TGF (see Chapter 2) in the setting of AKI may be partly beneficial because the resultant decrease in GFR limits sodium

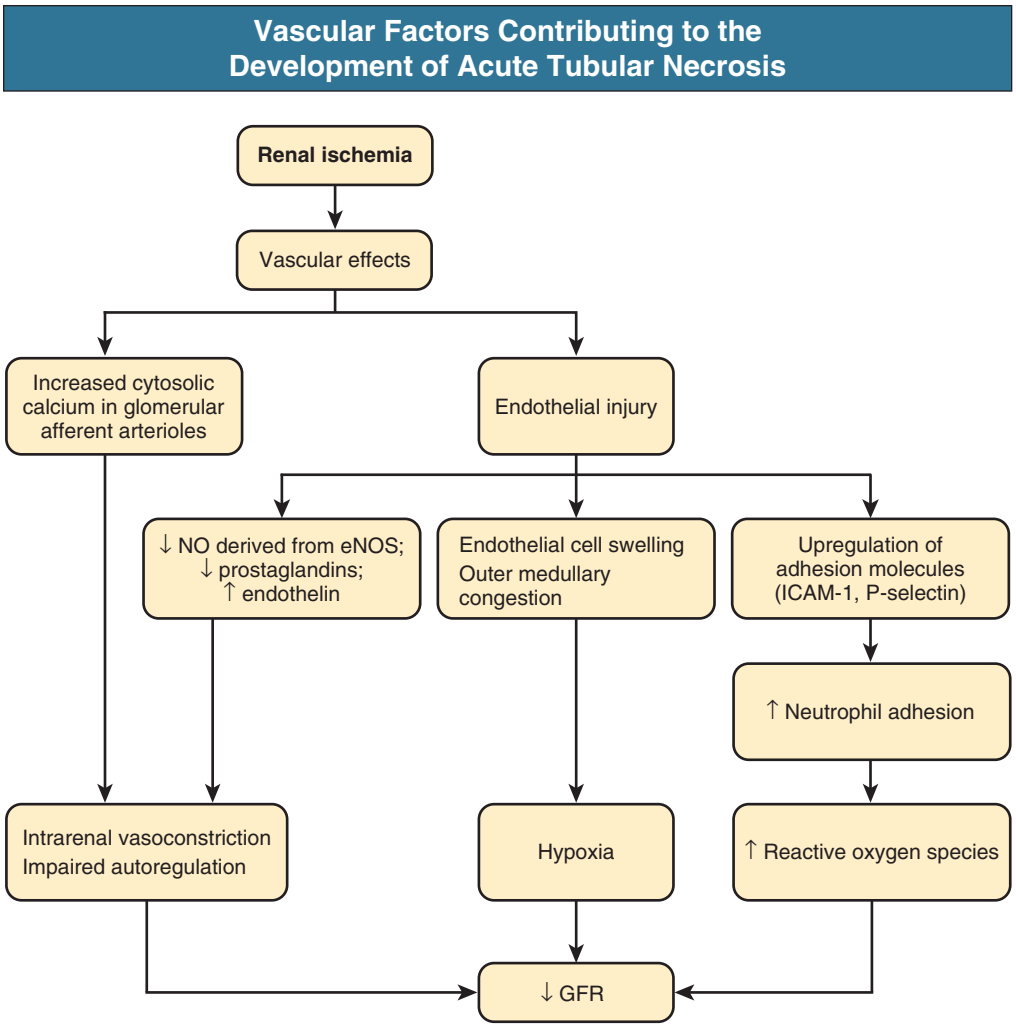

Figure 69-5 Vascular factors contributing to the development of acute tubular necrosis. *eNOS,* Endothelial nitric oxide synthase; *ICAM-1,* intercellular adhesion molecule 1; *GFR,* glomerular filtration rate; *NO,* nitric oxide.

delivery to damaged tubules and decreases ATP-dependent tubular reabsorption, protecting against intracellular ATP depletion augmenting renal injury. In this respect, adenosine A_1 receptor knockout mice with absent TGF have augmented AKI after ischemia reperfusion.

Endothelial Cell Injury and the Development of Acute Tubular Necrosis

Acute kidney injury is not limited to the tubular cell, and endothelial cell injury occurs partly as a result of acute renal ischemia and oxidant injury.[5] Endothelial injury is characterized by cell swelling, upregulation of adhesion molecules (with enhanced leukocyte–endothelial cell interactions), and impaired vasodilation (decreased endothelial nitric oxide synthase and vasodilatory prostaglandins) and may mediate some of the impaired autoregulation and intrarenal vasoconstriction described earlier. Endothelial injury within the peritubular capillaries (vasa recta) may produce congestion in the outer medulla, exacerbating hypoxic injury to the S_3 segment of the proximal tubule and the thick ascending loop of Henle.

Tubular Epithelial Cell Injury and the Development of Acute Tubular Necrosis

The tubular cell may be injured because of ischemia, with resulting depletion of cellular energy stores (ATP), or from direct cytotoxic injury. Following acute renal ischemia, tubular cell injury may also result from the restoration of RBF (reperfusion injury). Mediators of tubular cell injury include reactive oxygen species (ROSs), intracellular calcium influx, nitric oxide, phospholipase A_2, complement, and cell-mediated cytotoxicity. Mitochondrial injury can be caused by ROSs, depletion of antioxidants, and increased intracellular calcium. Disruption of mitochondrial function then exacerbates cellular injury because of disrupted energy metabolism and release of proapoptotic proteins. Autophagy is a mechanism by which cells degrade proteins, and it is a central part of the cellular response to stress and injury. Experimental work has shown that autophagy is important for removal of damaged mitochondria and recovery of tubular epithelial cells from ischemic injury. ROSs may be derived from local sources (including xanthine oxidase and COXs, and secondary to mitochondrial injury) or from infiltrating leukocytes. In models of ischemic ATN, a variety of methods that inhibit ROSs protect against renal injury.[6] Hypoxia inducible factor (HIF) and downstream mediators such as heme oxygenase 1 may protect cells against ischemic injury.[7]

Factors that affect the integrity and function of the renal tubular epithelial cells and contribute to the reduction in GFR include the following (Fig. 69-6):

Cell death—Despite the term *acute tubular necrosis,* only a small percentage of tubular cells undergo cell death, and of these, many actually die by apoptosis rather than necrosis. Indeed, recent studies in animal models have shown amelioration of renal injury

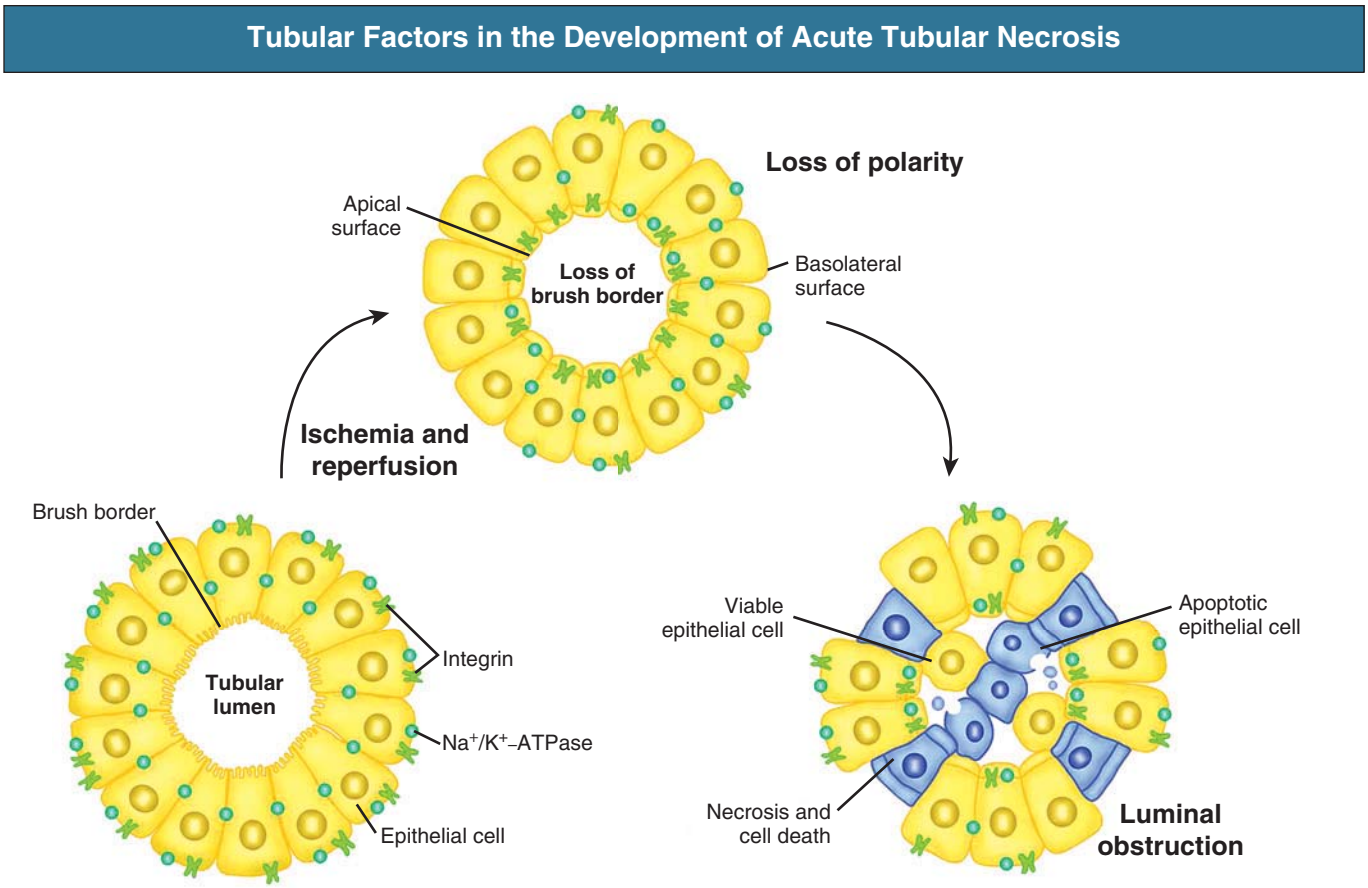

Figure 69-6 Tubular factors in the development of acute tubular necrosis. Loss of cell polarity results in weakening of cell-to-cell and cell matrix adhesion, resulting in cast obstruction and backleak of tubular fluid. *(Modified from reference 31.)*

with use of caspase inhibitors and p53 inhibitors that decrease apoptosis.[8]

Disruption of actin cytoskeleton—A characteristic feature of sublethally injured cells is the disruption of the actin cytoskeleton. Activation of the cysteine protease calpain (partly because of increased intracellular calcium) can degrade actin-binding proteins such as spectrin and ankyrin. This leads to abnormal translocation of Na^+-K^+-ATPase and other proteins from the basolateral membrane to the cytoplasm or apical membranes. In the proximal tubular cell, this loss of polarity results in impaired proximal reabsorption of filtrate with resultant increased distal NaCl delivery and activation of TGF.

Cast obstruction—Tubular cells are attached to the tubular basement membrane by $\alpha_3\beta_1$ integrins, which recognize RGD (arginine-glycine-aspartate) sequences in matrix proteins. Disruption of the actin cytoskeleton results in movement of integrins from basolateral positions to the apical membrane, leading to impaired cell matrix adhesion and cell detachment. Many of these detached cells are still viable and can be cultured from urine of patients with ATN. Sloughed proximal tubular cells can bind to RGD sequences in Tamm-Horsfall protein, resulting in cast formation and intratubular obstruction. In models of ischemic AKI, the elevation in tubular pressures may be inhibited by synthetic RGD peptides mitigating the obstructive process.

Backleak—The loss of adhesion molecules (E-cadherin) and tight junction proteins (ZO-1, occludin) results in the weakening of junctions between cells, allowing filtrate to leak back into the renal interstitium. Although this does not alter the actual GFR at the level of the glomerulus, the net effect is a reduction in the measured GFR. Earlier dextran sieving experiments suggest only a modest effect of backleak on the decrement of GFR in AKI (about 10%); however, in the renal allograft with delayed graft function because of severe ATN, backleak has been calculated to account for up to 50% of the reduction in inulin clearance.

Inflammatory Factors in the Development of Acute Tubular Necrosis

Although ischemia causes direct renal cytotoxicity, tissue inflammation during reperfusion also contributes to renal injury and may cause some of the systemic effects of AKI. Components of both the innate and the adaptive immune systems contribute to the pathogenesis of ATN.[9] The innate immune system is activated by cellular injury and certain pattern recognition molecules. Toll-like receptor 2 (TLR2) and TLR4 are upregulated within the kidney after ischemia, are activated by molecules released from injured cells, and induce renal epithelial cells to produce chemokines. The complement system is also activated within the tubulointerstitium after ischemia and reperfusion, predominantly by the alternative pathway. It can directly induce nearby epithelial cells to produce proinflammatory cytokines (such as tumor necrosis factor α [TNF-α], interleukin [IL]–6, IL-1β) and chemokines (such as monocyte chemoattractant protein 1[MCP-1], IL-8, regulated upon activation normal T cell expressed and presumably secreted [RANTES]) that promote the infiltration of the kidney by leukocytes and are also directly vasoactive.

A network of dendritic cells extends throughout the renal tubulointerstitium; these cells help shape the inflammatory response within the kidney after ischemia and reperfusion, likely through their

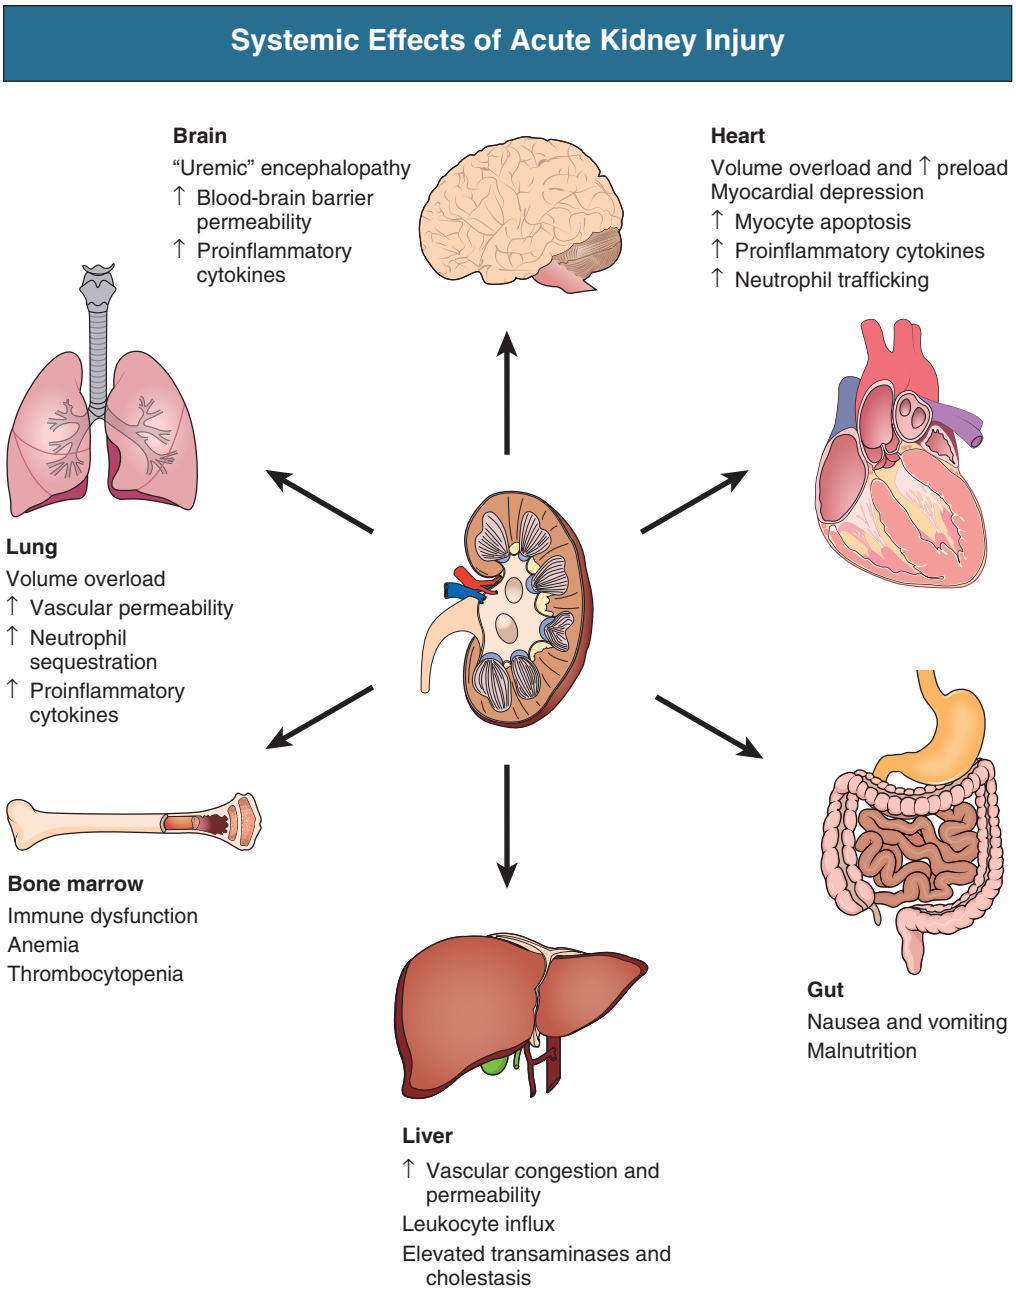

Figure 69-7 Systemic effects of acute kidney injury. Acute kidney injury (AKI) may contribute to remote organ injury, partly because of abnormalities in inflammatory and immune function from renal tubular dysfunction. *(Modified from reference 10.)*

interactions with other inflammatory cell types. Neutrophils and mononuclear cells are seen in peritubular capillaries on renal biopsy. Experimental studies have shown that neutrophil activation and the release of proteases and ROSs can exacerbate injury. By contrast, neutrophil depletion with antibody, or inhibiting neutrophil adhesion molecules (ICAM-1) with antibody or antisense oligonucleotides, ameliorates injury in ischemic ATN. ICAM-1 knockout mice are similarly protected. Monocytes infiltrate the reperfused kidney and differentiate into the M1, or inflammatory, type. M1 macrophages seem to exacerbate renal injury after ischemia, but studies have demonstrated that macrophages may later convert to the M2 "anti-inflammatory" type and promote repair of the kidney.

A number of studies have also demonstrated that cells of the adaptive immune system, including T and B lymphocytes, contribute to renal injury in models of ATN. Experimental ischemic reperfusion injury may be ameliorated by T cell or B cell deficiency. It is not known whether these responses are antigen specific. Furthermore, some B and T cell subsets, such as T regulatory cells, help limit renal injury.

We should also recognize that AKI may have systemic effects on other organ systems.[10] The injured kidney may prime and activate leukocytes, with the production of proinflammatory cytokines, which can mediate remote organ injury (Fig. 69-7). The lungs may be particularly vulnerable from the combined effects of volume overload, increased vascular permeability, and the proinflammatory environment. These distant organ effects may partly account for the increased mortality in patients with AKI (Chapter 72).

RECOVERY PHASE

Recovery from ATN requires the restoration of tubular cell number and coverage of denuded tubular basement membrane. A marked increase in cell proliferation occurs in recovering human ATN, and

mitotic figures may be seen by light microscopy (see Fig. 69-3). There has been some debate about the origin of the restored tubular cells. Some studies have suggested that mesenchymal stem cells locate to areas of tubular injury and transform into proximal tubular cells. Indeed, in experimental models, ischemia reperfusion injury may be ameliorated by infusions of mesenchymal stem cells. More recent evidence, however, suggests that the restoration of tubular cell number is a result of the dedifferentiation and proliferation of surviving tubular cells.[11] A number of growth factors have been implicated in the proliferative response, including insulin-like growth factor 1 (IGF-1) and hepatocyte growth factor (HGF); however, a therapeutic trial of subcutaneous recombinant IGF-1 in critically ill patients failed to show an acceleration in renal functional recovery.[12] After tubular epithelial cell proliferation, the dedifferentiated cells must migrate to areas of denuded tubular basement membrane, attach to the basement membrane, and differentiate into mature polar tubular epithelial cells.

NEPHROTOXIC AGENTS AND MECHANISMS OF TOXICITY

The identification and avoidance of nephrotoxic agents in AKI is critical in the management of this condition because AKI may be rapidly reversible on removal of the offending agent. The mechanisms of nephrotoxicity are very broad and include alterations in renal hemodynamics, induction of direct tubular injury, generation of allergic reactions resulting in interstitial nephritis, and intratubular obstruction. The list is extensive, but the more common agents are presented in Figure 69-8.

Nonsteroidal Anti-inflammatory Drugs

The NSAIDs are a common cause of AKI in the community because of the large amounts of these drugs either prescribed or bought over the counter.[13] The newer COX-2–specific NSAIDs have similar effects on renal function as the nonselective NSAIDs and thus are not safer with respect to AKI.

This type of NSAID-related AKI may be caused by a hemodynamically mediated reduction in GFR in particular clinical situations, such as atherosclerotic cardiovascular disease in elderly patients, preexisting CKD, states of renal hypoperfusion (including sodium depletion, diuretic use, hypotension), and sodium-avid states such as cirrhosis, nephrotic syndrome, and congestive heart failure. There is little evidence that NSAIDs impair renal function in otherwise healthy individuals. This form of AKI is usually reversible in 2 to 7 days after discontinuation of the drug.

Less frequently, NSAIDs induce ATN or, even more rarely, papillary necrosis.[13] NSAIDs, including the COX-2–specific NSAIDs, may also cause an acute interstitial nephritis, often with significant proteinuria (see Chapter 62). Other renal side effects of NSAIDs include fluid and electrolyte disturbances such as sodium retention exacerbating hypertension and congestive heart failure, hyponatremia, and hyperkalemia.

Angiotensin-converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme inhibitors and ARBs may also cause hemodynamically induced AKI in the setting of reduced renal perfusion resulting from impaired vasoconstriction of the efferent arteriole. They can also directly impair renal perfusion by their antihypertensive effects. Patients in whom renal perfusion is compromised because of dehydration, renovascular disease, or functionally impaired autoregulation are at risk for developing AKI after initiation of therapy with ACE inhibitors or ARBs.

Patients chronically treated with ACE inhibitors have an increased risk for postoperative renal dysfunction, probably as a consequence of intraoperative hypotensive episodes.

Aminoglycosides

Aminoglycosides are excreted by glomerular filtration, and toxicity may occur if the dose is not adjusted for underlying renal impairment. Cationic amino groups (NH_3^+) on the drugs bind to anionic megalin on the brush border of proximal tubular epithelial cells, and the drugs are then internalized by endocytosis. Aminoglycosides accumulate in proximal tubular cell lysosomes and can reach 100 to 1000 times their serum concentration. The drug interferes with cellular energetics, impairs intracellular phospholipases, and induces oxidative stress; however, the exact pathways culminating in tubular necrosis remain unclear.[14]

Nonoliguric AKI usually occurs after 5 to 10 days of treatment with gentamicin. Involvement of distal tubular segments may produce polyuria, potassium, and magnesium wasting. The risk for AKI correlates with the accumulation of gentamicin in proximal tubular cells and is related to the daily dose and duration of therapy. Prolonged accumulation in proximal tubular cells may allow development of AKI even after the drug has been discontinued. Additional risk factors for gentamicin toxicity include increasing age, preexisting renal disease, hypotension, concurrent liver disease, sepsis syndrome, and concurrent nephrotoxins.

Aminoglycoside serum levels should be followed to minimize nephrotoxicity. When possible, the drug may be administered in a single daily total dose, which leads to lower renal proximal tubular cell accumulation. Gentamicin, tobramycin, and netilmicin appear to have similar nephrotoxic effects. Amikacin, which has fewer amino groups per molecule, may be less nephrotoxic. Ototoxicity, and possibly nephrotoxicity, might be ameliorated by *N*-acetylcysteine.

The macrolide antibiotic vancomycin has rarely been associated with AKI when used as monotherapy, typically with very high serum drug levels. However, when used with gentamicin, it may increase the risk for aminoglycoside-induced AKI.

Amphotericin

The polyene macrolide antibiotic amphotericin binds to sterols in the cell membranes of both fungal walls (ergosterol) and mammalian (cholesterol) cell membranes, resulting in the formation of aqueous pores, which increase membrane permeability. The increased sodium influx leads to increased Na^+-K^+-ATPase activity and depletion of cellular energy stores.[15] In addition, the standard amphotericin formulation is suspended in the bile salt deoxycholate, which has a detergent effect on cell membranes. Nephrotoxicity relates to cumulative dosage, usually occurring after administration of 2 to 3 g.

Early signs of nephrotoxicity include a loss of urine-concentrating ability, followed by a decrease in GFR. Hypokalemia and hypomagnesemia from distal tubular toxicity are common. A distal renal tubular acidosis may be present because of proton backleak in the cortical collecting duct.

Prevention of nephrotoxicity requires the maintenance of high urine flow rates by saline loading during amphotericin administration. The more expensive liposomal amphotericin preparations reduce the incidence of AKI by 50%. The binding of amphotericin to ergosterol is more avid than to cholesterol, and by delivering

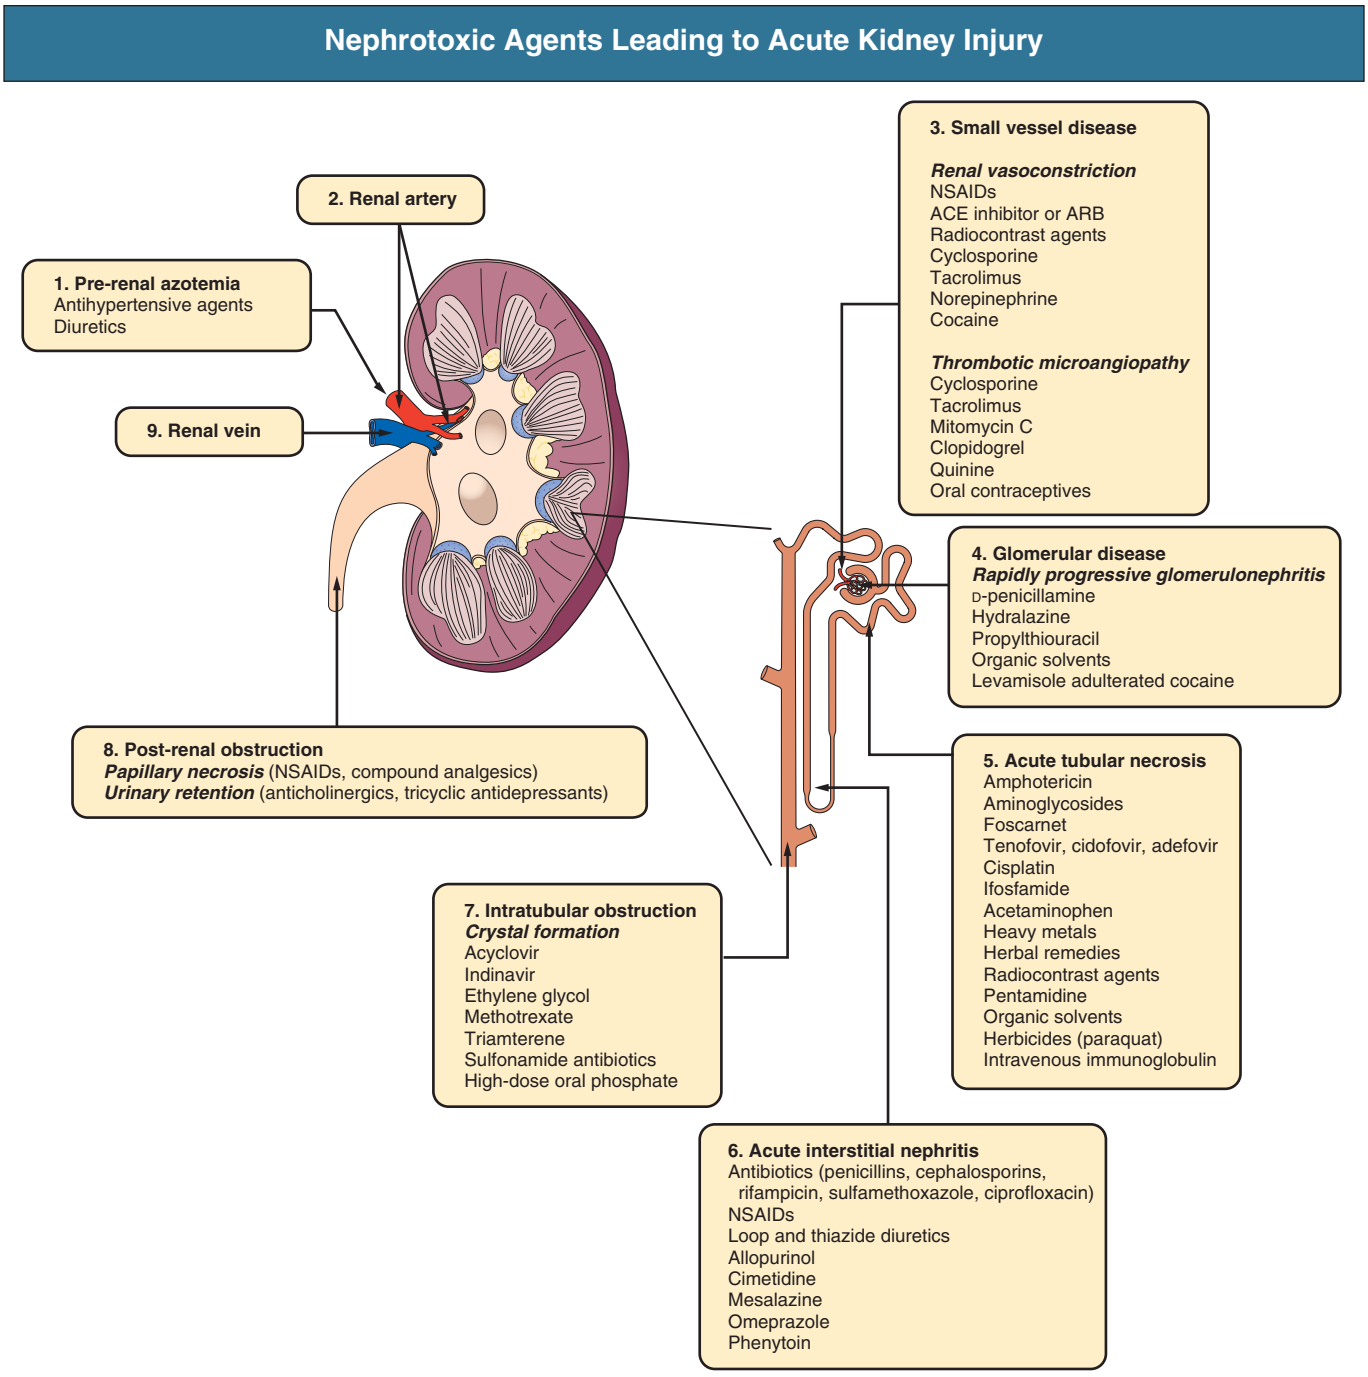

Figure 69-8 Common nephrotoxic agents leading to acute tubular necrosis. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

the drug as a cholesterol liposome, diminished binding to tubular epithelial cell membranes results without altering fungal binding. In addition, liposomal preparations do not contain deoxycholate. Amphotericin-induced AKI is usually reversible with discontinuation of treatment with the drug, although distal tubular injury as manifested by magnesium wasting may persist.

Antiviral Therapy

Acyclovir

Nephrotoxicity is typically seen after intravenous acyclovir administration and may be a result of direct tubular cell toxicity and the formation of intratubular acyclovir crystals. The latter appear as birefringent needle-shaped crystals on urine microscopy. However, crystals may also be seen in patients without AKI, and renal biopsy data suggest that acute interstitial nephritis may be the predominant mechanism of toxicity. Ceftriaxone appears to increase the risk for acyclovir nephrotoxicity. In contrast, ganciclovir has little nephrotoxicity.

Oliguric AKI typically occurs within a few days of treatment and may be associated with abdominal or loin pain. High serum levels of acyclovir resulting from decreased renal clearance may produce neurologic toxicity. The AKI is usually mild and recovers on stopping the drug.

Foscarnet

Foscarnet is a phosphate analogue used in the treatment of severe cytomegalovirus infection but also inhibits proximal tubule sodium-phosphate cotransport. AKI occurs in 10% to 20% of treated patients and may be caused by ATN or intratubular crystal obstruction and acute interstitial nephritis. The AKI is usually nonoliguric and associated with mild proteinuria (<1 g) and a benign urine sediment. Hypocalcemia caused by chelation of calcium may be present. The renal failure is usually reversible, although recovery may take several months. Prehydration markedly decreases the incidence of AKI.

Cidofovir and Adefovir

The nucleotide analogues cidofovir and adefovir have been associated with AKI secondary to proximal tubular injury in 12% to 24% of patients. These agents are transported into the proximal tubule by the human organic anion transporter (hOAT), and nephrotoxicity may be reduced by volume expansion and by concurrent use of probenecid, which blocks hOAT.

Other Antiviral Agents

Most other antiviral agents are not nephrotoxic. In the treatment of hepatitis C virus (HCV), there have been rare reports of ATN secondary to interferon-α.

Immunosuppressive Agents

Calcineurin Inhibitors

Cyclosporine and tacrolimus may cause acute renal impairment as a result of afferent arteriolar vasoconstriction partly mediated by endothelin. This is usually reversible on dose reduction. Persistent injury may lead to chronic interstitial fibrosis in a striped pattern along medullary rays, reflecting the ischemic nature of the insult as well as the development of arteriolar hyalinosis. Associated clinical features include hypertension, hyperkalemia, hyperuricemia, and wasting of phosphate and magnesium from tubular injury. Calcineurin inhibitors also cause reversible tubular dysfunction, and they are associated with the development of TMA, likely because of their effects on the endothelium (see Chapters 29 and 101).

Other Immunosuppressive Agents

The monoclonal anti-CD3 antibody (OKT3) or polyclonal antilymphocyte and antithymocyte preparations (ALG, ATG) may cause a first-dose cytokine release syndrome and pre-renal AKI secondary to capillary leak. OKT3 has rarely been associated with a hemolytic uremic syndrome (HUS). Intravenous immunoglobulin (IVIG) can cause AKI, which may be partly mediated by the high sucrose concentration in these products. Tubular uptake of sucrose may result in osmotic cell swelling and injury. Methotrexate is toxic to proximal tubular epithelial cells and rarely may cause intratubular crystal obstruction. Although it is not known to cause AKI, sirolimus delays the recovery of AKI in animal models and in kidney transplant patients with delayed graft function.

Acetaminophen (Paracetamol)

Isolated ATN with acetaminophen may occur in rare patients, but renal injury is more typically associated with acute hepatitis. Renal and liver toxicity usually occur when more than 15 g have been taken, but in alcoholics, normal doses may be toxic. Acetaminophen is conjugated in the liver and undergoes renal excretion. Less than 5% undergoes metabolism by P-450 (CYP2E1) enzymes to form a toxic metabolite, *N*-acetylimidoquinone, which is inactivated by the thiol group of glutathione. With high levels of acetaminophen, glutathione becomes depleted, and *N*-acetylimidoquinone can bind to thiol groups on intracellular proteins, resulting in cell injury. Because glutathione is a major intracellular antioxidant, its loss may predispose to oxidative injury of the tubular cells.

Clinically, acute hepatitis and ATN begin only when glutathione levels are depleted, and clinical manifestations usually present 3 to 4 days after ingestion. *N*-acetylcysteine can be protective, if administered early, because it provides a free thiol group, substituting for glutathione.

Ethylene Glycol

Ethylene glycol, found in antifreeze, remains a cause of both deliberate and accidental injury. It is rapidly metabolized by alcohol dehydrogenase to glycoaldehyde and glyoxylate, which are toxic to tubular cells. Further metabolism generates oxalic acid, which can precipitate in renal tubules, leading to intratubular obstruction.

The diagnosis is suggested by the presence of a severe anion gap metabolic acidosis and a serum osmolal gap. Oxalate crystals are typically, but not always, seen on urine microscopy (see Chapter 4, Fig. 4-4). Management includes inhibition of alcohol dehydrogenase with intravenous ethanol (aiming for blood levels of 100 mg/dl [22 mmol/l]) or preferably the specific alcohol dehydrogenase inhibitor fomepizole. Hemodialysis should be performed to remove the ethylene glycol and metabolites when the level is higher than 20 mg/dl and continued until it is below 5 mg/dl. Methanol intoxication may present with similar metabolic abnormalities, but rarely causes AKI (see Chapter 12).

Warfarin Nephropathy

Acute kidney injury has been described in patients taking warfarin who develop an acute rise in the international normalized ratio (INR), usually to greater than 3. This occurs mostly in patients with underlying CKD, and biopsy studies have suggested this may be a result of increased glomerular hematuria with obstruction of renal tubules by red blood cell casts.

Illicit Drug Use

Acute kidney injury is a common condition in those who abuse drugs and may be a result of nephrotoxicity of the drug, coexistent viral infection (human immunodeficiency virus [HIV], HCV), sepsis, infective endocarditis, rhabdomyolysis, or alcohol abuse.

Cocaine induces intense vasoconstriction, which may lead to severe hypertension and rhabdomyolysis.[16] Mechanisms for rhabdomyolysis include coma and pressure necrosis; vasospasm leading to ischemic muscle injury; and adrenergic stimulation and hyperpyrexia leading to increased cellular metabolism. It typically occurs in those who inject cocaine, and the patient often presents with fever, hypertension, tachycardia, and a decreased mental state.

Other illicit drugs associated with AKI include opiates (coma-associated, pressure-induced rhabdomyolysis); phencyclidine (rhabdomyolysis secondary to hyperpyrexia and vasoconstriction); heroin (rhabdomyolysis); and amphetamines (AKI secondary to rhabdomyolysis, acute interstitial nephritis, or acute necrotizing angiitis).

Bisphosphonates

Acute kidney injury resulting from tubular injury has been described with intravenous but not oral bisphosphonates (especially zoledronate and pamidronate). This typically occurs after several months of treatment.

Acute Phosphate Nephropathy

Oral sodium phosphate has been widely used as a bowel preparation for colonoscopic procedures, but recent cases of AKI have limited the use of this purgative.[17] AKI associated with oral sodium phosphate is believed to be caused by phosphaturia and acute calcium-phosphate deposition within the renal tubules. This occurs most frequently in patients with CKD, older-age patients, and those with volume depletion.

Occupational Toxins

Heavy Metals

Lead intoxication usually causes chronic nephropathy (see Chapter 64). Rarely, acute tubular injury occurs that may be associated with Fanconi syndrome. ATN may also occur in cadmium and mercury poisoning.

Organic Solvents

Organic solvents may cause acute tubular injury because of peroxidation of membrane lipids. A subacute renal failure resulting from anti–glomerular basement membrane (anti-GBM) antibody disease has also been reported with exposure to halogenated hydrocarbons.

Herbal Remedies

Specific herbs used in traditional African medicine (e.g., Cape aloes, *Callilepis laureola*) are common causes of AKI in parts of Africa. A subacute form of renal failure caused by aristolochic acid found in certain herbs used in traditional Chinese medicine has also been described (see Chapters 64 and 78).

Radiocontrast-induced Nephropathy

Acute kidney injury secondary to contrast nephrotoxicity typically occurs in patients with underlying renal impairment and is rarely seen in patients with normal renal function.[18] It may occur with both intravenous and intra-arterial contrast, but not with oral contrast (assuming the bowel is intact). The incidence of contrast nephropathy (as defined by an increase in serum creatinine of more than 0.5 mg/dl [44 µmol/l]) is about 20% in patients with serum creatinine levels exceeding 2 mg/dl (176 µmol/l) and 50% when levels exceed 5 mg/dl (440 µmol/l). Other risk factors for the development of this condition include diabetic nephropathy, advanced age (older than 75 years), congestive heart failure, volume depletion, and high or repetitive doses of radiocontrast agent. High osmolar contrast is more nephrotoxic than low or iso-osmolar contrast agents. Concurrent use of NSAIDs, ACE inhibitors, or diuretics may increase the risk.

Pathogenesis

Medullary hypoxia and direct tubular epithelial cell toxicity are the main factors in the pathogenesis of contrast nephrotoxicity. Typically, a biphasic hemodynamic response is seen. An initial vasodilation (lasting a few seconds to minutes) is followed by a more prolonged renal vasoconstriction. The consequent medullary hypoxia may be exacerbated by the osmotic diuresis, leading to increased sodium delivery to the medullary thick ascending loop and requiring greater oxygen consumption for reabsorption.

Radiocontrast agents also cause direct tubular epithelial cell injury and induce apoptosis of these cells. Human studies have demonstrated low-molecular-weight proteinuria, suggestive of proximal tubular injury, partly mediated by ROSs. Increased markers of lipid peroxidation have been described, and the administration of antioxidants ameliorates contrast nephrotoxicity in animals. Clinical features, prevention, and therapy are described in Chapter 73.

OTHER SPECIFIC CAUSES OF ACUTE KIDNEY INJURY

Heme Pigment Nephropathy

Heme pigment nephropathy is a common cause of AKI and usually secondary to the breakdown of muscle fibers (rhabdomyolysis), which release potentially nephrotoxic intracellular contents (particularly myoglobin) into the systemic circulation. Less commonly, heme pigment nephropathy may occur as a result of massive intravascular hemolysis. Prevention and therapy of heme pigment nephropathy are discussed in Chapter 73.

Causes of Rhabdomyolysis

Muscle trauma is the most common cause of rhabdomyolysis. The initial description was by Bywaters and Beall during the bombing of London in World War II.[19] Other common causes of muscle injury include marked exercise, seizures, pressure necrosis secondary to coma, alcohol abuse, and limb ischemia (Table 69-1). In skeletal muscles confined to rigid compartments, cell swelling after injury may result in increased intracompartmental pressures impairing local microvascular circulation, leading to compartment syndrome (Fig. 69-9). In the patient with alcohol abuse, rhabdomyolysis is often multifactorial. Contributing causes include pressure necrosis from coma ("found down"), direct myotoxicity from ethanol, seizures, and electrolyte abnormalities (hypokalemia and hypophosphatemia). Therapy with statins may be associated with rhabdomyolysis. The risk is increased by concomitant therapy with fibrates, cyclosporine, or erythromycin. Familial myopathies such as McArdle syndrome and carnitine palmitoyl transferase deficiency should be suspected in patients with a history of recurrent episodes of rhabdomyolysis associated with muscle pain, positive family history, onset in childhood, and the absence of other identifiable causes. In developing countries, ingestion of hair dye containing paraphenylenediamine as a means of self-harm may cause AKI secondary to rhabdomyolysis. Snake and spider bites, bee stings, and venomous caterpillar bites may all cause rhabdomyolysis (see Chapter 70).

Causes of Rhabdomyolysis

Muscle injury, ischemia	Trauma, pressure necrosis, electric shock, burns, acute vascular disease
Myofiber exhaustion	Seizures, excessive exercise, heat exhaustion
Toxins	Alcohol, cocaine, heroin, amphetamines, ecstasy, phencyclidine, snakebite
Drugs	Statins, fibrates, zidovudine, neuroleptic malignant syndrome, azathioprine, theophylline, lithium, diuretics
Electrolyte disorders	Hypophosphatemia, hypokalemia, excess water shifts (hyperosmolarity)
Infections	Viral (influenza, human immunodeficiency virus [HIV], Coxsackievirus, Epstein-Barr virus), bacterial *(Legionella, Francisella, Streptococcus pneumoniae, Salmonella, Staphylococcus aureus)*
Familial	McArdle disease, carnitine palmitoyl transferase deficiency, malignant hyperthermia
Other	Hypothyroidism, polymyositis, dermatomyositis

Table 69-1 Causes of rhabdomyolysis.

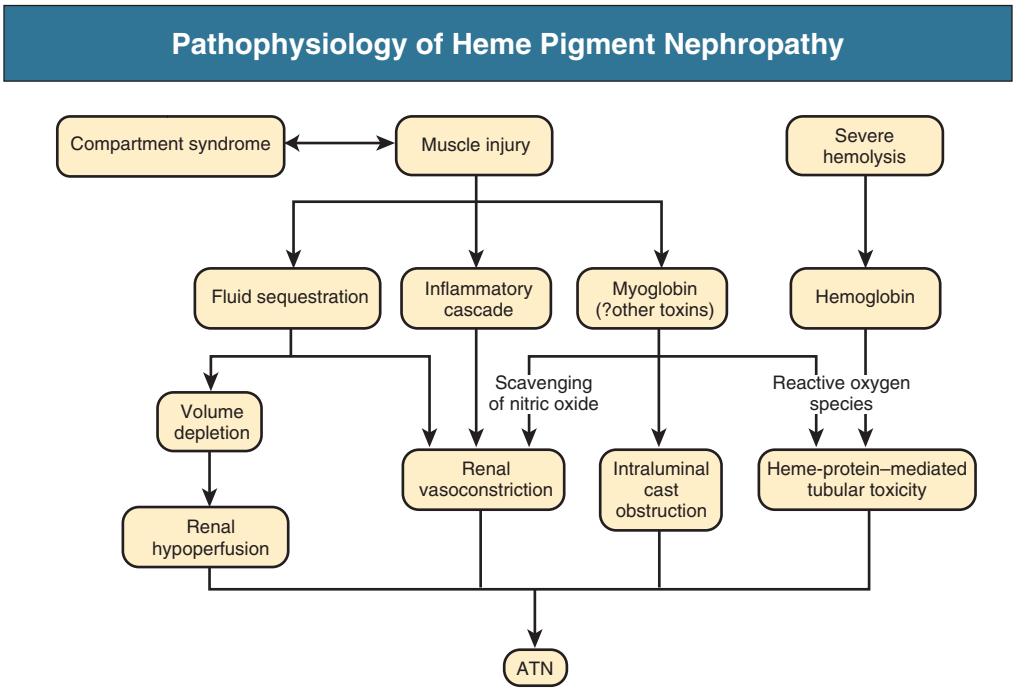

Figure 69-10 Pathophysiology of heme pigment nephropathy. *ATN,* Acute tubular necrosis.

Causes of Hemoglobinuria

Intravascular hemolysis results in circulating free hemoglobin. If the hemolysis is mild, the released hemoglobin is bound by circulating haptoglobin. With massive hemolysis, however, haptoglobin becomes exhausted. Hemoglobin (69 kd) then dissociates into α-β dimers (34 kd) which are small enough to be filtered, resulting in hemoglobinuria, hemoglobin cast formation, and heme uptake by proximal tubular cells. Like myoglobin, these processes can result in ATN and filtration failure. Causes of hemoglobinuric AKI include incompatible blood transfusion, autoimmune hemolytic anemia, malaria (blackwater fever), glucose-6-phosphate dehydrogenase deficiency, paroxysmal nocturnal hemoglobinuria, march hemoglobinuria, and toxins (dapsone, venoms).

Pathogenesis of Heme Pigment Nephropathy

The renal injury is caused by a combination of factors, including volume depletion, renal vasoconstriction, direct heme-protein–mediated cytotoxicity, and intraluminal cast formation (Fig. 69-10). Volume depletion is often prominent in patients with rhabdomyolysis because of the sequestration of large amounts of fluid (up to 15 to 20 liters) in injured muscle. Volume depletion activates the sympathetic nervous system and renin-angiotensin system, resulting in renal vasoconstriction. This may be exacerbated by the scavenging of nitric oxide by circulating heme proteins. Myoglobin (17 kd) is freely filtered at the glomerulus and is toxic to tubular epithelial cells. The heme center of myoglobin may directly induce lipid peroxidation and renal injury,[20] and liberated free iron catalyzes the formation

of hydroxyl radical through the Fenton reaction, inducing free radical–mediated injury. Renoprotection has been demonstrated in animal models with free iron scavengers and various antioxidants. Finally, the precipitation of myoglobin with Tamm-Horsfall protein and sloughed proximal tubular cells may result in obstructing casts in the distal nephron. This is enhanced by increased concentrations of tubular heme protein resulting from volume depletion with low tubular fluid flow rates. The binding of myoglobin to Tamm-Horsfall protein is enhanced in acidic urine.

Clinical features, prevention, and therapy are described in Chapter 73.

Atheroembolic Renal Disease

Atheroembolic renal disease, an under-recognized condition, occurs predominantly in older patients with atherosclerotic vascular disease, either spontaneously or, more frequently, precipitated by arteriography, vascular surgery, thrombolysis (streptokinase and tissue plasminogen activator), or anticoagulation. Destabilization of atherosclerotic plaques primarily in the aorta above the level of the renal arteries results in showers of cholesterol that lodge in small arteries in the kidneys (see Fig. 66-11) and the lower extremities (see Fig. 66-9). Characteristic needle-shaped clefts may be seen on renal or skin biopsy, denoting the localization of cholesterol plaques before dissolution with tissue fixation (see Fig. 66-11). The cholesterol emboli produce a marked and progressive inflammatory reaction, resulting in occlusion of the involved vasculature. (Renal atheroembolism is discussed further in Chapter 66.)

Renal Artery Occlusion

Acute kidney injury caused by renal artery occlusion occurs when the occlusion is bilateral or, in the case of unilateral acute occlusion, with a single nonfunctioning kidney. Thrombosis or embolization (noncholesterol) of the renal artery or its intrarenal branches is more common in elderly patients. An important risk factor for renal emboli is the presence of atrial fibrillation. Aortic dissection may also progress to occlude the renal arteries.

Renal vein thrombosis most commonly occurs in the setting of nephrotic syndrome and rarely may cause AKI if bilateral (see Chapter 66).

Acute Interstitial Nephritis

Acute interstitial nephritis is most commonly a drug-induced phenomenon and is an important differential diagnosis in AKI because removal of the offending agent can result in reversal of the condition. Less commonly, it may be caused by infection or immune-mediated diseases. Acute interstitial nephritis is discussed further in Chapter 62.

Thrombotic Microangiopathy

Thrombotic microangiopathy constitutes a wide range of conditions that should be considered when a patient presents with AKI and thrombocytopenia, although the condition may occur in the absence of a low platelet count. Endothelial activation is followed by the formation of platelet thrombi that occlude small vessels and lead to downstream ischemic injury. Endothelial injury may be triggered by infections (such as with *Escherichia coli*), drugs, or immune complexes. Thrombotic thrombocytopenic purpura is associated with reduced von Willebrand factor protease (ADAMTS13) activity, and atypical HUS is associated with genetic and acquired defects of the complement system. These entities can be difficult to distinguish clinically, and all forms of TMA can present with AKI. TMA is discussed further in Chapter 29.

Glomerular Disease

All forms of glomerular disease may present with AKI, but it is more commonly seen with forms of acute GN such as postinfectious GN, antineutrophil cytoplasmic antibody (ANCA)–associated small vessel vasculitis, anti-GBM disease, lupus nephritis, and IgA nephropathy. The term *rapidly progressive glomerulonephritis* has been used in this setting and may be associated with glomerular crescents on renal biopsy. Glomerular disease associated with a nephrotic presentation is less likely to present as AKI, but may occur as a result of volume depletion from diuretic use, superimposed ATN, or renal vein thrombosis, and rarely from a superimposed acute GN (e.g., anti-GBM disease in membranous nephropathy). Minimal change disease in adults is the most common nephrotic disorder associated with AKI. Glomerular disease is discussed further in Section IV.

SPECIFIC CLINICAL SITUATIONS

Determining the cause of AKI is often aided by recognizing common patterns of presentation and determining the likely causes arising in each of these situations.

Acute Kidney Injury in the Patient with Multiorgan Failure

About 20% of patients with sepsis and 50% of those with septic shock develop AKI. This significantly worsens the prognosis, and when dialysis is required, intensive care unit mortality increases to 45% to 80%. Sepsis is classically associated with infection. A similar condition, termed the *systemic inflammatory response syndrome* (SIRS), may occur secondary to noninfectious insults such as acute pancreatitis, major trauma, or ischemia reperfusion. Activation of the innate immune system may be caused by a number of bacterial products (lipopolysaccharide, flagellin, lipoteichoic acid, others) with pattern recognition receptors (such as Toll-like receptors) on immune cells. This leads to the activation of a wide range of cellular and humoral mediator systems, including the cytokine cascade (TNF-α, IL-1β, IL-6); the complement, coagulation, and fibrinolytic systems; and the release of mediators such as eicosanoids, platelet-activating factor, endothelin-1, and nitric oxide. Widespread endothelial injury results, leading to peripheral vasodilation, increased vascular permeability, and leukocyte infiltration. Peripheral vasodilation causes hypotension, with consequent activation of the renin angiotensin system, increased vasopressin, and increased cardiac output to maintain organ perfusion. This neurohormonal activation may constrict the afferent arterioles of the kidney and further impair renal perfusion. The causes of the AKI in this setting are typically multifactorial, resulting from a combination of hypotension, impaired renal perfusion, inflammatory mediators, and nephrotoxic agents.[21-23]

Acute Kidney Injury in the Postoperative Patient

Acute kidney injury in the postoperative period is commonly a result of problems with fluid balance, perioperative hemodynamic instability, or nephrotoxic agents. The critically ill postoperative patient may

develop SIRS. AKI may be particularly common after vascular, cardiac, and hepatobiliary surgery.

There is evidence that anesthetic agents may impair renal function. This may occur partly because of their hypotensive effects, but the metabolism of fluorinated agents can lead to the production of potentially nephrotoxic fluoride ions. Modern inhaled agents (e.g., isoflurane, halothane, enflurane) all cause a transient decrease in GFR, and the use of methoxyflurane had to be discontinued because of nephrotoxicity.

After Vascular Surgery

In patients with peripheral vascular disease, prior ischemic renal disease is often present, and preoperative diminished renal function is the strongest predictor of the risk for postoperative AKI. In aortic aneurysm surgery, most aneurysms are infrarenal; however, surgery that directly involves the renal arteries or aortic cross-clamping above the renal arteries can result in severe renal ischemia. Furthermore, aortic manipulation may dislodge atherosclerotic plaque, resulting in renal atheroembolism. Peripheral limb surgery may be complicated by rhabdomyolysis, and radiocontrast is frequently used for diagnostic purposes.

After Cardiac Surgery

Risk factors for postoperative AKI include duration of cardiac bypass, preoperative renal function, hyperuricemia, age, diabetes, valvular surgery, blood transfusions, and poor cardiac function.[24] The surgery is often performed with the patient cooled to below 30° C to protect cells against ischemic injury; however, systemic hypothermia may cause intravascular coagulation. Aortic instrumentation and clamping may lead to renal atheroembolism. Cardiac bypass causes exposure of blood to a nonendothelialized surface, resulting in activation of neutrophils, platelets, complement, and fibrinolytic systems. Significant hemolysis may also occur, potentially resulting in hemoglobinuria. Perioperative myocardial infarction or left ventricular dysfunction may impair renal perfusion postoperatively, although the low cardiac output is often transient and recovers within 24 to 48 hours. Atrial fibrillation is a common complication and may be associated with peripheral embolization. Studies have suggested that off-pump coronary artery bypass operations have a lower risk of AKI than surgeries in which patients are put on cardiopulmonary bypass.

After Hepatobiliary Surgery

Surgery to relieve obstructive jaundice is more commonly associated with AKI than other forms of abdominal surgery. This may be a result of the absence of bile salts in the gut lumen, which normally break down lipopolysaccharide endotoxin, preventing absorption. One study suggested a decreased incidence of postoperative endotoxemia when patients were treated with oral bile salts. Other factors may include direct nephrotoxic effects of bile salts on renal tubular cells and an increased incidence of biliary sepsis.

Abdominal Compartment Syndrome

Markedly raised intra-abdominal pressures (above 20 mm Hg) may occur after trauma, after abdominal surgery, or secondary to massive fluid resuscitation and can cause AKI.[25] The mechanism remains unclear, but it may be related to increased renal venous pressure and vascular resistance. Intra-abdominal pressures are poorly assessed by examination and are best estimated by measurement of intravesical (bladder) pressures. Efforts to reduce intra-abdominal pressures, including paracentesis, nasogastric suction, ultrafiltration, or surgical decompression, may occasionally improve renal function.

Causes of Pulmonary-Renal Syndrome	
Systemic vasculitis	Anti-GBM disease (Goodpasture) ANCA associated Granulomatosis with polyangiitis (Wegener) Microscopic polyangiitis Churg-Strauss syndrome Drugs (penicillamine, hydralazine, propylthiouracil) Immune complex disease Lupus erythematosus Henoch-Schönlein purpura Mixed cryoglobulinemia Rheumatoid vasculitis
Infection	Severe bacterial pneumonia; postinfectious glomerulonephritis; *Legionella;* hantavirus; opportunistic infection in immunocompromised patients; infective endocarditis
Pulmonary edema and AKI	Volume overload; severe left ventricular failure
Multiorgan failure	Acute respiratory distress syndrome and AKI
Other	Paraquat poisoning; renal vein or IVC thrombosis with pulmonary emboli

Table 69-2 Causes of pulmonary-renal syndrome. *AKI,* Acute kidney injury; *ANCA,* antineutrophil cytoplasmic antibody; *GBM,* glomerular basement membrane; *IVC,* inferior vena cava.

Pulmonary-Renal Syndromes

The term *pulmonary-renal syndrome* usually describes the presence of pulmonary hemorrhage in a patient with AKI. It can be caused by anti-GBM disease (Goodpasture syndrome), systemic vasculitis, or systemic lupus erythematosus (Table 69-2; see Chapters 24, 25, and 26). Given the fulminant course of these diseases, patients with pulmonary-renal syndrome require urgent evaluation, and specific testing for these diseases should be pursued.

A similar clinical presentation may occur with infection and AKI, or as a result of pulmonary edema secondary to volume overload in AKI. Other conditions that may masquerade as a pulmonary-renal syndrome include upper respiratory infection triggering a flare of IgA nephropathy; severe bacterial pneumonia complicated by ATN or postinfectious GN; *Legionella* species infection causing a severe atypical pneumonia; and acute interstitial nephritis or rhabdomyolysis.

Acute Kidney Injury and Liver Disease

The patient with liver cirrhosis is predisposed to the development of AKI, and the differential diagnosis typically includes pre-renal AKI, hepatorenal syndrome, and ATN.[26] In patients with cirrhosis, bacterial translocation from the gut lumen may trigger the release of vasoactive and inflammatory mediators. Arterial underfilling also induces the release of vasoconstrictive agents, impairing renal perfusion, even in patients who clinically appear volume overloaded. Assessment of intravascular volume status can be difficult, and a therapeutic trial of volume replacement is typically undertaken. Impaired renal perfusion and hyperbilirubinemia are predisposing risk factors. Alternatively, the same causative agent may be responsible for both the liver and renal injuries. This occurs with certain infections (e.g., leptospirosis, hantavirus) and nephrotoxic agents (Table 69-3). Rarely, hyperbilirubinemia from hemolysis may cause jaundice in the absence of liver disease. AKI in patients with liver disease is discussed further in Chapter 76.

Causes of Acute Kidney Injury and Liver Disease	
Pre-renal uremia	Diuretic use, gastrointestinal loss, peritoneal aspiration, hypoalbuminemia
Hepatorenal syndrome	
Acute tubular necrosis	Hyperbilirubinemia, sepsis, toxic shock syndrome
Drugs	Acetaminophen (paracetamol), NSAIDs, tetracycline, rifampin, isoniazid, anesthetic agents, sulfonamides, allopurinol, methotrexate
Infections	Hepatitis C and cryoglobulinemia, hepatitis B and polyarteritis nodosa, leptospirosis, hantavirus, Epstein-Barr virus, gram-negative sepsis, spontaneous bacterial peritonitis
Other	Papillary necrosis and obstruction, inhalation of chlorinated hydrocarbons, mushroom poisoning *(Amanita phalloides)*

Table 69-3 Causes of acute kidney injury and liver disease. *NSAIDs,* Nonsteroidal anti-inflammatory drugs.

Acute Kidney Injury in Heart Failure (Cardiorenal Syndrome)

The development of AKI in patients with decompensated heart failure is a common finding and is associated with a poor prognosis. Reduced renal perfusion secondary to decreased cardiac output has long been considered the primary cause; however, there are important contributions from right ventricular dysfunction leading to renal venous hypertension, and activation of the renin-angiotensin and sympathetic nervous systems.[27]

Acute Kidney Injury in the Cancer Patient

Patients with cancer are prone to AKI as a consequence of both their underlying disease and its treatment, and AKI may occur in up to 50% of critically ill cancer patients.[28] There is also a high incidence of pre-renal AKI in this patient group because of the high frequency of nausea, vomiting, and diarrhea (Table 69-4). More specific causes of AKI are noted in the following sections.

Tumor Lysis Syndrome

Necrosis of tumor cells, typically following chemotherapy, may release large amounts of nephrotoxic intracellular contents (uric acid, phosphate, xanthine) into the circulation.[29] This usually occurs after treatment of lymphomas (particularly Burkitt) and leukemias but may occur with solid tumors. Rarely, a spontaneous form of tumor lysis syndrome occurs in rapidly growing tumors that outstrip their blood supply. Hyperuricemia can cause acute uric acid nephropathy in patients with tumor lysis syndrome as a result of intratubular crystal obstruction and interstitial nephritis, although this is usually prevented by prophylactic use of allopurinol before chemotherapy. The release of other intracellular components can also cause tubular injury. For example, the release of intracellular phosphate can promote the precipitation of calcium phosphate in the tubules. The AKI is typically oligoanuric, and the condition should be suspected in patients with high lactate dehydrogenase levels suggestive of massive cell lysis. Markedly elevated phosphate and uric acid levels may be found. Hyperkalemia may be prominent and life-threatening.

Causes of Acute Kidney Injury in Patients with Cancer	
Pre-renal	Nausea and vomiting, hypercalcemia, cardiomyopathy secondary to chemotherapy
Vascular	Thrombotic microangiopathy (adenocarcinoma of stomach, pancreas, prostate; radiation nephropathy), renal vein thrombosis secondary to hypercoagulability, disseminated intravascular coagulation (acute promyelocytic leukemia)
Glomerular	Rapidly progressive glomerulonephritis
Acute tubular necrosis	Sepsis and antibiotic nephrotoxicity, hypercalcemia
Malignant infiltration	Lymphoma, acute lymphoblastic leukemia
Intraluminal obstruction	Tumor lysis syndrome, cast nephropathy
Post-renal obstruction	Transitional cell carcinoma of the ureters and bladder, extrinsic ureteral compression (tumor, nodes, retroperitoneal fibrosis)
Chemotherapeutic agents	
Tubular toxicity	Cisplatin, ifosfamide, plicamycin (mithramycin); 5-fluorouracil, thioguanine (6-thioguanine), cytarabine
Thrombotic microangiopathy	Mitomycin C, bleomycin, cisplatin, calcineurin inhibitors
Other mechanisms	Capillary leak syndrome (IL-2 therapy), acute interstitial nephritis (interferon-α), intraluminal obstruction (methotrexate)

Table 69-4 Causes of acute kidney injury in patients with cancer. *IL-2,* Interleukin-2.

Preventive measures include the use of high-dose allopurinol (100 mg/m^2 given orally every 8 hours [maximum, 800 mg per day]) started 2 to 3 days before chemotherapy, and either oral or intravenous fluid loading to ensure a urine output exceeding 2.5 l/day. Urine alkalinization is of less benefit than merely maintaining a high urine flow with saline, and it may promote tubular calcium phosphate deposition. However, it should be considered when serum uric acid levels are elevated (>12 mg/dl [714 µmol/l]) or urinary uric acid crystals are present. Recombinant uricase (rasburicase) is very effective in lowering serum uric acid levels (to <1 mg/dl in 24 hours) and should be considered for prophylaxis in high-risk patients.

Once the patient has developed AKI with hyperuricemia, rasburicase, which lowers uric acid much more effectively than dialysis, should be considered. It can lower uric acid levels within hours and is effective even in patients with impaired renal function. If this is not available or the patient is markedly hyperphosphatemic, early dialysis should be considered to remove these potential causes of further renal damage. Because phosphate is less well removed by dialysis than uric acid, frequent (every 12 to 24 hours) or prolonged treatments should be considered.

Hypercalcemia

Volume depletion secondary to hypercalcemia-induced nausea and vomiting may cause AKI, which may be exacerbated by hypercalcemia-induced nephrogenic diabetes insipidus. Other hypercalcemia-associated factors that may contribute to AKI include direct intrarenal vasoconstriction, acute interstitial nephritis, and intratubular obstruction.

Chemotherapeutic Agents

Cisplatin is commonly associated with a nonoliguric renal impairment.[30] Nephrotoxic injury affects both the proximal and distal nephron and clinically may be associated with magnesium wasting, impaired urinary concentration, and rarely salt wasting with volume depletion. Chloride ions in the *cis* position on the molecule may be replaced by water, releasing toxic hydroxyl radicals. Prophylaxis against nephrotoxicity includes volume loading and reducing the dose when possible. The alternative agent carboplatin appears to be less nephrotoxic. Once renal impairment is present, recovery may be poor and magnesium wasting may persist.

Ifosfamide is a cyclophosphamide analogue with a nephrotoxic metabolite, chloroacetaldehyde. AKI is usually mild, although proximal tubular dysfunction (Fanconi syndrome) and hypokalemia may be prominent.

High-dose intravenous methotrexate is also nephrotoxic, possibly because of precipitation of the drug within the renal tubules and direct toxicity to the renal epithelial cells.

Cytosine arabinoside and 5-fluorouracil may increase the likelihood of AKI when included in multidrug regimens. Both agents, for example, are associated with AKI when given in combination with cisplatin.

CHAPTER 70

Acute Kidney Injury in the Tropics

Emmanuel A. Burdmann, Vivekanand Jha, and Visith Sitprija

Acute kidney injury (AKI) in the tropics is heavily influenced by the local disease burden, which is dominated by particular infections, consumption of unsafe drinking water, use of natural medicines, exposure to environmental toxins, and envenomation by snakes or arthropods. Poverty, malnutrition, lack of an adequate sanitary infrastructure and public health system, and uncontrolled and unplanned urbanization are frequent problems that add significantly to the observed disease burden. In fact, the rupture of the ecologic balance by humans has induced particular causes of renal injury in the tropics, such as accidents involving Africanized bees or *Lonomia* genus caterpillars.[1,2]

Acute kidney injury epidemiology in the tropical area has a peculiar, bimodal pattern. Most patients are encountered in the community, and previously healthy, young individuals are frequently affected. In contrast, the epidemiology of hospital-acquired AKI in large cities and tertiary hospitals is similar to that seen in nontropical countries.[1-4]

The uniqueness of the tropical environment has a direct influence on water quality and pattern of disease. A strong seasonal variation in the incidence of AKI is noted in the tropics, with a spike during and immediately after the rainy seasons. Heavy precipitation leads to soil erosion, leaching of minerals and organic compounds, and waterlogging, conditions favorable to survival of organisms causing or transmitting infectious diseases such as leptospirosis, dengue, and malaria.[5-7] Tropical rains force venomous snakes to come out of the flooded burrows in the fields, making accidents more likely to occur.

The importance of the different causes of AKI in the tropics varies from region to region. Malaria, leptospirosis, typhus, diarrheal diseases, and envenomation are the common causes of AKI in South Asia; malaria, diarrheal diseases, obstetric accidents, and indigenous herbal remedies are frequent causes of AKI in Africa; and leptospirosis, dengue fever, envenomation, and obstetric complications are important causes of AKI in Latin American countries.[8] In addition, classical AKI caused by rhabdomyolysis from heat stroke or overexertion may also occur (see Chapter 69).

SNAKEBITES

Snakebite is an occupational hazard in the rural tropics and subtropical regions. Data based on 2005 Global Burden of Disease study suggest that globally at least 421,000 envenomations and 20,000 deaths occur each year as a result of snakebite, with the highest burden in South Asia, Southeast Asia, and sub-Saharan Africa.[9] Renal injury may develop following bites by hemotoxic or myotoxic snakes belonging to the Viperidae and Elapidae families, such as the Russell viper, saw-scaled viper, puff adder, rattlesnake, tiger snake, and green pit viper, *Bothrops* species, *Lachesis* species, *Crotalus* species, the boomslang, gwardar, and dugite, *Hypnale* species, *Cryptophis* species, and sea snakes. AKI is more frequent following Russell viper, *Bothrops,* or *Crotalus* bites, with incidences ranging from 10% to 32% (Fig. 70-1).[1,2,10-12] The prevalence is higher in children, probably because of the higher venom dose in relation to the body size.[12]

Clinical Features

Manifestations depend on the nature and injected venom dose. Local pain, swelling, blistering, ecchymosis, and tissue necrosis are frequent in Russell viper and *Bothrops* bites (Figs. 70-2 and 70-3). The commonest systemic manifestation in accidents involving these snakes is coagulation abnormalities leading to bleeding diathesis (see Fig. 70-3). Muscle paralysis and rhabdomyolysis may occur following bites by sea snakes and *Crotalus* snakes. AKI develops within a few hours to as late as 96 hours after the bite. Cola-colored urine is noted in patients with hemolysis or rhabdomyolysis. AKI is usually oliguric and catabolic, with rapidly rising levels of blood urea nitrogen (BUN), serum creatinine, and potassium. Oliguria generally lasts for 1 to 2 weeks, and its persistence suggests the likelihood of acute cortical necrosis.[1,2,10-12] Significant proteinuria and hematuria have been described in some studies and may reflect differences in venom composition.[10,13]

Laboratory investigation may show hemolysis (elevated free plasma hemoglobin and lactate dehydrogenase [LDH] and reduced haptoglobin) along with hypofibrinogenemia; reduced factors V, X, and XIIIa, protein C, and antithrombin III; and elevated fibrin degradation products. Rhabdomyolysis may be indicated by raised creatinine phosphokinase. Other findings include leukocytosis and elevated hematocrit resulting from hemoconcentration.[1,2,10-12]

Pathology

Grossly, the kidneys may show petechial hemorrhages. Light microscopy usually discloses acute tubular cell injury ranging from mild changes to overt tubular necrosis, with hyaline or pigment casts, variable degree of interstitial edema and infiltration, and scattered hemorrhages. Mesangiolysis may occur (especially with crotalid envenomation), and blood vessels may show fibrin thrombi. Electron microscopic findings include dense intracytoplasmic bodies representing degenerated organelles in the proximal tubules and electron-dense mesangial deposits. Less common findings are acute interstitial nephritis, necrotizing vasculitis, and proliferative and crescentic immune-complex glomerulonephritis (GN). Acute cortical necrosis is seen in about 20% to 25% of patients who have sustained Russell viper and *Echis carinatus* bites and has been described after *Bothrops* accidents.[1,2,10-12]

Pathogenesis

Snake venom is a complex mixture of enzymes, toxins, and peptides. Kidney injury may develop as a result of direct nephrotoxicity, renal vasoconstriction, hypovolemia, hypotension, depression of the medullary vasomotor center or the myocardium, hemolysis, altered

Figure 70-1 Russell viper. This large snake is an important cause of venomous snakebite–induced acute kidney injury in Asia.

Figure 70-3 Hemorrhagic blister developing a few hours after Bothrops snakebite. *(Courtesy Carlos A. C. Mendes, São José do Rio Preto, Brazil.)*

fibrinolysis, myoglobinuria, or disseminated intravascular coagulation.[1,2,10-12] Experimental studies have shown evidence of tubular injury manifested by increased excretion of tubular enzymes, altered fractional sodium excretion, and acute tubular necrosis.[1,2,10-12,14] Other changes including mesangiolysis, disrupted integrity of the cellular junctions, proteolysis of extracellular matrix, lysis of vessel walls (leading to mesangiolysis), and alterations in function of enzymes vital to cellular integrity have been noted. [1,2,10-12] Recently, intense inflammatory mediator release, induction of oxidative stress, and release of mitochondrial alarmins have been evoked as possible pathogenic factors in snake venom–induced AKI.[15-17]

Management

The basic therapeutic approach is the same as that for AKI from any cause (see Chapters 73 and 74). Key steps for reducing morbidity and mortality include early administration of specific monovalent antivenom, appropriate volume replacement, maintenance of good urine flow, urinary alkalization in patients with rhabdomyolysis, correction of electrolyte imbalance, administration of tetanus immunoglobulin, and treatment of infections.[1,2,10-12,14] Locally available polyvalent antivenom is effective against envenomation by multiple snakes or an unknown type of snake.[18] Unavailability of antivenom in rural hospitals and poor infrastructure that hampers transportation to health centers are major factors that delay administration of antivenom and contribute to high mortality,[19] which may reach 30%.[1,2,10-12] Recent studies suggest that up to 40% of affected patients may be found to have developed chronic kidney disease (CKD) on long-term follow-up after snakebite-induced AKI.[20,21]

ARTHROPODS

Poisonous arthropods such as bees, wasps, caterpillars, and spiders may cause AKI. Patients who have sustained hundreds of simultaneous bee stings frequently develop a multifaceted clinical picture, which includes intravascular hemolysis; rhabdomyolysis; low platelet count; coagulation disorders and bleeding; cardiovascular, hepatic, and pulmonary injury; and AKI, with mortality up to 16%.[1,22,23] In the same way, AKI can follow incidents involving multiple wasp, yellow jacket, or hornet stings.[22] The mechanisms leading to kidney injury are direct venom nephrotoxicity, intrarenal vasoconstriction, hemoglobinuria, myoglobinuria, hypotension, thrombotic microangiopathy,[24] and activation of inflammatory and oxidative stress pathways.[25] Renal histology usually shows acute tubular necrosis.[1,22,24]

Accidents involving caterpillars of the genus *Lonomia* produce severe hemorrhagic disorders. The venom induces a complex hemorrhagic diathesis with both fibrinolytic and disseminated intravascular coagulation–like activity.[22,26] Severe and prolonged AKI with renal histology suggesting ischemic injury, which evolves to CKD in some patients, has been reported after *Lonomia obliqua* accidents (Fig. 70-4).[22,27,28] Availability of *Lonomia* antivenom has led to an apparent decrease in the number of severe cases in Brazil.[27] The pathogenesis of the kidney injury might be associated with glomerular deposition of fibrin microthrombi, intravascular hemolysis, kidney tissue deposition, and direct venom nephrotoxicity and activation of the endothelial cell inflammatory pathway.[22,29-31]

Spiders of the genus *Loxosceles* may induce local necrosis at the bite site, intravascular hemolysis, rhabdomyolysis, coagulation system changes, and AKI (Figs. 70-5 and 70-6).[22,32] Even patients with mild cutaneous lesions may develop severe hemolysis and AKI, which is the main cause of death after these accidents. The pathogenesis of the kidney injury has been related to massive

intravascular hemolysis, renal vasoconstriction, direct nephrotoxicity, and rhabdomyolysis.[22,32-34]

NATURAL MEDICINES

Herbs and indigenous remedies are used extensively in poor societies living in the tropics. About 80% of the population in Africa depends on traditional medicine prepared by herbalists and faith healers using unknown ingredients. Poisoning with traditional medicines is an important cause of renal injury and mortality in sub-Saharan Africa.[35-37] AKI has been described in association with several natural remedies. An accurate assessment of their contribution to AKI is

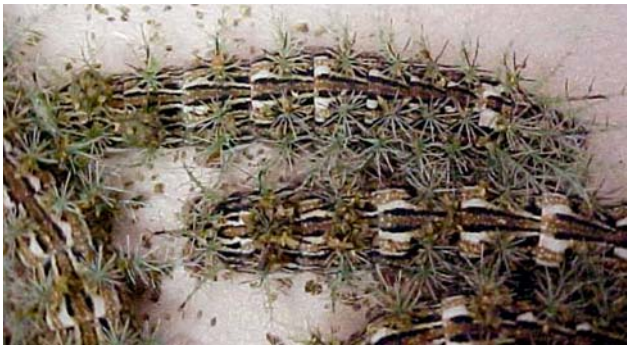

Figure 70-4 *Lonomia obliqua* caterpillars. Each hair works as a miniature hypodermic needle to inject the hemolymph, which contains powerful venom that is able to induce severe coagulation system changes. *(Courtesy Elvino J. G. Barros, Porto Alegre, Brazil.)*

Herbal Causes of Acute Kidney Injury in Tropical Countries

Plant (Common or Local Name)	Country	Active Molecule	Renal Manifestations	Other Manifestations
Averrhoa bilimbi (irumban puli)	South India	Oxalic acid	Intratubular obstruction	
Callilepis laureola (impila)	Sub-Saharan Africa	Atractyloside	Acute tubular necrosis	Abdominal pain, diarrhea, vomiting, jaundice, seizures, and coma
Catha edulis (khat leaf)	East Africa, Arabian peninsula	*S*-cathinone and ephedrine	Acute tubular necrosis	Hepatotoxic effects
Cleistanthus collinus (oduvan)	India	Cleistanthin A and B, collinusin, and diphyllin	AKI	Hypotension, hypokalemia, arrhythmia
Colchicum autumnale (autumn crocus)	Turkey	Colchicine	Acute tubular necrosis	Hemorrhagic gastroenteritis, muscle paralysis, respiratory failure
Crotalaria laburnifolia (bird flower)	Zimbabwe, Sri Lanka	Pyrrolizidine alkaloids	Acute tubular necrosis and hepatorenal syndrome	Hepatic veno-occlusive disease, pulmonary injury, thrombocytopenia
Dioscorea quartiniana (yam)	Africa, Asia	Dioscorine and dioscin	Acute tubular necrosis	Convulsions
Pithecellobium lobatum and *Pithecellobium jiringa* (djenkol beans)	South East Asia	Djenkolic acid	Intratubular obstruction and acute tubular necrosis	Lumbar and lower abdominal pain, hypertension
Dodonaea angustifolia (sand olive)	South Africa	Unknown	Acute interstitial nephritis	Pulmonary embolism
Euphorbia metabelensis (spurge)	Zimbabwe	Irritant chemicals in plant latex	Acute tubular necrosis	Thrombocytopenia
Larrea tridentate (chaparral)	Chile, South Africa	Nordihydroguaiaretic acid and S-quinone	Renal cysts, renal cell carcinoma	Hepatic failure
Propolis resin	Brazil	Unknown	Acute interstitial nephritis	Contact dermatitis
Rhizoma rhei (rhubarb)	Hong Kong	Anthraquinones (emodin, aloe-emodin)	Acute interstitial nephritis	None
Securidaca longepedunculata (violet tree or wild wisteria)	Congo, Zambia, and Zimbabwe	Methylsalicylate, securinine, saponins	Acute tubular necrosis	Vomiting, diarrhea
Sutherlandia frutescens (cancer brush)	South Africa	Unknown	Acute interstitial nephritis	Pulmonary embolism
Takaout roumia	Morocco, Sudan	Paraphenylenediamine	Acute tubular necrosis	Rhabdomyolysis
Semecarpus anacardium (marking nut)	India	Unknown	Acute tubular necrosis and acute cortical necrosis	Corrosive blisters in pharynx, gastrointestinal irritation, shock, coma
Taxus celebica (Chinese yew)	Asia	Flavonoid	Acute tubular necrosis and acute interstitial nephritis	Hepatitis, hemolysis, DIC
Thevetia peruviana (yellow oleander)	India, Sri Lanka	Cardiac glycosides	Acute tubular necrosis	Liver failure, cardiac arrhythmias
Tripterygium wilfordii (thunder god vine)	Taiwan	Triptolide	Acute tubular necrosis	Diarrhea, shock
Uncaria tomentosa (cat's claw)	Peru	Alkaloids and flavonols	Acute tubular necrosis	Diarrhea, hypotension, bruising, bleeding gums

Table 70-1 Herbal causes of acute kidney injury (AKI) in tropical countries. *DIC,* Disseminated intravascular coagulation. *(From reference 8.)*

rendered difficult by the failure to elicit a history as a result of the physicians' ignorance or denial or the patients' fear of stigmatization or social pressure. Often it is difficult to discount the contribution of the original illness to the AKI.[8,35-37]

About 25% to 35% of all AKI from medical causes in African hospitals are related to herbal remedies. The plant sources more frequently associated with AKI are impila *(Callilepis laureola),* djenkol beans *(Pithecellobium),* irumban puli (*Averrhoa bilimbi*), mushrooms (genera *Amanita, Galerina, Cortinarius,* and *Inocybe),* cape aloe, and raw carp bile.[8,36,37] In addition, single case reports of other natural medicines inducing AKI have been described (Table 70-1).[8,36,37]

Kidney injury may be either the sole manifestation or part of a multisystem and metabolic involvement. Management of AKI is usually supportive and includes volume replacement and correction of metabolic abnormalities. Dialytic support is given for usual indications. About 60% all patients with herbal remedy–related AKI need dialysis, with 25% to 75% mortality. Charcoal hemoperfusion is effective in clearing α-amanitin from circulation in those with poisoning from *Amanita* mushrooms.[37]

Pathogenesis of Natural Medicine–Induced Acute Kidney Injury

Several factors affect the toxicity and likelihood of kidney injury. Incorrect identification by inexperienced personnel may lead to substitution of a medicinal plant with a toxic one. An example is the substitution of *Takaout el badia*, a hair dye made from *Tamarix orientalis* seeds, with the toxic *Takaout roumia* (paraphenylenediamine), which causes AKI on accidental or intentional digestion. Incorrect methods of preparation or use can lead to nephrotoxicity, such as consumption of improperly cooked djenkol beans, intake of large quantities of star fruit or yam, and failure to ingest *impila* in the prescribed way (with sufficient water, followed by regurgitation soon after consumption). Finally, potentially nephrotoxic exogenous substances such as paint thinners, turpentine, chloroxylenol, ginger, pepper, soap, vinegar, copper sulfate, and potassium permanganate are often added to the plant extracts. The mechanisms that cause AKI are variable. Djenkol beans, star fruit juice, and *Averrhoa bilimbi* juice may induce intratubular precipitation of djenkolic acid or oxalate crystals. Raw bile of the grass carp, poisonous mushrooms, and cottonseed oil are directly toxic to renal tubules. Indirect mechanisms include interaction with metabolism of conventional drugs. St John's wort *(Hypericum perforatum)* decreases plasma levels of drugs that are metabolized by cytochrome P450 enzyme system. In kidney transplant recipients, this interaction can lower levels of calcineurin inhibitors and precipitate AKI from allograft rejection. Concomitant administration of other nephrotoxic substances can also potentiate herbal nephrotoxicity.[8,37]

AKI caused by herbal medicines is also discussed in Chapter 78.

MALARIA

Malaria is caused by five species of malarial *Plasmodium* parasites: *Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae, Plasmodium ovale,* and *Plasmodium knowlesi.* The World Health Organization (WHO) estimated that globally malaria affects more than 200 million patients annually with nearly 1 million deaths, mostly of children with *P. falciparum* infection. There has been an increasing incidence of *P. knowlesi* infection in Southeast Asia, predominantly in Sarawak, Malaysia.[38] The contribution of malaria as the cause of AKI among different geographic areas ranges from 2% to 39%. The incidence of AKI in *P. falciparum* malaria can be as high as 60% and in *P. vivax* malaria varies from 10% to 19%. *P. malariae*–, *P. knowlesi*–, and *P. ovale*–induced AKI are less common but may be observed in patients with complicated cases.[39] In this chapter, we focus on *P. falciparum* malaria–associated AKI, which is a classical model of malaria-induced AKI. Glomerular disease associated with malarial infection is discussed in Chapter 57.

Pathophysiology

The inherent characteristics of each species of malarial parasite are important determinants in malaria pathogenesis. *P. vivax*, *P. ovale,* and *P. knowlesi* infect young erythrocytes, and *P. malariae* infects aging cells. *P. falciparum* infects erythrocytes of all ages, producing a higher number of merozoites (Fig. 70-7). Heavy parasitemia is therefore commonly observed in *P. falciparum* malaria, creating adverse effects on the microcirculation. The pathophysiologic process of malaria involves membrane changes, inflammation, and hemodynamic alterations. *Plasmodium* parasites primarily infect erythrocytes with secondary effects on the microcirculation and immune system. Parasitized erythrocytes are integral to the pathophysiologic process of the disease through decreased erythrocyte deformability and sequestration, knob and rosette formation, cytoadherence, and changes in membrane transport and permeability. It is interesting to note that nonparasitized erythrocytes also have decreased deformability. Knobs on parasitized erythrocyte membranes and cytoadherence between parasitized erythrocytes and vascular endothelial cells are characteristic of *P. falciparum* malaria; other forms of *Plasmodium* do not have this property. Recently, it has been reported that mature *P. vivax*–parasitized erythrocytes can cytoadhere to vascular endothelial cells through binding of ICAM-1 (intercellular adhesion molecule 1) and chondroitin sulfate A receptors. This cytoadherence is lower than that of *P. falciparum*–infected erythrocytes.[40] Similarly to other infectious diseases, several proinflammatory cytokines and vasoactive mediators are released. Hemodynamic changes in malaria are similar to those of bacterial sepsis, including decreased systemic vascular resistance, increased cardiac output, and increased renal vascular resistance. The initial hypervolemia is followed by hypovolemia and decreased cardiac output, with renal blood flow and glomerular filtration rate decrease. Increased blood viscosity, intravascular coagulation, hemolysis, rhabdomyolysis, jaundice, fever, lactic acidosis, complement activation, and reactive oxygen species further compromise renal blood flow. Activation of poly (ADP-ribose) polymerase by peroxynitrite and free radicals decreases oxygen usage. AKI in malaria is therefore ischemic and hypoxic in origin and usually occurs in the patient with heavy parasitemia, intravascular coagulation, or intravascular hemolysis or rhabdomyolysis.[39]

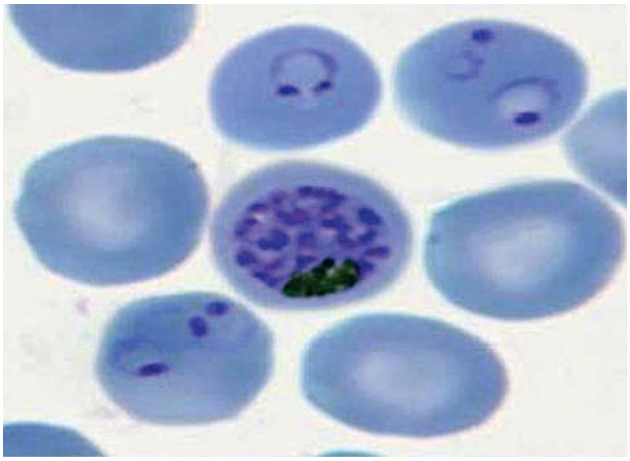

Figure 70-7 Ring form and merozoites of *Plasmodium falciparum* in infected erythrocytes.

Immune responses in malaria involve Th1 and Th2 activation. Immune complex GN is usually observed, with granular deposition of C3, IgM, and malarial antigen in the mesangial area and *in situ* immune complex deposition. Tubular changes vary from cloudy swelling to tubular degeneration with tubulorrhexis in the patient with AKI (Fig. 70-8). Bile and hemoglobin casts and Tamm-Horsfall protein (uromodulin) are present in the tubular lumen. Interstitial mononuclear infiltration and edema can be observed. Thrombotic microangiopathy has been reported.[41] Malarial antigens are occasionally seen along the glomerular endothelium and medullary capillaries. Adhesion molecules and proinflammatory cytokines are overexpressed in the vascular endothelium and proximal tubules.[39]

Clinical Manifestations

Malarial AKI affects predominantly nonimmune adults, mostly infected by *P. falciparum.* The increasing reports of severe AKI in

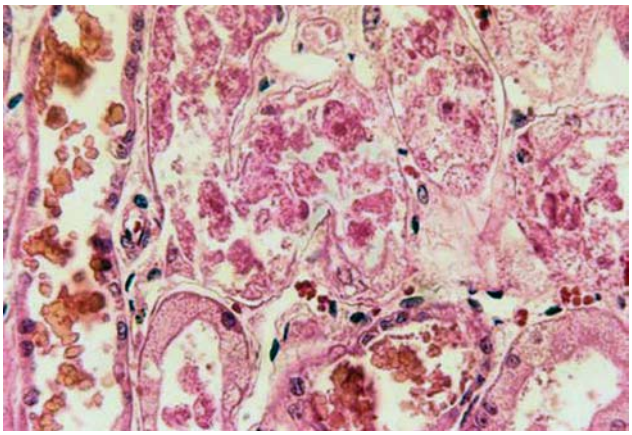

Figure 70-8 **Acute tubular necrosis in *P. falciparum* malaria.**

P. vivax infection with thrombotic microangiopathy are of interest. Mixed plasmodium infections and comorbidities resulting from sepsis are likely important contributing factors. Constitutional symptoms include fever, chills, headache, and prostration. Jaundice may be present. The urinalysis usually shows few erythrocytes, leukocytes, and granular casts and mild proteinuria (often less than 1 g/24 h). Hemoglobinuria is noted in the patient with intravascular hemolysis, frequently associated with glucose-6-phosphate dehydrogenase deficiency. Rhabdomyolysis with myoglobinuria has been observed. Fluid and electrolyte changes are common in malaria.[39,42] Hyponatremia, usually asymptomatic, is observed in 67% of patients and is related to the severity of malaria. Decreased response to water load is seen in 20% of hyponatremic patients. Fluid should be administered cautiously in hyponatremic patients to avoid fluid overload. Hyponatremia resolves within a few days after antimalarial treatment. The causes of hyponatremia are multiple, including increased antidiuretic hormone with water retention, intracellular shift of sodium caused by decreased Na^+,K^+-ATPase activity, and sodium depletion. Hypernatremia is uncommon and when present indicates hypothalamic lesions with diabetes insipidus, associated with an unfavorable prognosis. Hypokalemia caused by respiratory alkalosis occurs in 20% to 40% of the patients. Hyperkalemia is observed in patients with intravascular hemolysis, rhabdomyolysis, or AKI. Hypocalcemia with prolonged QTc intervals occurs in 45% of patients with severe malaria, is transient, and resolves when infection is controlled.[42] Decreased activities of Na^+,K^+-ATPase, Ca^{2+}-ATPase, and parathyroid hormone are considered the main causes for hypocalcemia. Hypophosphatemia secondary to respiratory alkalosis is observed in 6% to 30% of the patients. The clinical significance of both hypocalcemia and hypophosphatemia is unknown. Hypomagnesemia is seen in 30% of patients.[42] Downregulation of epithelial sodium channels (ENaCs) on the apical membrane of alveolar epithelial cells and increased vascular permeability account for the development of pulmonary edema and acute respiratory distress syndrome.[43]

Malarial AKI is characterized by a rapid increase in BUN and serum creatinine and is often associated with cholestatic jaundice. Hepatocellular jaundice may be observed with hypotension and secondary hepatic injury. Hemolytic uremic syndrome (HUS) has been described. Severe acidosis, hypoglycemia, and central nervous system symptoms can be observed. The duration of AKI ranges from one to several weeks, and the condition is oliguric in 60% of the patients. Quinine and artesunate are the antimalarial agents of choice. Early and frequent renal replacement therapy (hemodialysis or peritoneal dialysis) is lifesaving.[39] Continuous veno-venous hemofiltration (CVVH) yields good results in patients with multiorgan involvement, especially those with pulmonary edema or acute respiratory distress syndrome.[39] Exchange blood transfusion and erythrocytapheresis are adjunctive for the patient with heavy parasitemia.[43] The mortality rate of malarial AKI ranges from 10% to 50%. Multiple organ involvement carries a poor prognosis. The use of dopamine with furosemide has been successful in attenuating the progress of mild uncomplicated malarial renal injury. This is in contrast to the experience in other causes of AKI and requires larger randomized controlled studies for validation.

LEPTOSPIROSIS

Leptospirosis, a worldwide distributed zoonosis, is caused by *Leptospira* genus spirochetes. There are more than 200 pathogenic serovars of *Leptospira,* occurring in tropical and subtropical areas, which makes this infection a major public health burden. In fact, the WHO included leptospirosis as a reemerging infectious disease in both developed and developing areas, and cases have been increasingly reported in developed countries.[44,45] Wild and domestic mammals such as rodents, dogs, pigs, cattle, and horses are the typical vectors for leptospirosis. The infection is transmitted to humans through animal urine.[1,2,8,46]

Human leptospirosis is endemic in many tropical countries and usually reaches epidemic levels after either higher rainfall periods with flooding, or natural disasters such as hurricanes. Human cases range from 10 to 100 per 100,000 population per year in the humid tropics. These figures rise during outbreaks and in high-risk groups. Epidemic leptospirosis was reported in Nicaragua and Puerto Rico after hurricane strikes and in Brazil after summer floods. Some studies showed a high seroprevalence of anti-*Leptospira* antibodies in the general asymptomatic population, ranging from 18% to 33%. Indeed, leptospirosis is considered to be one of the candidates responsible for the epidemic of CKD occurring in the agricultural communities of Central America (Mesoamerican nephropathy; see Chapter 64). With use of polymerase chain reaction assay, 29% of wild small animals in the Peruvian Amazon were found to be infected with leptospirae.[1,2,8,46]

Leptospira interrogans, the only parasitic species, is mobile, aerobic, and unstained by the Gram method. Its endotoxins affect the tubulointerstitial cells. Glomerular changes are usually not relevant. The bacterial outer membrane contains lipopolysaccharide (LPS), cytotoxic glycolipoprotein (GLP) and lipoprotein (LipL), especially LipL32, which is immunogenic. As leptospirae have special tropism for kidneys, the effect of GLPs on tubular Na^+,K^+-ATPase activity is potentially involved in AKI cellular pathophysiology,[47] in the urinary concentrating defects, and in the paradoxical hypokalemia frequently seen in these patients.[1,2,8,46-49] High serum free fatty acids, mainly oleic acids (C18:1), are also potentially implicated in pulmonary hemorrhagic manifestations of the acute respiratory distress syndrome associated with this disease.[50]

Kidney involvement is almost universal in leptospirosis but becomes relevant in Weil disease, the most severe form of leptospirosis. Weil disease is characterized by multiorgan involvement, with diffuse alveolar hemorrhage, pulmonary edema, acute respiratory distress syndrome, or a combination of these features, accompanied by AKI; the disease has an elevated mortality rate.[46,48] The incidence of leptospirosis-associated AKI varies from less than 10% to more than 80%, and its severity is associated with increasing mortality.[51-54] AKI is typically nonoliguric and associated with hypokalemia.[1,2,8,46] Oliguria, jaundice, and arrhythmias have been shown to be predictors of AKI development.[51] Tubular changes characterized by high urinary fractional excretion of sodium and potassium precede

glomerular filtration rate decrease, which could explain the high prevalence of hypokalemia.[48] Antibiotic treatment is considered efficient in the disease early and in the late and severe phases, but a recent study failed to show a decrease in mortality in leptospirotic patients receiving antibiotics.[46,55] Treatment recommendations include a high dialysis dose, conservative fluid intake, and approaches to minimize lung injury, such as low tidal volume and high positive end-expiratory pressure, when artificial ventilation is required. [46,56]

HEMORRHAGIC FEVERS

Viral hemorrhagic fevers (VHFs) are caused by RNA viruses of four different families (Flaviviridae, Arenaviridae, Bunyaviridae, and Filoviridae). They can be acquired through infected arthropod bites (dengue, Rift Valley yellow fever, and Crimean-Congo virus) or by inhalation of infected rodent excreta particles (Lassa virus, Junin virus, Machupo virus, and Hantavirus). The clinical picture of VHF is characterized by fever, malaise, increased vascular permeability, and coagulation abnormalities that may lead to bleeding. AKI is an unusual complication of these diseases but has been reported in association with several forms of VHF.[1,2,8,57] Dengue and yellow fever are the most prevalent forms of VHF in tropical regions.[57]

Dengue Fever

Dengue is an acute febrile disease caused by an arbovirus, transmitted primarily by mosquitoes, with a benign evolution in most patients. The main dengue vector is the *Aedes aegypti* female mosquito. Dengue is currently the most important urban arboviral disease, affecting more than 50 million people annually in more than 100 countries in all WHO regions except Europe. Two fifths of the entire world population, approximately 2.5 billion individuals, are at risk for dengue. It is more prevalent in tropical and subtropical areas, where the environment is favorable for the mosquito's development. Several factors account for the rising incidence and widespread prevalence of dengue, such as climate changes (global warming, intensity and duration of rain season, hurricanes), ecosystem modifications, demographic increases, uncontrolled and unplanned urbanization, and migration of people.[57]

There are four serotypes of dengue flavivirus (DEN1 to DEN4). They are antigenically related, but immunity to one serotype does not confer enduring immunity to another. The introduction of a new serotype in a determinate area accounts for the occurrence of epidemics and the hemorrhagic fever dengue form, which is a more severe form of the disease that may be lethal.[57]

Dengue virus infection may manifest as undifferentiated fever, dengue fever, dengue hemorrhagic fever (DHF), or dengue shock syndrome (DSS). Common clinical manifestations of dengue fever are high fever, myalgia, arthralgia, retro-ocular pain, headache, anorexia, nausea, vomiting, and a cutaneous rash similar to measles or rubella. DHF and DSS are severe forms of the disease, characterized by fever, hemorrhagic phenomena, thrombocytopenia, evidence of plasma leakage (increased hematocrit, pleural effusion, ascites, and hypoalbuminemia), mental disorientation, shortness of breath, tachycardia, shock, and death.[57]

Kidney involvement in dengue includes AKI, proteinuria (sometimes nephrotic), GN, and HUS.[57-64] Peak proteinuria has been suggested to potentially predict DHF in patients with dengue.[65]

The reported frequency of dengue-associated AKI is extremely variable, ranging from 1% to approximately 30%, but AKI development and severity are consistently related to poor prognosis.[58-61] Dengue-induced AKI is usually associated with shock, hemolysis, and/or rhabdomyolysis[57] but may occur without any of these triggering factors.[64] DHF grade IV and obesity in children, and DSS in adults have been identified as risk factors for AKI development.[60,61]

There is no specific treatment for dengue fever. Therapy is mostly supportive, avoiding the use of aspirin and nonsteroidal anti-inflammatory drugs. [57]

Yellow Fever

Yellow fever is a noncontagious infectious disease that is endemic in tropical Africa, South America, and Panama. The yellow fever virus is part of the *Flavivirus* genus (Flaviviridae family).[57,66]

Yellow fever is transmitted to humans by the bites of blood-eating insects, especially the *Aedes* and *Haemagogus* genera. There are sylvatic and urban cycles. The sylvatic cycle affects individuals who sporadically get in contact with the vectors when performing economic or recreational activities in infested forests. The urban cycle is characterized by virus transmission by *A. aegypti* to individuals living in urban areas. The urban cycle was eliminated in the Americas in the 1940s to 1950s, but its resurgence was recently documented in Bolivia. The movement of infected individuals when viremic to cities with high vector populations can potentially generate explosive urban epidemics affecting thousands of unvaccinated people.[57,66] It is interesting to note that there is no evidence of yellow fever in Asia, despite an extensive presence of vectors. It is possible that the hyperendemicity of dengue in southwest Asia has afforded protection as a result of cross-reactive antibodies. This mechanism might also explain why urban yellow fever has not reemerged in Brazil after the reintroduction and spread of the *Aedes* vector and why a large number of cases of dengue have occurred in the last 20 years.[57,66]

The diagnosis of yellow fever is made by measuring serum specific IgM, by viral isolation in insect or mammal cells, and by molecular methods such as reverse transcription polymerase chain reaction (RT-PCR). The most specific pathologic finding of yellow fever is liver injury with formation of Councilman bodies. Both viral RNA and antigens are found in these cells, suggesting a direct viral cytopathy.[57,67]

Clinically, yellow fever infection may be asymptomatic, may cause moderate febrile disease, or may be severe, causing hemorrhagic fever, liver failure, AKI, and death. Most patients (85%) fully recover after 3 to 4 days and become permanently immunized against the disease. About 20% develop the severe form, with mortality rates up to 50% in these patients.[57,66]

After 3 to 6 days of incubation, the clinical picture of yellow fever starts abruptly with high fever, chills, anorexia, myalgia, headache, vomiting, and bradycardia. Hemorrhagic manifestations may occur. There is then a remission period with symptom improvement, and patients with mild cases do not have any further manifestation. In the severe forms the fever comes back, followed by vomiting, epigastric pain, and jaundice, the so-called "intoxication phase." There are large increases in transaminases and bilirubin. Leukopenia and ST-segment abnormalities are also found. Hemorrhagic events, associated with hepatic damage and consumptive coagulopathy, can occur; these include hematemesis, melena, petechiae, bruises, mucosal bleeding, and metrorrhagia in women. Microcirculatory thrombosis, disseminated intravascular coagulation, tissue anoxia, oliguria, and shock may follow.[57,66]

Yellow fever–associated kidney injury is usually observed after 5 days of disease in the severe forms; it may evolve to anuria and acute tubular necrosis, with increased mortality. In Africa, AKI is observed earlier and in the absence of jaundice or liver abnormalities, with higher mortality. The mechanisms of kidney injury are poorly

understood. In experimental studies performed in Rhesus monkeys in the 1980s, the renal disorder appeared to be pre-renal until the last 24 hours of life of the animal. The final phase was characterized by marked oliguria, azotemia, and acidosis, with severe tubular necrosis found at autopsy. In humans, an eosinophilic degeneration of the renal epithelial cells has been described. Viral antigen identification in human kidney tissue and after experimental infection in animals suggests a direct viral action on renal tissue.[57,66,68,69]

CHAPTER 71

Diagnosis and Clinical Evaluation of Acute Kidney Injury

Eric Judd, Paul W. Sanders, and Anupam Agarwal

The term *acute renal failure* (ARF) describes the clinical syndrome in which an abrupt (hours to days) decrease in renal function leads to the accumulation of nitrogenous waste products and, commonly, a reduction in urine output. *Acute kidney injury* (AKI) is the new consensus term for ARF.[1-4] This change in terminology served to standardize a definition for the syndrome as well as incorporate new knowledge that small rises in serum creatinine (0.3 mg/dl) are associated with increased mortality and morbidity.[5]

The Acute Dialysis Quality Initiative first defined AKI with the RIFLE criteria (risk, injury, failure, loss, end stage) in 2004 (Table 71-1).[2] The Acute Kidney Injury Network (AKIN) later supported the RIFLE criteria with minor modifications (see Table 71-1).[3,4] Both definitions have been validated in large patient cohorts, and the Kidney Disease: Improving Global Outcomes (KDIGO) group merged the two definitions in a recent guideline update (Table 71-2). AKI is now defined as an increase in serum creatinine of 0.3 mg/dl or more within 48 hours of observation or 1.5 times baseline or greater, which is known or presumed to have occurred within 7 days, or a reduction in urine volume below 0.5 ml/kg/h for 6 hours.[1]

The incidence of AKI varies depending on the population studied and the definition used in the analysis. In a community-based cohort in northern California, from 1996 to 2003, the annual incidence of AKI in which dialysis was not required was 3841 per million population per year when AKI was defined as an increase in serum creatinine of 0.5 mg/dl or more from a baseline of below 2.0 mg/dL, or an increase of 1.0 mg/dl or more from a baseline of 2.0 to 5.0 mg/dl.[6] In the United States, AKI is present in 1.9% of hospital inpatients and is especially common in critically ill patients, in whom the prevalence is higher than 60% during intensive care unit (ICU) stays.[7,8] AKI severity increases in the ICU, with 5% to 6% of patients requiring renal replacement therapy, and in the United States the incidence of AKI patients who require dialysis is growing at a rate of 10% annually.[9,10]

The development of AKI has significant short- and long-term consequences. Despite major advances in dialysis and intensive care, the mortality rates for patients with AKI in the ICU remain high, 37% to 60%.[9,11] In a large population of almost 20,000 hospitalized adults, AKI severity was directly associated with increased in-hospital mortality, lengthened hospital stay, and higher overall cost. The associations were present for changes in serum creatinine as low as 0.3 mg/dl.[5] Patients with AKI who survive hospitalization also have an increase in long-term mortality, with an adjusted mortality risk of 1.4, which is amplified with increasing AKI stage.[12] Furthermore, AKI survivors are at increased risk for developing comorbidities including chronic kidney disease (CKD).[13]

DIAGNOSIS AND CLINICAL EVALUATION OF ACUTE KIDNEY INJURY

Early Detection of Acute Kidney Injury

With the knowledge that patient outcomes worsen with increasing severity of AKI beginning with small declines in renal function, research efforts have focused on early detection of AKI. Increases in serum creatinine levels currently define AKI, yet when used as a marker of renal function, serum creatinine concentrations have multiple limitations. In addition to a steady-state balance of creatinine production and excretion being required for appropriate estimation of glomerular filtration rate (GFR), serum creatinine concentrations may not rise for subtle declines in GFR and are slow to rise for rapid falls in GFR. Furthermore, the generation of creatinine from muscle is reduced in sepsis-induced AKI, and serum creatinine concentrations may not increase proportionally to GFR decline.[14] A window of time exists in which kidney injury goes undetected until serum creatinine concentrations rise (8 to 48 hours) (Fig. 71-1).[15] Novel serum and urine biomarkers are undergoing investigation as potential early indicators of AKI. These biomarkers, which include kidney injury molecule 1 (KIM-1), neutrophil gelatinase–associated lipocalin (NGAL), cystatin C, interleukin (IL)–18, and others, not only offer the potential for early detection of AKI but also may allow for improved prognostication and insight into the specific cause of AKI.

Figure 71-2 depicts the continuum of kidney injury severity and a number of biomarkers that have been proposed to be useful in early detection. Serum cystatin C, a cysteine protease inhibitor that is freely filtered at the glomerulus and normally reabsorbed by proximal tubule cells, may be more sensitive than serum creatinine concentrations at detecting small reductions in GFR.[16] Urinary cystatin C has been shown to detect AKI in multiple clinical settings including after cardiac surgery, sepsis-AKI, and delayed graft function after kidney transplantion.[15]

Kidney injury molecule 1 is a cell membrane glycoprotein that is upregulated in proximal tubular cells injured by ischemia or nephrotoxins in animals and humans. KIM-1 can act as a nonmyeloid phosphatidylserine receptor that transforms epithelial cells into semiprofessional phagocytes.[17] The ectodomain of this membrane-associated mucin-rich molecule is shed into the urine of human and rodent kidneys with renal injury, but it is not found in urine produced by healthy kidneys. Urinary levels are increased specifically with AKI resulting from ischemia or toxin exposure.[18,18a]

Neutrophil gelatinase–associated lipocalin (NGAL), a protein expressed in proximal and distal renal tubule cells as well as neutrophils, binds and traffics free iron. It also mediates the tubular response

Acute Kidney Injury Network (AKIN) and RIFLE Classifications of Acute Kidney Injury			
AKIN Staging **Serum Creatinine**	**Urine Output (Common to Both)**	**RIFLE Class**	**RIFLE Serum Creatinine or GFR**
Stage 1: Increase of ≥0.3 mg/dl (≥26.5 µmol/l) or increase to ≥150% to 200% (1.5-fold to twofold) from baseline	<0.5 ml/kg/h for >6 h	Risk	Increase in serum creatinine ×1.5 or GFR decrease >25%
Stage 2: Increased to >200% to 300% (more than twofold to threefold) from baseline	<0.5 ml/kg/h for >12 h	Injury	Serum creatinine ×2 or GFR decreased >50%
Stage 3: Increased to >300% (more than threefold) from baseline, or ≥4.0 mg/dl (≥354 µmol/l) with an acute increase of at least 0.5 mg/dl (44 µmol/l) or on RRT	<0.3 ml/kg/h for 24 h or anuria for 12 h	Failure	Serum creatinine ×3, or serum creatinine > 4 mg/dl (>354 µmol/l) with an acute rise >0.5 mg/dl (>44 µmol/l) or GFR decreased >75%
		Loss	Persistent acute renal failure = complete loss of kidney function for longer than 4 weeks
		End-stage kidney disease	ESRD > 3 months

Table 71-1 AKIN and RIFLE classifications of acute kidney injury. For conversion of creatinine expressed in SI units to mg/dl, divide by 88.4. For AKIN, the increase in creatinine must occur in less than 48 hours. For RIFLE, AKI should be both abrupt (within 1 to 7 days) and sustained (more than 24 hours). *ESRD,* End-stage renal disease; *GFR,* glomerular filtration rate; *RIFLE,* risk, injury, failure, loss, end stage; *RRT,* renal replacement therapy. *(Modified from reference 1.)*

Kidney Disease: Improving Global Outcomes (KDIGO) Composite Staging of AKI		
Stage	**Serum Creatinine**	**Urine Output**
1	1.5-1.9× baseline OR ≥0.3 mg/dl (≥26 µmol/l) increase	<0.5 ml/kg/h for 6-12 h
2	2.0-2.9× baseline	<0.5 ml/kg/h for ≥12 h
3	3.0× baseline OR Increase in serum creatinine to ≥4.0 mg/dl (≥352 µmol/l) OR Initiation of renal replacement therapy OR, in patients younger than 18 years, decrease in eGFR to <35 ml/min/1.73 m^2	<0.3 ml/kg/h for ≥24 h OR Anuria for ≥12 h

Table 71-2 KDIGO composite staging of AKI. *AKI,* Acute kidney injury; *eGFR,* estimated glomerular filtration rate. *(From reference 1.)*

to epidermal growth factor and is thereby involved in the progression of renal disease.[19] Urinary NGAL levels are increased in the setting of tubular stress or injury, but not in pre-renal disease.[20] NGAL is the most studied renal biomarker, with a large number of studies correlating urinary NGAL levels to the early detection of AKI.[15]

Interleukin (IL)-18 is an inflammatory cytokine found in macrophages and proximal tubule cells. Urinary IL-18 levels are upregulated in the setting of renal ischemic injury in multiple clinical settings: general ICU care, acute respiratory distress syndrome, contrast nephropathy, and cardiac surgery.[15]

Novel biomarkers of AKI have not reached clinical practice; however, they hold potential for detecting AKI early, identifying minor kidney injuries that do not raise serum creatinine concentrations, monitoring therapeutic benefits of novel treatment interventions, and specifying the cause of AKI. Whether the additional cost of screening for AKI or whether early detection of AKI will permit research that produces beneficial therapies for human AKI has not been established.[20]

Diagnostic Approach to Acute Kidney Injury

The basic diagnostic approach to patients with AKI is to determine the cause (see Chapter 69). This process should start by excluding or correcting both pre-renal and post-renal causes. In hospitalized patients, determining the correct causative diagnosis often involves selecting the most probable cause among many potential choices.[21] In this setting, assessing urine volume can narrow the differential diagnosis, dividing AKI into oliguric (less than 500 ml of urine output per day) and nonoliguric causes.

To correctly identify the cause of AKI, one needs an understanding of the natural history of AKI from different causes, a chronologic sequence of events preceding the AKI, and analysis of the available patient data. Although the differential diagnosis for AKI in

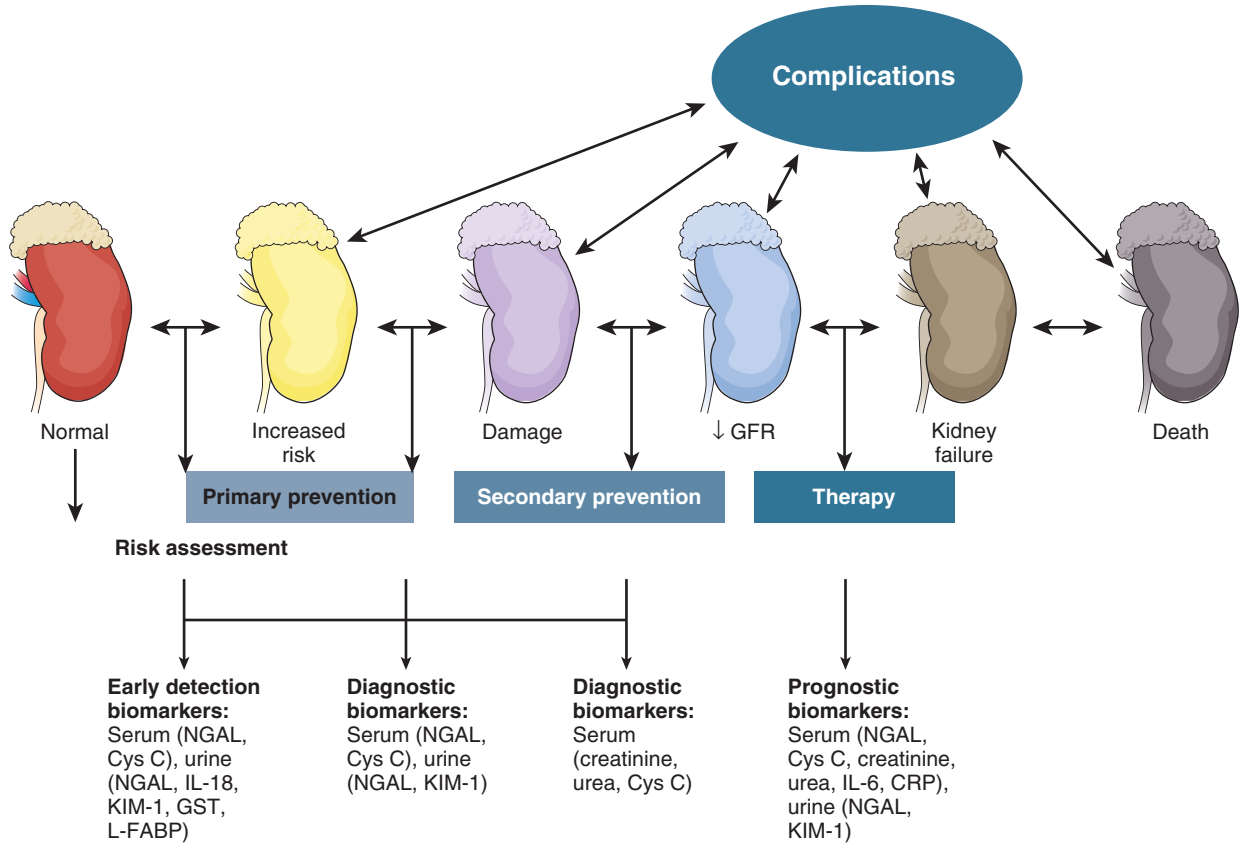

Figure 71-2 Continuum of kidney injury and biomarkers of acute kidney injury (AKI). Injury begins before excretory function is lost (i.e., decreased GFR) and can potentially be detected by the measurements of biomarkers. *CRP,* C-reactive protein; *Cys C,* cystatin C; *GFR,* glomerular filtration rate; *GST,* glutathione-*S*-transferase; *IL-6,* interleukin-6; *IL-18,* interleukin-18; *KIM-1,* kidney injury molecule 1; *L-FABP,* liver fatty acid–binding protein; *NGAL,* neutrophil gelatinase-associated lipocalin. *(Modified from reference 20.)*

hospitalized patients is large, a careful history and physical examination and basic laboratory tests often suffice for diagnosis (Table 71-3).[21]

Acute Kidney Injury Versus Chronic Kidney Disease

On occasion, it can be difficult to determine if a patient with renal failure has AKI or AKI superimposed on CKD. The patient's history and information about prior serum creatinine values are invaluable for differentiation of AKI and CKD. Ultrasonographic evidence of small, scarred kidneys is consistent with CKD. Notably, CKD caused by diabetic nephropathy, infiltrative disorders such as amyloidosis, human immunodeficiency virus–related nephropathy, or polycystic kidney disease can be present with normal or increased kidney size. The findings on presentation of normocytic anemia, hyperparathyroidism, peripheral neuropathy, and broad waxy casts in the urinary sediment would suggest CKD. Patients with CKD are at high risk for the development of episodes of AKI.[22] For patients with AKI superimposed on CKD, knowledge of prior serum creatinine concentrations is required to determine the degree of potentially reversible AKI.

Clinical Assessment

The evaluation of a hospitalized patient with AKI should begin with a complete medical history and review of the hospital records. Once the prior serum creatinine concentration or other evidence of underlying kidney disease has established the level of baseline kidney disease, the history should be directed toward the events preceding the AKI. These events may be part of a systemic disease process (e.g., sepsis, rhabdomyolysis), an inpatient event (e.g., surgical procedure, radiocontrast exposure, nephrotoxic medication exposure), or an outpatient event (e.g., medication or drug use, intravascular volume contraction from diarrhea or vomiting). Particular attention should be paid to the medication record including the use of nonsteroidal anti-inflammatory drugs (NSAIDs), renin-angiotensin-aldosterone antagonists, and antibiotic medications. Other features of the history include the use of Chinese herbs that contain aristolochic acid, a known nephrotoxin, or the use of a synthetic cannabinoid, a newly identified potential nephrotoxin.[23] In Africa and India the accidental or intentional ingestion of hair dyes containing paraphenylenediamine (PPD) may result in AKI. Clues in the history that point toward a post-renal cause (e.g., urinary hesitancy, frequent nocturia, pelvic or flank pain, overflow urinary incontinence, metastatic cancer) should be assessed early to prevent further kidney injury from a delay in treatment.

Physical examination often reveals signs that support a particular cause of AKI. Reduced body weight, marked orthostatic decrease in blood pressure, an increase in pulse, and lack of jugular venous distention all suggest a reduction in extracellular fluid volume. Notably, patients with pre-renal AKI can appear volume overloaded in cases of heart failure, cirrhosis, and nephrotic syndrome when effective arterial blood volume is reduced. In critically ill patients, assessment of intravascular volume status by physical examination can be challenging, and invasive hemodynamic monitoring of central

Differential Diagnosis by Pathophysiologic Classification of Acute Kidney Injury (AKI)	
Cause	**Comments**
Pre-renal	30%-60% of AKI
Volume depletion	Renal losses, GI losses, hemorrhage
Decreased cardiac output	Right- or left-sided heart failure, cardiac tamponade
Systemic vasodilation	Sepsis, anaphylaxis, anesthetics
Afferent arteriolar vasoconstriction	NSAIDs, calcineurin inhibitors, radiocontrast, hepatorenal syndrome, hypercalcemia
Efferent arteriolar vasodilation	ACE inhibitors, ARBs
Intrinsic	Approximately 40% of AKI
Acute tubular injury Ischemic Nephrotoxic (drug) Nephrotoxic (pigment)	 Aminoglycosides, lithium, amphotericin, pentamidine, cisplatin, ifosfamide, radiocontrast Rhabdomyolysis, intravascular hemolysis
Acute interstitial nephritis (AIN) Drug induced Infection related Autoimmune diseases Malignancy	 Penicillins, cephalosporins, NSAIDs, PPIs, allopurinol, rifampin, sulfonamides Pyelonephritis, viral nephritides Sjögren syndrome, sarcoidosis, SLE Lymphoma, leukemia
Intratubular obstruction Paraprotein Crystals	 Immunoglobulin light chains Acute phosphate nephropathy, tumor lysis syndrome, ethylene glycol, acyclovir, indinavir, methotrexate
Acute glomerulonephritis	Postinfectious, cryoglobulinemia, RPGN, SLE
Macrovascular	Increased renal vein pressure from increased intra-abdominal pressure, bilateral renal vein thrombosis, bilateral renal artery emboli
Microvascular	Atheroembolic disease, HUS, TTP, scleroderma renal crisis, malignant hypertension
Post-renal (Obstruction)	Approximately 10% of AKI
Intrinsic	Bilateral ureteral stones, bladder outlet obstruction (prostatic enlargement or blood clot), neurogenic bladder
Extrinsic	Retroperitoneal fibrosis, metastatic cancer

Table 71-3 Differential diagnosis by pathophysiologic classification of AKI. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *GI,* gastrointestinal; *HUS,* hemolytic uremic syndrome; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *PPIs,* proton-pump inhibitors; *RPGN,* rapidly progressive glomerulonephritis; *SLE,* systemic lupus erythematosus; *TTP,* thrombotic thrombocytopenic purpura.

venous pressure or pulmonary capillary wedge pressure (PCWP) may be necessary to differentiate volume overload from noncardiogenic pulmonary infiltrates. A low PCWP suggests noncardiogenic pulmonary edema.[21] Trends in daily intake and output volumes also assist in determining the extracellular fluid volume of the critically ill patient.

The initial physical examination should include a careful examination of the abdomen. A tender, distended bladder indicates a lower urinary tract obstruction, and when this is present, sterile postvoid bladder catheterization should be performed. A distended, tense abdominal wall may represent ascites, aggressive intravenous fluid resuscitation, or recent abdominal surgery. Intra-abdominal pressure can be measured in the ICU to identify AKI from abdominal compartment syndrome, defined as an intra-abdominal pressure exceeding 20 mm Hg.[24]

Fever, skin rash, and arthralgias may be signs of a systemic disease process, such as systemic lupus erythematosus, vasculitis, endocarditis, or drug allergy with acute interstitial nephritis (AIN). A leukocytoclastic rash on the lower extremities may, for example, be Henoch-Schönlein purpura in a younger patient or cryoglobulinemia in an older patient with a hepatitis C infection. A history of recent aortic catheterization (e.g., cardiac catheterization) and the findings of livedo reticularis or a discolored toe are diagnostic clues for cholesterol or atheromatous emboli. Painless hematuria suggests acute glomerulonephritis (GN) or genitourinary malignancy, whereas painful hematuria is more consistent with obstruction.[21]

Laboratory Tests

Differentiating the two most common causes of AKI in hospitalized patients, pre-renal AKI and acute tubular necrosis (ATN), may be difficult when both the effective arterial blood volume and the time course of the kidney injury are unknown.[25] Here the term *acute tubular injury* (ATI) may be added to ATN to more accurately describe the pathology involved in intrinsic AKI from ischemic or toxic insults.[26] Evaluation of urine volume, urinary sediment, and urinary indices (the last is useful only in patients with oliguria) is particularly helpful in making the correct diagnosis (Table 71-4). Initial laboratory tests include a urinalysis and basic metabolic panel with measurement of blood urea nitrogen (BUN) and serum sodium, potassium, bicarbonate, and creatinine levels. These tests are important not only for the diagnosis but also for assessment of complications of AKI.[21]

Results from initial laboratory testing may prompt further testing. For example, glycosuria occurring with a normal plasma glucose level offers evidence for proximal tubular dysfunction. The presence of amino acids and bicarbonate in the urine along with elevated urinary levels of phosphate and uric acid confirm Fanconi syndrome, a form of proximal tubular injury seen with AKI from cisplatin or tenofovir use and immunoglobulin free light-chain (FLC) cytotoxicity.

Ratio of Blood Urea Nitrogen to Creatinine

The BUN-creatinine ratio is 10:1 to 15:1 (when both are expressed in mg/dl; 40 to 60 when expressed in mmol/l) in normal individuals.

Clinical and Laboratory Variables in the Differential Diagnosis Between Pre-renal and Renal Acute Kidney Injury (AKI)

	Pre-renal	Renal
History	GI, urinary, skin volume loss, blood loss, or third spacing	Drugs or toxin exposure, hemodynamic change
Clinical presentation	Hypotension or volume depletion	No specific symptoms or signs
Laboratory studies		
BUN/S_{Cr}	>20	<20
Sediment	Normal to few casts	"Muddy brown" casts
U_{osm} (mmol/kg)	>500	<350
Proteinuria	None to trace	Mild to moderate
U_{Na} (mmol/l)	<20	>40
FE_{Na} (%)	<1	>1
FE_{Urea} (%)	<35	>35
Novel biomarkers	None	KIM-1, cystatin C, NGAL, CYR61, others

Table 71-4 Clinical and laboratory variables in the differential diagnosis between pre-renal and renal AKI. *BUN,* blood urea nitrogen; *CYR61,* cysteine-rich protein 61; FE_{Na}, fractional excretion of sodium; FE_{Urea}, fractional excretion of urea; *GI,* gastrointestinal; *KIM-1,* kidney injury molecule 1; *NGAL,* neutrophil gelatinase–associated lipocalin; S_{Cr}, serum creatinine; U_{Na}, urinary sodium; U_{osm}, urinary osmolality.

In pre-renal AKI the ratio may be greater than 20:1 because of a disproportionate increase in urea reabsorption resulting from elevated antidiuretic hormone levels. A high ratio is not specific for pre-renal injury because gastrointestinal bleeding, impaired protein anabolism (e.g., systemic corticosteroid or tetracycline administration), increased catabolism (e.g., sepsis), and increased protein intake can raise BUN levels. Pre-renal AKI should not be excluded by a normal ratio because diminished urea production from decreased protein intake or underlying liver disease can prevent the expected rise in the BUN by increased tubular reabsorption. Also, elevations in creatinine levels may exceed BUN levels in patients with creatinine kinase release from muscle breakdown, as in rhabdomyolysis.

Urine Volume

In AKI, urine volume has been shown to directly correlate with residual GFR.[27] Urine volume therefore can both indicate the severity of AKI and provide important diagnostic information. Oliguric AKI (urine output less than 500 ml/day) is typically associated with worse outcomes than AKI with preserved urine volume, especially with a positive fluid balance in the critical care setting.[28-30] Oliguria commonly occurs in AKI caused by ATN, although it can also be seen in pre-renal AKI with early detection or AIN. Wide variations in daily urine output suggest obstruction. Complete anuria (no urine output) suggests obstruction or an acute vascular catastrophe, such as renal vein or renal artery occlusion, although it can be seen in ATN and AIN. For a vascular event to cause complete anuria, it must affect both kidneys or a single functioning kidney.[21]

Urinalysis and Urine Microscopy

In the setting of AKI a dipstick urinalysis provides the first clue to the presence of red blood cells (RBCs) or protein in the urine. However, urinary dipstick results have significant limitations and must be interpreted in conjunction with more specific tests such as a spot urinary protein- or albumin-creatinine ratio and urine microscopy. A few notable limitations of the dipstick urinalysis include an inability to detect FLC protein components of immunoglobulins and the false-positive detection of protein in the setting of radiographic contrast or alkaline urine. The dipstick urinalysis can provide useful diagnostic information when used in conjunction with urine microscopy. For example, the presence of hemoglobin or myoglobin in the urine is supported by finding blood by dipstick and no RBCs by urine microscopy. Urine microscopy has been validated as a diagnostic and prognostic tool in hospitalized patients with AKI.[25] A fresh urine sample is centrifuged and the sediment examined by light microscopy for the presence of cells, casts, and crystals (Figs. 71-3 and 71-4). A normal urine sediment contains few cells or casts, termed a "bland" sediment. Urine microscopy in early pre-renal AKI is typically normal with occasional hyaline casts. "Muddy brown" granular casts and renal tubular epithelial cells in the urine support ATN-related AKI. In a study of 197 hospitalized patients with AKI defined by the AKIN criteria, the presence of more than 10 granular casts per low power field had a positive predictive value of 100% for a final diagnosis of ATN. In this same study, a urine sediment score based on granular casts and renal tubular epithelial cells was directly associated with worsening AKI, defined as a composite outcome of higher AKIN stage, dialysis requirement, and death. These findings suggest that urine microscopy is useful both in distinguishing ATN-related AKI from pre-renal AKI and in predicting the severity of AKI.[25]

Findings on urinalysis and urine microscopy may offer insights into renal history (broad, waxy casts are often seen in CKD) but, more important, may be diagnostic clues to a rare cause of AKI. A proliferative GN is characterized by a urinary dipstick with 3+ to 4+ blood and 2+ to 3+ protein with an active sediment of RBCs and RBC casts identified with urine microscopy. In this setting the history and physical examination findings should be supported by serologic testing and a kidney biopsy, if the kidneys are normal in size. The presence of white blood cells in clumps and casts, in the absence of bacteria, suggests AIN.[21] Renal tubular epithelial cells, granular casts, RBCs, and even RBC casts can be seen in the urinary sediment of patients with AIN. Urinary eosinophils are neither highly sensitive nor specific for diagnosis of drug-associated AIN. Cystitis, prostatitis, pyelonephritis, atheroembolic disease, ATN, and rapidly progressive glomerulonephritis (RPGN) may all cause eosinophiluria in the absence of AIN.[31,32] A urine sediment with abundant uric acid crystals accompanying high serum phosphorus levels in a patient undergoing chemotherapy may indicate tumor lysis syndrome.

Urinalysis and urine microscopy are discussed further in Chapter 4.

Fractional Excretion of Sodium and Urea

The urine-serum concentrations of sodium in relation to the urine-serum concentrations of creatinine (fractional excretion of sodium [FE_{Na}]) has been used to approximate renal tubular function:

$$FE_{Na} = \frac{[U/S]_{Na}}{[U/S]_{Cr}} \times 100\%$$

where U = urine, S = serum, Na = sodium, and Cr = creatinine.

The basic premise is that renal tubular cells will reabsorb sodium in the pre-renal setting, whereas tubules damaged by ATN will not.[33] FE_{Na} below 1% is consistent with pre-renal AKI, and FE_{Na} above 3% is typical of ATN. However, many exceptions to these cutoffs have been discovered since FE_{Na} was first introduced into clinical practice in 1976. FE_{Na} may be less than 1% despite the presence of ATN in the setting of sepsis, hemoglobinuria or myoglobinuria, radiocontrast exposure, nonoliguria, heart failure, and advanced cirrhosis. Underlying CKD, diuretic use, recent intravenous fluid administration, glucosuria, bicarbonaturia, and salt-wasting disorders may be

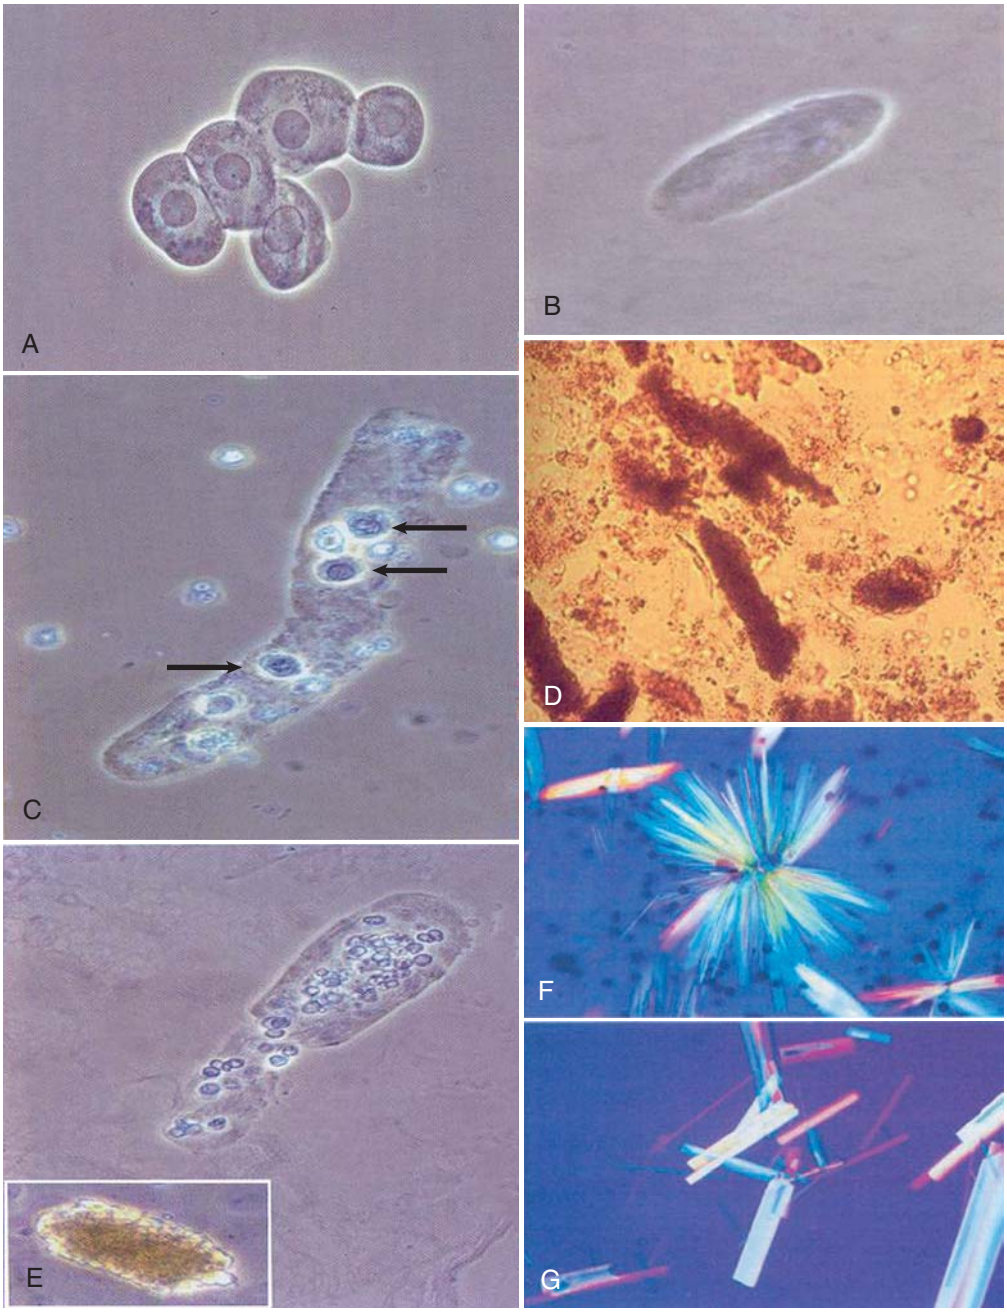

Figure 71-3 Examples of urinary sediments seen in acute kidney injury. **A,** Epithelial cell aggregate. **B,** Hyaline cast as can be seen in pre-renal acute kidney injury. **C,** Epithelial cast as can be seen in early acute tubular necrosis (*arrows* indicate epithelial cells). **D,** Muddy brown cast, typical of established acute tubular necrosis. **E,** Erythrocyte cast as seen in glomerulonephritis and vasculitis. *Inset:* Hemoglobin cast. **F** and **G,** Two forms of indinavir crystals.

associated with elevated FE_{Na} despite the presence of pre-renal AKI.[33] Therefore FE_{Na} has significant limitations in the setting of hospital-acquired AKI, where confounders abound, yet may be helpful in differentiating pre-renal AKI from ATN in specific patient populations with oliguria. Urea reabsorption, primarily occurring in proximal tubules, is less affected by loop and thiazide diuretics, and the fractional excretion of urea (FE_{Urea}) may be a useful alternative to FE_{Na} in patients receiving diuretics. FE_{Urea} calculation is identical to that of FE_{Na}, with replacement of urea for sodium, and values less than 35% favor pre-renal AKI over ATN.

Imaging Studies

Kidney imaging may not be necessary if a clear diagnosis of AKI exists (e.g., pre-renal AKI or ATN). However, when the diagnosis is uncertain, and especially if the clinical picture supports urinary obstruction or renal vascular occlusion, then further diagnostic testing is indicated.[21] Renal ultrasound is a reliable, noninvasive method of assessment of the kidney and urinary tract. It can identify urinary obstruction, polycystic kidney disease, and the size and number of kidneys. When Doppler flow is used, renal artery and veins can be assessed for patency. High-resolution, noncontrast computed tomographic imaging is the preferred test for the detection of urinary tract calculi. Radioisotope renography may be used to estimate the renal plasma flow in a transplanted kidney with AKI but is increasingly replaced by Doppler ultrasound. Other radionuclide methods are less useful in AKI (e.g., tagged white blood cell scan for AIN). Magnetic resonance imaging without contrast is now recommended to evaluate renal arterial or venous thrombosis.[21]

Renal Biopsy

Renal biopsy is reserved for patients in whom pre-renal and post-renal AKI have been excluded and the cause of intrinsic renal AKI remains unclear. Renal biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. Examples include RPGN, vasculitis, systemic lupus erythematosus, and AIN.

ACUTE KIDNEY INJURY IN SPECIFIC SETTINGS

Acute Tubular Necrosis

Acute tubular necrosis is a clinical syndrome of abrupt and sustained decline in GFR that is triggered by an acute ischemic or nephrotoxic event and develops within minutes to days after the insult.[21] Apart from kidney biopsy, no definitive test exists to diagnose ATN. The diagnosis is suggested by a history of recent hypotension, volume depletion, sepsis, or nephrotoxic exposure. Muddy-brown, coarse, granular casts are present on urine microscopy in the majority of patients with ATN, particularly those who are oliguric.[21] Other laboratory findings consistent with the diagnosis of ATN are shown in Table 71-4.

The pathophysiology of ATN involves multiple pathways (see Chapter 69). Obstruction of flow within the tubule by cellular debris, disruptions of tubular cell polarity and cytoskeleton, loss of the lining epithelium with resulting backleak of glomerular filtrate into the renal interstitium, and afferent arteriolar constriction have all been proposed as playing pathophysiologic roles in ATN. In general, ATN has been described as a (mal)adaptive response of the kidney—"trading away" GFR for the preservation of medullary oxygenation and tubular integrity.[26]

Acute tubular necrosis in the setting of ischemia-reperfusion is usually most severe within the outer medulla of the kidney (see Chapter 69).[34] The typical histologic features of human proximal tubular injury include vacuolation, loss of brush border, disruption of the epithelial cells lining the tubule, and presence of intratubular casts. Necrosis of tubular cells is patchy and is not usually dominant in the biopsy specimen, perhaps in part because most biopsy specimens are from the cortex and the outer medulla is not sampled adequately. Apoptosis of tubular cells is present in renal biopsy specimens from humans with ATN, and evidence of cellular regeneration is often seen, most commonly in those areas of greatest tubular cell loss. Furthermore, regenerative changes and signs of fresh epithelial injury are often observed in the same biopsy specimen, suggesting that recurrent episodes of tubular ischemia continue to occur during the maintenance phase of ATN. The morphologic appearance of the common forms of nephrotoxin-induced ATN is similar to that of ischemic ATN. Correlations of morphologic findings to functional endpoints has been difficult, especially because the biopsy represents a limited view of the pathologic process at one point in time and usually samples only the cortex of the kidney.

Acute Interstitial Nephritis

Acute interstitial nephritis is characterized by the presence of inflammatory infiltrates and edema within the interstitium, with an accompanying, acute deterioration in renal function (see Chapter 69).[35] It is not an uncommon cause of AKI, accounting for 15% to 27% of renal biopsies performed because of AKI, yet AIN may be overlooked as a cause of AKI in settings where ATN is common (e.g., sepsis). Drug use is the most common cause of AIN (see Table 71-3), with antimicrobials and NSAIDs being the most frequently responsible agents.[35]

The variability in clinical presentation of patients with AIN makes the diagnosis, which generally requires kidney biopsy, challenging. In patients with drug-induced AIN the mean delay between drug exposure and the appearance of renal manifestations is 10 days, although the latent period can be as short as 1 day with some antibiotics or as long as several months with NSAIDs.[35] In a total of 121 pooled patients with AIN, the reported frequency of symptoms included arthralgias, 45%; fever, 36%; and skin rash, 22%. In the same analysis, urinary findings included non-nephrotic proteinuria (93%), leukocyturia (82%), and microscopic hematuria (67%).[35] The classic

clinical presentation of maculopapular rash, peripheral eosinophilia, and arthralgias may not be present in drug-induced AIN and is uncommon in infection-related or idiopathic AIN (see Table 71-3).

Acute Kidney Injury from Intratubular Obstruction

Several endogenous and exogenous molecules can precipitate in the tubular lumen to produce AKI. These include uric acid, calcium phosphate, calcium oxalate, immunoglobulin free–light chains, myoglobin, and medications (e.g., acyclovir, indinavir, methotrexate and methotrexate analogues, sodium phosphate–containing cathartics, and sulfadiazine).[21] Medication-induced crystal nephropathy occurs more commonly when high doses of medication are combined with low tubular flow rates from volume contraction or underlying CKD.

Ethylene glycol ingestion may result in AKI from calcium oxalate crystal deposition. Ethylene glycol is an odorless, sweet-tasting liquid found in solvents and antifreeze. Patients with ethylene glycol poisoning typically present with disorientation and agitation and are found to have a plasma osmolar gap that progresses into a high anion gap metabolic acidosis as the ethylene glycol is metabolized into glycolic acid. The glycolic acid is converted to oxalic acid, which binds free calcium to form calcium oxalate crystals. Crystal deposition resulting in AKI typically manifests 48 to 72 hours after ingestion; however, calcium oxalate crystals can be readily identified in the urine soon after exposure.

Intratubular obstruction from calcium phosphate and uric acid crystals is the presumed pathogenesis of AKI in tumor lysis syndrome. Tumor lysis syndrome is characterized by a constellation of metabolic derangements caused by massive and abrupt release of intracellular components in the blood after rapid lysis of malignant cells. It is typically seen after initiation of cytotoxic therapy for hematologic malignancies with large tumor burden or cell counts as in acute lymphoblastic lymphoma (ALL), Burkitt lymphoma, or acute myeloid leukemia (AML).[36] Clinical features of tumor lysis syndrome result from the effects of the metabolic derangements. Hyperkalemia may induce cardiac arrhythmias, weakness, and paresthesias. Hyperphosphatemia initially produces muscle cramps and lethargy but can also promote nausea, vomiting, diarrhea, and seizure. Hypocalcemia, primarily caused by phosphorus binding, causes similar symptoms with muscle cramps, tetany, cardiac arrhythmias, and seizures.[36] The presence of hyperkalemia and hypocalcemia associated with AKI in a patient receiving cytotoxic chemotherapy may be the only initial clues to the syndrome because blood uric acid and phosphate levels are not routinely monitored. In this setting, urine microscopy can assist in the diagnosis of AKI by revealing the presence of many uric acid crystals.

Rhabdomyolysis

Rhabdomyolysis is characterized by the leakage of muscle-cell contents, including myoglobin, electrolytes, creatinine kinase, aldolase, lactate dehydrogenase, and aspartate aminotransferase (AST) into the circulation.[37] AKI, occurring primarily in severe rhabdomyolysis, results from renal vasoconstriction, proximal tubular cell injury from oxidant stress, and intranephronal obstruction. Myoglobin, a heme pigment protein that contains iron in the ferrous (Fe^{2+}) state, has less nephrotoxicity in alkaline urine. Intravascular volume contraction and acidic urine promote distal tubule obstruction from myoglobin precipitation.

Muscle injury leading to rhabdomyolysis frequently follows trauma (e.g., crush syndrome or limb compression from prolonged immobilization); however, causes unrelated to trauma exist and include increased exertion (e.g., seizure, alcohol withdraw, strenuous exercise), genetic defects (e.g., disorders of glycolysis or gluconeogenesis, disorders of lipid metabolism, and mitochondrial disorders), infections (e.g., influenza A and B), body temperature changes (e.g., heat stroke, neuroleptic malignant syndrome, and hypothermia), and drug or toxin exposure (e.g., lipid-lowering drugs, alcohol, cocaine, and heroin).[37]

Patients with acute rhabdomyolysis often present with muscle pain and reddish-brown urine. The presence of pigmented granular casts and the lack of RBCs on urine microscopy coupled with a blood-positive urinary dipstick are important diagnostic clues for rhabdomyolysis-related AKI. However, the diagnosis must be confirmed by elevated serum creatinine kinase levels and the presence of urinary myoglobin.[21] A weak correlation exists between creatinine kinase values and the incidence of AKI, and the risk of AKI is lower when creatinine kinase levels at admission are less than 20,000 U/l. Rhabdomyolysis may contribute to AKI with creatinine kinase levels as low as 5000 U/l when coexisting conditions such as sepsis, intravascular volume contraction, and acidosis are present.[37]

Acute Kidney Injury in Multiple Myeloma

Monoclonal immunoglobulin FLCs are responsible for the majority of severe AKI in patients with multiple myeloma. In the setting of plasma cell dyscrasia, monoclonal FLCs are overproduced, often with circulating levels hundreds times higher than normal.[38] These low-molecular-weight proteins are freely filtered through the glomerulus and reabsorbed in the proximal tubule. Unlike most endogenously produced proteins, monoclonal FLCs have a strong propensity to cause tubular damage (see Chapter 27).[38] Some monoclonal FLCs are cytotoxic and promote proximal tubular cell injury, with one mechanism resulting in a defect in sodium-coupled cotransport processes producing type II renal tubular acidosis, aminoaciduria, phosphaturia, and glycosuria (i.e., Fanconi syndrome).[39] A separate mechanism of FLC-mediated AKI is intratubular obstruction from precipitation of monoclonal FLCs in the distal nephron, cast nephropathy.[21] Cast formation occurs under specific conditions mediated by the ionic composition of tubule fluid, tubule fluid flow rates, the concentration of Tamm-Horsfall glycoprotein and FLCs, the strength of the binding interaction between Tamm-Horsfall glycoprotein and FLC, and the presence of furosemide.[38] AKI attributed to cast nephropathy occurs in approximately one third of patients with multiple myeloma and AKI. Other causes of AKI include extrarenal obstruction (e.g., nephrolithiasis, amyloid deposition in the ureters), hypercalcemia, hyperviscosity syndrome, and non–myeloma-related causes (e.g., AIN or contrast-induced nephropathy [CIN]).[21]

Cast nephropathy should be considered, particularly in an older patient with unexplained AKI. Predisposing conditions may include hypercalcemia, intravascular volume contraction, furosemide use, exposure to radiocontrast, and/or NSAID use. AKI may be the presenting event in patients with an undiagnosed plasma cell dyscrasia. Because FLC may not be detected on dipstick analysis, urinalysis in cast nephropathy will often show no or trace protein, and the urinary sediment is typically bland. Assay of serum FLC levels is critical in assisting in the differential diagnosis of unexplained AKI: levels above 500 mg/L strongly support a diagnosis of cast nephropathy. However, cast nephropathy may still occur when the monoclonal FLC level is below 500 mg/l if the FLC is particularly nephrotoxic, and kidney biopsy may be needed to diagnose cast nephropathy. In a study querying a renal biopsy database, a low urinary albumin excretion (<10%) assessed with 24-h urine electrophoresis was found

useful in distinguishing cast nephropathy from ATN and less acute causes of kidney injury in multiple myeloma (e.g., amyloid light-chain [AL] amyloidosis and monoclonal immunoglobulin deposition disease).[40]

Contrast-Induced Nephropathy

Contrast-induced nephropathy, defined as AKI occurring shortly after exposure to intravenous radiocontrast, is a common cause of AKI. However the incidence of CIN is low (<1%) in patients with normal renal function and no other risk factors for AKI.[21] Risk factors for CIN include CKD, diabetic nephropathy, advanced heart failure, states of reduced renal perfusion, high total dose of contrast, and concomitant exposure to other nephrotoxins. Data from animal models suggest that both renal vasoconstriction from direct effects of the contrast media and toxic injury of tubular cells are the main factors in the pathophysiology of CIN.[41] The kidney injury likely occurs within minutes of contrast exposure; however, the detection of AKI is typically delayed by 24 to 48 hours after contrast exposure. The timing of AKI in relation to contrast exposure and the exclusion of other causes of AKI generally suffice for diagnosis. Urinalysis and urine sediment findings are typically consistent with ATN. Renal biopsy is generally not helpful in the setting of CIN because the expected findings of ATN are nonspecific, no CIN-specific treatment exists, and the renal injury is typically short lived.

ACKNOWLEDGMENT

The authors gratefully acknowledge Li Yang, MD, and Joseph V. Bonventre, MD, for their contributions to the previous edition, from which this present version was updated.

CHAPTER 72

Epidemiology and Prognostic Impact of Acute Kidney Injury

Neesh Pannu and Marcello Tonelli

Over the last decade, there has been a paradigm shift in our understanding of acute kidney injury (AKI). Although the condition was initially described and defined as a complete loss of kidney function, it is now widely recognized that lesser degrees of kidney injury have important implications for health. AKI represents a heterogeneous clinical syndrome with multiple causes rather than a specific disease. However, whether occurring in isolation or in critically ill patients with multiple organ failure, AKI (as defined by small, often reversible changes in kidney function) is consistently associated with an increased risk of adverse outcomes.[1] This chapter reviews the incidence, risk factors, and outcomes associated with AKI as well as recent evidence linking AKI to the development of chronic kidney disease (CKD).

INCIDENCE OF ACUTE KIDNEY INJURY

The incidence of AKI in unselected hospitalized patients has been estimated to be 0.4% to 18% depending on the definitions used, and AKI accounts for 1% to 4% of all hospital admissions. Several large U.S. studies suggest that the incidence of AKI in hospitalized patients has increased dramatically over the last several decades; one study suggested that the number of hospitalizations of patients with a diagnosis of acute renal failure (ARF; defined by *International Classification of Diseases,* Ninth Edition [ICD-9] codes) increased from 35,000 in 1979 to 650,000 in 2002—an increase of 13% per year.[2] Available studies are based on ICD-9 diagnostic codes, which are highly specific for AKI (defined as a 100% increase in serum creatinine) but are relatively insensitive, especially for milder forms of AKI. Thus the reported incidence of AKI in these studies is likely a gross underestimate of the true incidence. Also pointing to an increased burden of AKI in the general population are the observed 10% annual increase in acute dialysis episodes in the United States between 2000 and 2009 and the twofold increase in the number of deaths attributable to AKI over a similar period (Fig. 72-1).[3] The reasons underlying the increased incidence of AKI have not been determined but are likely related to increasing patient age and a higher burden of comorbidity, including a higher prevalence of CKD. Although these studies showed a decrease in attributable mortality over time, AKI survivors had prolonged hospital length of stay and a greater requirement for posthospitalization care,[4] therefore incurring significantly increased health care costs.[5]

The incidence of AKI as determined by use of consensus definitions based on serum creatinine (S_{Cr}) and urine output has been best characterized in critically ill populations in which laboratory and urine output data are frequently measured. Despite the use of common definitions for AKI in these populations, multicenter studies have reported the incidence of AKI to be 10% to 67%, likely reflecting case mix differences among health care systems and countries.

CAUSES OF ACUTE KIDNEY INJURY

The causes of AKI in hospitalized patients have not been well characterized. However, several smaller studies have reported acute tubular necrosis (nephrotoxic and ischemic) and prerenal causes to account for the majority of patients (see also Chapter 69).[6] Other potentially modifiable causes of AKI include more widespread use of radiocontrast and other nephrotoxic medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, diuretics, and chemotherapeutic agents. Exposure to potentially nephrotoxic medications is particularly common in patients with CKD, which further suggests that AKI could have increasingly important effects on the incidence of CKD.

RISK FACTORS FOR ACUTE KIDNEY INJURY

Risk factors for AKI have been determined in a variety of clinical settings, including cardiac surgery, contrast-induced AKI, and critically ill populations; however, risk prediction models that accurately predict the occurrence of AKI have been elusive. Diabetes and volume depletion as a result of drugs, gastrointestinal losses, and intercurrent illnesses are well described risk factors for AKI. Nonmodifiable risk factors common to all populations are presented in Box 72-1. Recent observational studies have more accurately quantified the risk associated with some of these factors.

Age

The incidence of AKI is highest in people aged 65 and older, and an independent association exists between AKI and older age (Fig. 72-2).[2,3] In a community-based prospective study, the very elderly (aged 80 to 89) were 55 times more likely to develop AKI than adults younger than the age of 50.[7] The association between age and AKI is found in studies that use administrative data (ICD-9 codes) to define AKI, and also in large databases in which inpatient and outpatient S_{Cr} values are used to define AKI. There are several possible reasons for this association: (1) structural and functional changes associated with age that lead to diminished nephron reserve and reduced renal capacity for autoregulation; (2) accumulation of comorbidities (e.g., vascular disease, diabetes, hypertension, CKD), which increases susceptibility to AKI; and (3) increased exposure among the elderly to medications (ACE inhibitors, NSAIDs,

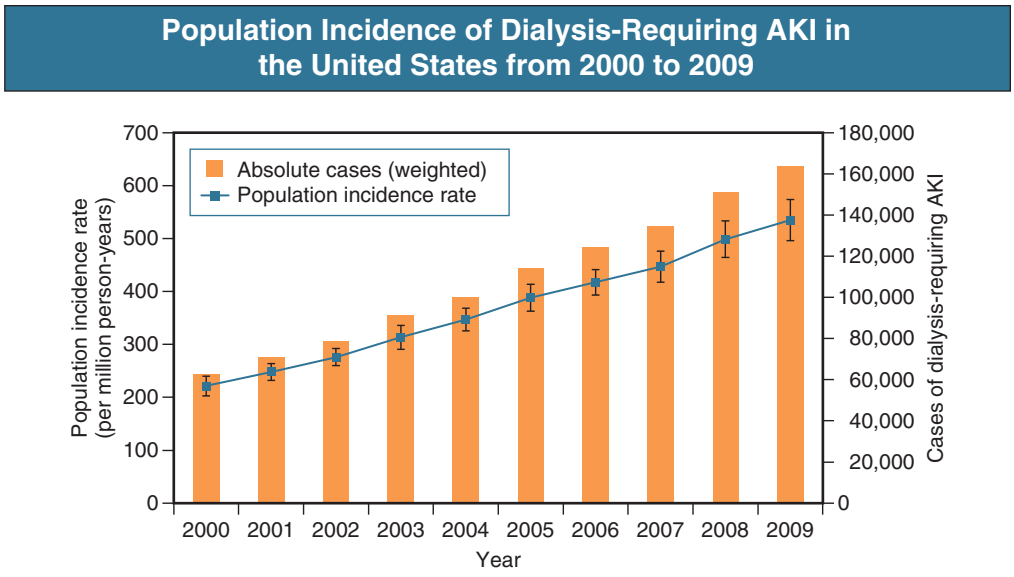

Figure 72-1 Population incidence of patients with AKI who require dialysis in the United States from 2000 to 2009 (absolute count and incidence rate per million person-years). Whiskers represent 95% confidence interval (CI) for incidence rates. The number of cases of AKI in which patients required dialysis increased from 63,000 in 2000 to almost 164,000 in 2009; the population incidence increased at 10% per year from 222 to 533 cases per million person-years. *(From reference 3.)*

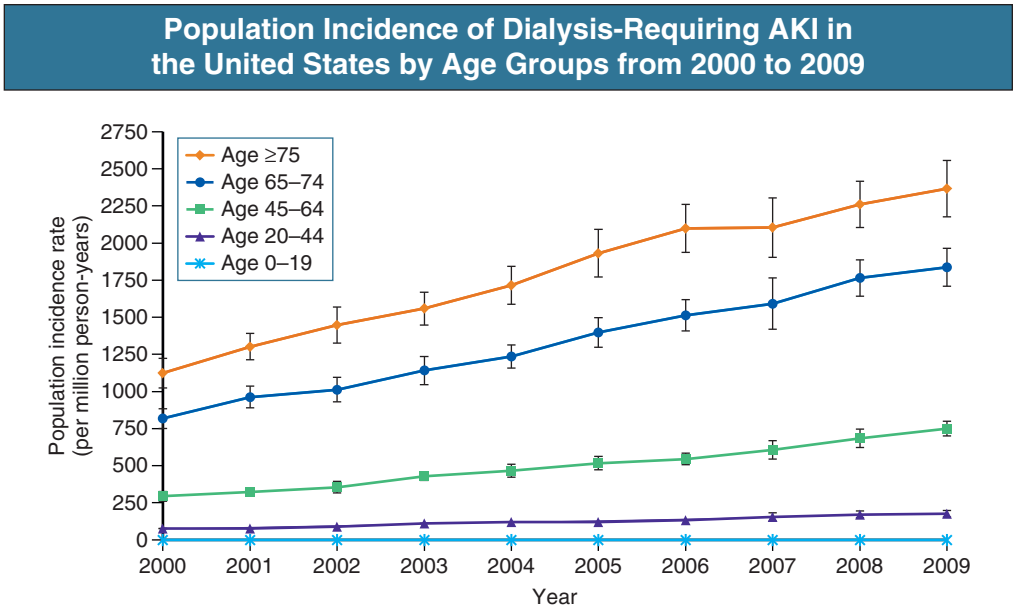

Figure 72-2 Population incidence of acute kidney injury (AKI) patients requiring dialysis in the United States by age group from 2000 to 2009. Whiskers represent 95% confidence interval (CI) for incidence rates. All age groups showed a similar pattern of increase in incidence. *(From reference 3.)*

Patient-Specific Risk Factors for Acute Kidney Injury (AKI)

Age	Congestive heart failure
Gender (male)	Sepsis
Chronic kidney disease	Volume depletion
Proteinuria	Chronic liver disease
Diabetes	Hyperuricemia

Box 72-1 Patient-specific risk factors for AKI.

diuretics) and procedures (surgery, diagnostic testing with radiocontrast) that are associated with the development of AKI.[8]

Chronic Kidney Disease

Chronic kidney disease appears to be among the most potent risk factors for AKI after exposure to radiocontrast, major surgery, and other medical conditions. A U.S. study demonstrated a direct relationship between underlying CKD stage and AKI in which renal replacement therapy (RRT) was required,[9] whereby even patients with mild underlying CKD (estimated glomerular filtration rate [eGFR] 45 to 60 ml/min/1.73 m^2) had a twofold increased risk of dialysis requirement. Patients with more severe CKD (eGFR below 30 ml/min/1.73 m^2) had a 30- to 40-fold higher risk of developing AKI. It is interesting to note that patients with CKD have been reported to have a lower absolute in-hospital mortality as compared with patients without CKD who develop AKI (see later).

Proteinuria

A case-control study of more than 600,000 patients that evaluated the association between CKD and AKI patients identified proteinuria as an independent predictor for AKI.[9] These findings have since been confirmed in a number of clinical settings. A cohort study of 1235 adults undergoing coronary artery bypass graft in Taiwan demonstrated that mild and heavy degrees of proteinuria detected by

dipstick were associated with an increasingly higher odds ratio of postoperative AKI, independent of CKD stage.[10] A U.S. study of more than 11,000 patients determined that elevated urine albumin-creatinine ratio (UACR) was an independent risk factor for hospitalizations with AKI; after stratification by albuminuria the adjusted relative hazards of AKI were 1.9, 2.2, and 4.8, for albumin creatinine ratios of <30 mg/g, 3-299 mg/g, and >300 mg/g, respectively, relative to patients without proteinuria.[11] A large population-based retrospective cohort of more than 900 000 adults in Canada found the same magnitude of association and demonstrated increased rates of hospital admissions with AKI for patients with mild and moderate dipstick proteinuria across all values of eGFR (Fig. 72-3).[12]

ASSOCIATIONS BETWEEN ACUTE KIDNEY INJURY AND ADVERSE OUTCOMES

Acute kidney injury is associated with high costs and adverse clinical outcomes, including excess mortality, increased length of hospital stay, the development and/or progression of CKD, and the requirement for chronic dialysis in survivors. In its most severe form (requirement for acute dialysis), AKI is associated with mortality ranging from 15% in patients with isolated AKI to as high as to 80% in critically ill patients.

MORTALITY

Mortality is increased among patients who experience AKI during hospitalization.[1] However, the comparison of patients with AKI to those without AKI does not distinguish between the increased risk for death caused by AKI and the increased risk imparted by the severity of illness that causes AKI. Nonetheless, the development of AKI is an important marker of prognosis.

A meta-analysis of studies of hospitalized patients confirms a graded relationship between increasing severity of AKI and short-term mortality. Most important, even mild forms of AKI were shown to be clinically relevant; an increase in serum creatinine of 26 µmol/l

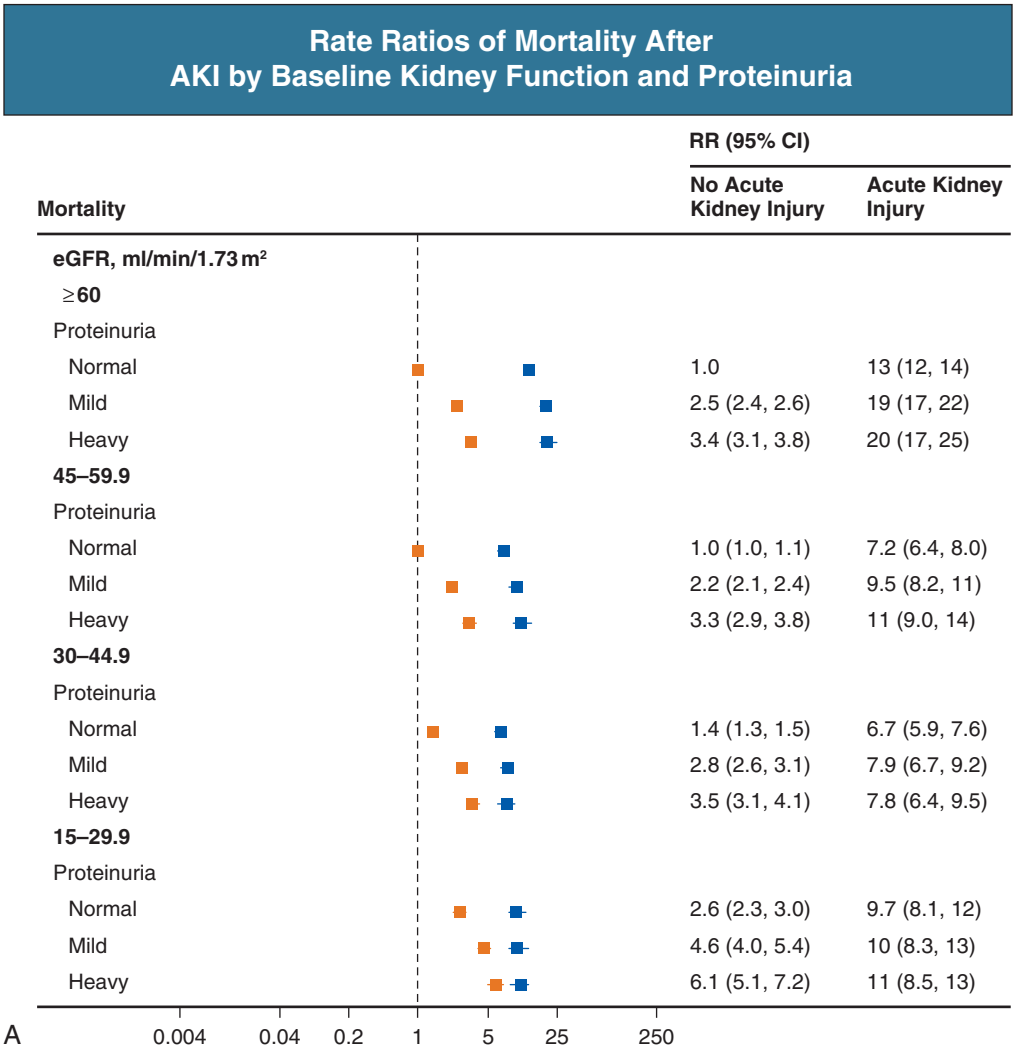

Figure 72-3 Rate ratios of mortality (A) and the composite outcome of end-stage renal disease or doubling of serum creatinine (B) after acute kidney injury (AKI) by baseline kidney function and proteinuria. *Blue squares* and *horizontal bars* represent point estimates and 95% confidence intervals (CIs), respectively, for rate ratios of participants who had AKI for various values of eGFR and proteinuria. The *orange squares* and *horizontal bars* similarly represent the point estimates and 95% CIs for participants who did not have acute kidney injury. The referent group for all rate ratios was participants who did not have AKI and had normal proteinuria and eGFR of 60 ml/min/1.73 m^2 or greater. *eGFR,* Estimated glomerular filtration rate; *ESRD,* end-stage renal disease; S_{Cr}, serum creatinine; *RR,* rate ratio. *(From reference 12.)*

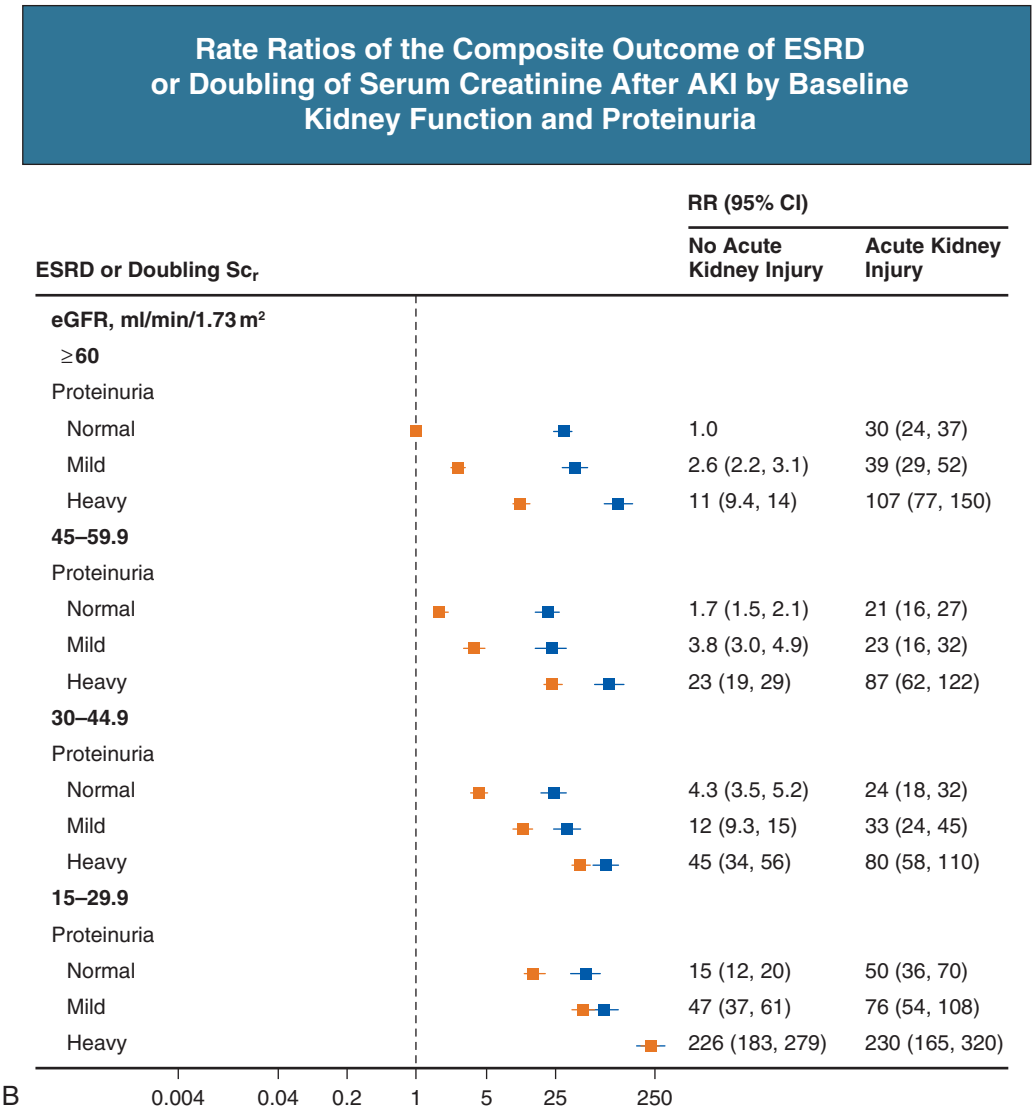

Figure 72-3, cont'd

(0.3 mg/dl) was associated with a short-term relative risk for death of 2.3 (95% confidence interval [CI] 1.8-3.0). In the studies that adjusted risks for comorbidities, the odds or hazards ratios for death ranged from 1.7 to 1.9, all of which were statistically significant. Similar findings were reported in a recent meta-analysis evaluating the RIFLE criteria for AKI. Whereas these studies have focused on critically ill patients or on specific patient populations (congestive heart failure [CHF] patients, patients who have undergone cardiac surgery) in which AKI may simply be a reflection of the burden of morbidity, several population-based studies of hospitalized patients confirm these mortality associations.

Recent findings suggest that the association between AKI and mortality is likely influenced by several factors including the presence of underlying CKD, the duration and severity of AKI, and the degree of recovery of kidney function. In a population-based cohort of CKD patients after hospitalization with an AKI episode, a graded relationship was observed between the risk of in-hospital death and prehospitalization eGFR; mortality was lowest in patients who had stage 5 CKD at baseline.[13] A population-based cohort study of hospitalized AKI patients in Canada found that the relation between AKI and in-hospital mortality was strongest in hospitalized patients with severe AKI and a baseline eGFR exceeding 60 mL/min/1.73 m^2 (adjusted hazard ratio [HR] 10.6, 95% CI 8.8-12.8).[14] By comparison, in patients with a baseline eGFR below 30 ml/min/1.73 m^2, the adjusted HR of in-hospital mortality in patients with the most severe AKI was 4.7 (95% CI 3.6-6.2).

Although the incidence of AKI continues to increase over time, there has been a corresponding improvement in survival. A recent analysis of AKI incidence and associated outcomes in a nationally representative dataset in the United States revealed a 19% decrease in mortality between 2000 and 2009 in patients who required acute dialysis. Although the observed increased incidence of AKI and the improved survival could both be explained by increased use of diagnostic codes for milder forms of AKI (code creep) and a trend toward earlier and more aggressive use of dialysis, similar improvements in survival have been reported in other cohorts in which alternative definitions of AKI were used.

Chronic Kidney Disease

Until recently it was accepted that whereas severe AKI was associated with a high mortality rate, survivors generally recovered renal function and were independent from dialysis. This assumption was supported by the findings of small cohort studies of critically ill patients.

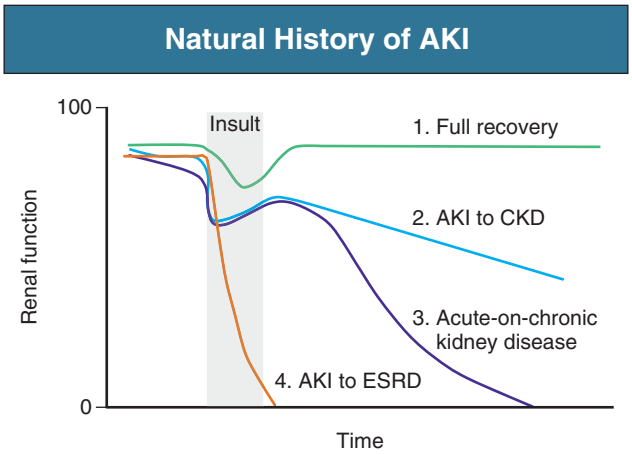

Figure 72-4 Natural history of acute kidney injury (AKI). Patients who develop AKI may experience (1) complete recovery of renal function, (2) development of progressive chronic kidney disease (CKD), (3) exacerbation of the rate of progression of preexisting CKD, or (4) irreversible loss of kidney function and evolution to end-stage renal disease (ESRD). *(From reference 21.)*

However, others have reported lower rates of renal recovery, particularly in patients with underlying CKD, and it is likely that the trajectory of kidney function in AKI survivors is variable depending on underlying kidney disease and AKI severity (Fig. 72-4).[15]

Recent studies have linked AKI survivorship to the development of CKD or end-stage renal disease (ESRD). A large U.S. cohort found that AKI was associated with an eightfold increased risk of ESRD as compared with patients without AKI or CKD.[16] A similar Canadian study compared the incidence of ESRD in patients who required dialysis for AKI but were independent of dialysis within 30 days of discharge, and a group of matched controls without AKI. There was a threefold increase in the risk of ESRD, with a population incidence of 26.3 per 1000 person-years in AKI survivors. Another U.S. study evaluated the risk of progressive CKD after AKI in patients with a baseline eGFR exceeding 45 ml/min/1.73 m^2.[17] Survivors of hospitalization who required dialysis for an episode of AKI but were dialysis independent at least 30 days after discharge had a 28-fold increased risk of subsequently developing CKD stage 4 or worse.

Since then, a meta-analysis of 13 cohort studies reported that the pooled incidences of CKD and ESRD after AKI were 25.8 and 8.6 per 100 person-years, respectively.[18] Pooled adjusted hazard ratios for CKD and ESRD were 8.8 (95% CI 3.1-25.5) and 3.1 (95% CI 1.9-5.0) compared with patients without AKI. In older adults the risk for ESRD after a single episode of AKI is elevated 2-fold to 13-fold depending on the severity of AKI. The annual absolute risk for developing ESRD after an episode of AKI ranges from 0.6% to 1.2% in those who experience mild AKI and up to 9% in those with preexisting CKD.[12]

The association between AKI and CKD could be confounded by age, frailty, and unmeasured comorbidity; however, AKI has also been linked to the development of CKD in children, who are generally free of these confounders. A study of 126 critically ill pediatric AKI survivors who fully recovered kidney function revealed that 10% of patients developed CKD (albumin-creatinine ratio at or above 30 mg/g or eGFR below 60 ml/min/1.73 m^2) over 3 years of follow-up.[19] It is important to note that 38% of the cohort had mildly decreased eGFR (60 to 90 ml/min) and 3.2% had hypertension—both risk factors for future CKD. Given its short-term follow-up, this study likely underestimates the long-term risk of CKD and its associated morbidity.

Health Care Costs

Most studies describing the costs associated with AKI are from the United States. A U.S. study of AKI in hospitalized patients demonstrated a direct relationship between severity of AKI and associated hospital length of stay and hospital costs.[1] AKI defined as a 0.3-mg/dl (26-µmol/l) increase in serum creatinine was associated with an incremental total hospitalization cost of $4886; a doubling of serum creatinine was associated with an incremental cost of $9000. Studies of specific populations of hospitalized patients support these findings; the average excess costs associated with AKI after cardiac surgery ranges from $9000 to $14,000 depending on AKI severity. In multivariable analysis, AKI was the single most costly postoperative complication for these patients and resulted in the largest proportion of resource use compared with all other complications. Another study of 5875 surgical patients found that severe AKI necessitating dialysis was the second most costly postoperative complication, with an estimated mean increase in hospital expenditures of $28,359 compared with an uncomplicated postoperative course, and resulted in almost twice the excess cost compared with a cardiac arrest. However, none of these studies accounted for the impact of CKD on AKI and attendant costs, which is likely to be substantial.

ACUTE KIDNEY INJURY AS A PUBLIC HEALTH ISSUE

Conservative population-based estimates of AKI incidence in hospitalized adults are in the range of 3000 per 100,000 person-years.[20] The majority of these patients will survive hospital discharge. The incidence of stage 4 CKD (eGFR below 30 ml/min/1.73 m^2) or greater in AKI survivors is approximately 120 per 100,000 person-years.[21] The number of adult Americans developing new CKD after AKI may be as high as 100,000 per year. Given adverse outcomes with progressive CKD, as well as the morbidity, mortality, and cost associated with ESRD, strategies that mitigate the progression of CKD after AKI should be a public health priority.

CHAPTER 73

Prevention and Nondialytic Management of Acute Kidney Injury

Etienne Macedo, Josée Bouchard, and Ravindra L. Mehta

Acute kidney injury (AKI) acquired in the hospital is often a result of a combination of insults. The most commonly associated causes are failure of renal autoregulation, direct nephrotoxicity, ischemia-reperfusion, and inflammatory states. AKI severity predicts adverse outcomes, such as requirement for renal replacement therapy (RRT), length of hospital stay, and mortality. In addition, the widespread use of the RIFLE and Acute Kidney Injury Network (AKIN) classification systems (see Chapter 71) has shown that even small changes in creatinine levels are associated with short- and long-term increased mortality.[1-6] Furthermore, the distant effects of AKI contribute to dysfunction of other organs, such as the heart, lung, brain, and liver. Consequently, primary prevention and early diagnosis of AKI are of central clinical importance. Once a decline in glomerular filtration rate (GFR) has been detected, secondary prevention to attenuate the effects of injury and treatment of the consequences of injury are necessary.

RISK ASSESSMENT

Considering the conceptual model of AKI illustrated in Figure 73-1, the first step in preventing AKI is an adequate risk assessment. The initial care of patients at risk should be focused on identification and, if possible, reversal of the risk factors. Determination of baseline kidney function is fundamental for assessing the risk of AKI in hospitalized patients. However, baseline creatinine is not available for most patients, and the first creatinine measured in the hospital is likely to be affected by the disease process that occurred before hospital admission. This problem reflects the need for more sensitive and specific biomarkers of cellular damage to enable early risk assessment and limit the extent of renal injury. Tables 73-1 and 73-2 summarize risk factors for AKI in different clinical settings. For a further discussion of risk factors and scoring systems, see Chapters 69 and 71.

PRIMARY PREVENTIVE MEASURES

Optimizing Volume Status and Hemodynamic Status

Regardless of the nature of an insult, hemodynamic stabilization, with optimization of the cardiac output and blood pressure (BP), is a key factor in preventing AKI. The general aims are to optimize volume status based on physiologic measurements, to maintain adequate hemodynamic status and cardiac output to ensure renal perfusion, and to avoid further insults. In the injured kidney, autoregulation of blood flow, the mechanism responsible for maintaining a constant flow during fluctuations in BP, is lost. This loss increases the susceptibility to develop AKI after episodes of hypotension. Therefore, fluid and vasoactive drug management is an important intervention for patients in the initiation or extension phase of AKI. Volume expansion can decrease the risk of AKI in the perioperative period after major vascular surgeries, renal transplantation, and procedures to correct obstructive jaundice. In these clinical scenarios, fluid volume administration is most beneficial at the initiation phase. However, once the injury is initiated and the extension phase starts, the impact of volume expansion with intravenous fluids on clinical outcomes has not been well described and needs to be balanced with the unwanted consequence of fluid accumulation and overload.

Assessment of the volume status is challenging, particularly in patients in the intensive care unit (ICU).[7] In most patients the effect of fluid expansion on hemodynamic status and renal function is retrospective and frequently evaluated by trial and error. In patients in the pre-renal phase of AKI, fluid expansion can increase organ perfusion and improve renal function. In other circumstances, as in patients with severe congestive heart failure (CHF) or diastolic dysfunction, renal perfusion is inadequate despite normal volume status or volume overload. In these patients, fluid expansion can lead to worsening of cardiac function and pulmonary edema.

There are no specific guidelines for optimizing hemodynamic and fluid status for renal function preservation, but extrapolation of data from clinical settings associated with AKI can be instructive. International guidelines for sepsis management have been recently revised by the Surviving Sepsis Campaign. The recommendations include initial fluid resuscitation with crystalloids for a minimum of 30 ml/kg and adding albumin in patients who continue to require substantial amounts of crystalloid to maintain adequate mean arterial pressure (MAP).[8] Fluid challenge should be continued as long as there is hemodynamic improvement, based on dynamic or static variables. Vasopressors should be initiated to maintain MAP above 65 mm Hg, and norepinephrine is the first-choice vasopressor. With regard to the kidney, there is currently no evidence that norepinephrine has a different effect on kidney function and need for RRT than vasopressin in septic patients. Inotropic agents such as dobutamine should be administered if myocardial dysfunction or ongoing signs of hypoperfusion are present.[8] Late and prolonged aggressive fluid resuscitation in critically ill patients has also been associated with worse kidney outcomes and increased mortality. Therefore fluid expansion should be stopped when patients are no longer fluid responsive—not only patients with sepsis, but all patients. Data from the Fluid and Catheter Treatment Trial (FACTT) trial indicate that after initial resuscitation, a conservative approach to fluid administration is associated with faster weaning from mechanical ventilation and decreased length of ICU stay without any deterioration of kidney function or worse kidney outcomes in patients with acute lung injury.[9] The Vasopressin and Septic Shock Trial (VASST) study compared the effects of vasopressin (0.01 to 0.03 U/min) to norepinephrine (5 to 15 μg/min) infusion on mortality rates in patients with

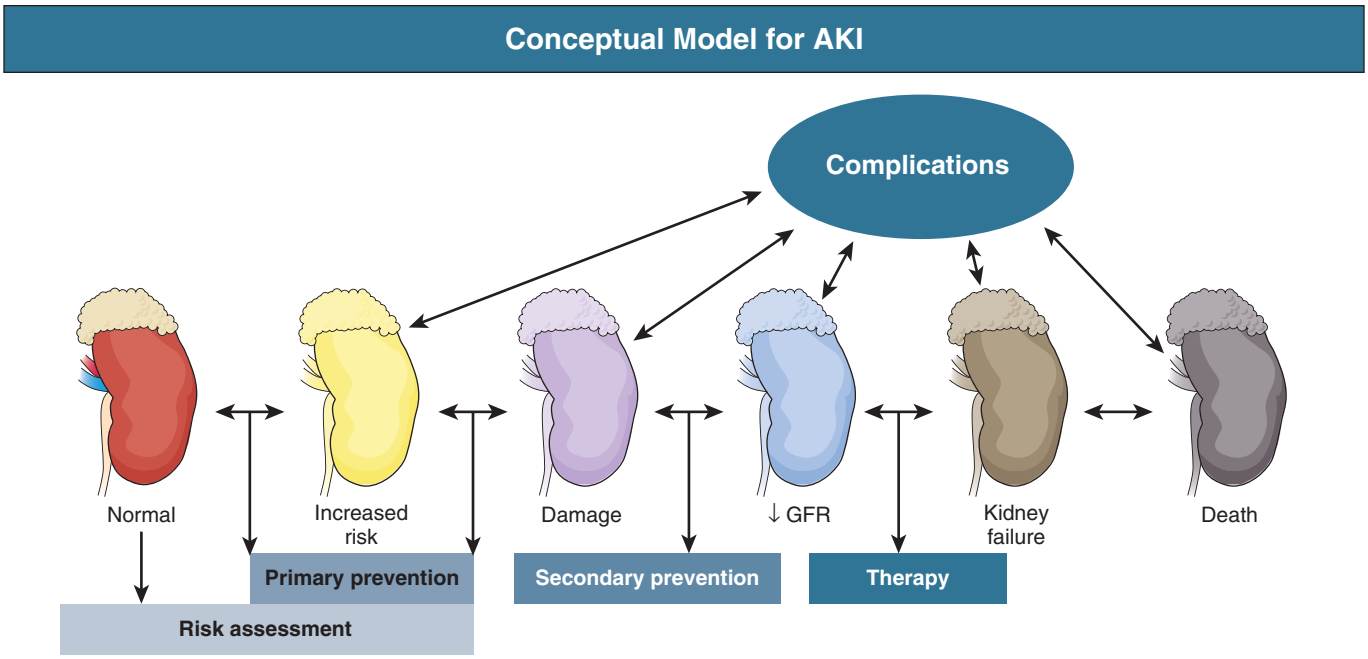

Figure 73-1 Conceptual model for acute kidney injury (AKI). *GFR,* Glomerular filtration rate. *(Modified from reference 7.)*

Major Risk Factors for Acute Kidney Injury (AKI)

Patient Factors	Medications and Agents	Procedures
Older age (>75 years) Diabetes Hepatic failure Chronic kidney disease Atherosclerosis Renal artery stenosis Hypertension Hypotension Hypercalcemia Sepsis Perioperative cardiac dysfunction Rhabdomyolysis Tumor lysis syndrome	Nonsteroidal anti-inflammatory drugs Cyclooxygenase-2 inhibitors Cyclosporine or tacrolimus Angiotensin-converting enzyme inhibitors Angiotensin receptor blockers Iodinated contrast agents Hydroxyethyl starch (HES) Aminoglycosides Amphotericin	Cardiopulmonary bypass procedures Surgery involving aortic clamp Increased intra-abdominal pressure Large arterial catheter placement with risk for atheroembolization Liver transplantation Kidney transplantation

Table 73-1 Major risk factors for AKI.

septic shock and did not show any differences between groups.[10] A secondary analysis from this study found that survival is optimal with a positive fluid balance of approximately 3 liters within 12 hours.[11] In conclusion, a liberal fluid approach as part of early goal-directed therapy appears to be beneficial during the first hours of shock, and a conservative approach should be followed after resolution of shock. Whether these same principles apply for patients with AKI in the absence of shock is unknown. The potential risks of fluid accumulation and overload in the setting of AKI need to be considered.[12]

There is controversy about the optimal fluid to use for resuscitation. The recent KDIGO AKI guidelines suggest that isotonic crystalloids should be used instead of synthetic (hydroxyethyl starch [HES]) and nonsynthetic colloids (albumin) for intracellular volume expansion in patients at risk or presenting with AKI, in the absence of hemorrhagic shock.[13] For albumin, the Saline Versus Albumin Fluid Evaluation (SAFE) trial of 6997 patients found that fluid resuscitation with saline or albumin resulted in similar relative risks of death in critically ill patients.[14] There were also no significant differences in the proportion of patients with new single-organ and multiple-organ failure or days on RRT. Two subgroup analyses from the same study showed that use of albumin may be deleterious in patients with traumatic brain injury[15] and potentially beneficial in sepsis.[16] In the past, HES preparations were commonly used as nonprotein intravascular volume expanders. In addition to their efficiency in fluid management, they also have anti-inflammatory properties and reduced cost compared with albumin. However, they potentially alter coagulation and platelet function, as well as increasing the risk for AKI. The mechanism of HES-induced kidney injury may be associated with proximal renal epithelial cell uptake of HES causing an acquired lysosomal storage disease. This dose-dependent phenomenon is more pronounced in patients with impaired renal function, potentially resulting in a diffuse tissue storage and acculation of foamy-appearing macrophages.[17] An experimental study with an isolated perfusion model of 10% HES 200/0.5 and 6% HES 130/0.42 compared with Ringer lactate proposed that renal interstitial proliferation, macrophage infiltration, and tubular damage are other potential pathologic mechanisms of HES-induced kidney injury.[18] HES solutions are identified by three numbers, indicating the concentration of the solution, the mean molecular weight, and—the most significant one—the molar substitution (e.g., 10% HES 200/0.5 or 6% HES 130/0.4). In the past, 6% HES 130/0.4 solutions were considered safer than 10% HES 200/0.5 solutions. A recent large multicenter randomized study, including 804 patients with severe sepsis, has shown that even 6% HES 130/0.4 is detrimental to kidney function and survival compared with Ringer acetate.[19] Another larger trial in 7000 ICU patients has shown that 6% HES 130/0.4 increased need for RRT but not mortality compared with 0.9% sodium chloride (saline).[20] Therefore, HES should be avoided in patients at risk for and with AKI. The use of albumin may be considered when patients require

Specific Risk Factors for the Development of Acute Kidney Injury (AKI) in Common Clinical Situations		
Postoperative (General)		
Miscellaneous	**Hemodynamic**	**Gastrointestinal and Endocrine**
Age <70 yr	Congestive heart failure	Cirrhosis/biliary surgery
Proteinuria	Aortic cross-clamping	Obstructive jaundice
Hyperglycemia	Cardiac instability	Diabetes mellitus
Hypertension	Major vascular surgery	
Massive blood transfusion	Infection/sepsis	
	Multiorgan failure	
Cardiac Surgery		
Female gender	ACE inhibitor therapy	Emergency surgery
COPD	Heart failure	Valve surgery only
Proteinuria	LV ejection fraction <35%	Previous cardiac surgery
Preoperative S_{Cr} >2.1 mg/dl	Preoperative IABP	Other cardiac surgery
Anemia	Hyperglycemia	Combination of CABG + valve surgery
Insulin-requiring diabetes		Blood transfusion
Critically Ill	**Sepsis**	
High A-a gradient*	Age	
Low serum albumin	S_{Cr} >1.3 mg/dl	
Proteinuria	Serum bilirubin >1.5 mg/dl	
Hyperglycemia	Elevated CVP >8 cm	
High intraabdominal pressure	Hemodynamic instability	
Active cancer		
Contrast Nephropathy		
Age >75 yr	Volume of contrast >100 ml	
Heart failure	Intra-arterial injection	
Diabetes mellitus	Systolic BP <80 mm Hg for >1 hr and need for inotropic support or IABP 24 hr after procedure	
S_{Cr} > 1.5 mg/dl or eGFR <60 ml/min/1.73 m^2	Use of IABP	
History of pulmonary edema		
Anemia/blood loss (Hct: <39% for men; <36% for women)		
Nephrotoxic antibiotics		
Aminoglycosides	**Amphotericin**	
Old age	Volume depletion	
Pre-existing renal dysfunction	Concurrent other nephropathy	
Duration of therapy >7 days		
Volume depletion		
Divided dose regimens		
Liver disease		

Table 73-2 Specific risk factors for the development of AKI in common clinical situations. *CABG,* Coronary arterial bypass graft; *COPD;* chronic obstructive pulmonary disease; *CVP,* central venous pressure; *Hct,* hematocrit; *IABP:* intra-aortic balloon pump. *A-a gradient, alveolar-arterial oxygen gradient calculated with the sea level standard formula (713 × Fio_2) – (Pco_2/0.8) – Pao_2, where Fio_2 is fractional inspired oxygen concentration, Pao_2 is arterial partial oxygen pressure, and Pco_2 is partial carbon dioxide pressure. *(Modified from reference 77.)*

substantial amounts of crystalloid to maintain adequate MAP, and its effect must be balanced against its potential risks (possibly deleterious in patients with trauma and low potential for transmitting infectious diseases).

Some animal studies have suggested that hyperchloremia resulting from 0.9% saline infusion may affect renal hemodynamics. In healthy male adults, a double-blind crossover study compared renal artery flow velocity and renal cortical tissue perfusion after a 2-liter intravenous infusion of 0.9% saline (chloride: 154 mmol/l) and a balanced buffered solution with a chloride concentration of 98 mmol/l. They showed a significant reduction in mean renal artery flow and renal cortical tissue perfusion with saline but not with the use of chloride-restrictive fluids.[21] A recent retrospective study showed that chloride-restrictive fluids (lactated solution with

balanced buffer–chloride concentration of 98 mmol/l or chloride-poor 20% albumin–chloride concentration of 19 mmol/l) compared with chloride-rich intravenous fluids (0.9% saline, 4% succinylated gelatin solution, or 4% albumin solution) were associated with a significant decrease in AKI incidence and RRT requirement.[22] These results will need to be confirmed with other studies.

Prevention of Contrast-Induced Acute Kidney Injury

The Prevention of Contrast-Induced Acute Kidney Injury (CI-AKI) Consensus Working Panel recommends that measures to reduce the AKI risk should be implemented in patients with a baseline estimated glomerular filtration rate (eGFR) below 60 ml/min/1.73 m^2. According to the KDIGO guidelines, this threshold could probably be lowered to 45 ml/min/1.73 m^2. For prevention of CI-AKI, patients at risk should receive intravenous hydration (Fig. 73-2). Hydration with isotonic saline started the morning of the procedure or immediately before in cases of emergency interventions is superior to half-isotonic (0.45%) saline.[23] A randomized controlled trial (RCT) compared isotonic saline with isotonic sodium bicarbonate (three 50-ml ampules of 1 mmol/ml sodium bicarbonate added to 850 ml of 5% dextrose) at 3 ml/kg/h for 1 hour before the procedure followed by 1 ml/kg/h for the 6 hours after the procedure. CI-AKI was significantly lower in the bicarbonate compared with the saline group (2% vs. 14%).[24] The rationale for isotonic bicarbonate is based on animal studies showing that bicarbonate is capable of scavenging reactive oxygen species, and the increased pH in the proximal tubule and the renal medulla associated with bicarbonate administration could reduce generation of superoxide. In addition, isotonic saline contains high amounts of chloride, with a potential renal vasoconstrictor effect. Considering that most hydration studies with isotonic bicarbonate use shorter infusion protocols (7 hours) than those with isotonic saline (usually 12 to 24 hours), hydration with bicarbonate is also an attractive alternative for emergency procedures. The superiority of bicarbonate was observed in some but not all further RCTs. The KDIGO AKI guidelines recommend either isotonic sodium chloride or sodium bicarbonate solutions in patients at risk for CI-AKI unless there are contraindications to volume expansion.[13] The Prevention of Serious Adverse Events Following Angiography (PRESERVE) study is an ongoing RCT (NCT01467466) with a 2×2 factorial design aiming to compare the effectiveness of sodium bicarbonate with isotonic sodium chloride and oral *N*-acetylcysteine (NAC) with placebo in 8680 high-risk patients scheduled to undergo coronary or noncoronary angiography. The study should be completed in 2016. The use of NAC is discussed later in this chapter.

Iodinated contrast medium can be categorized according to osmolality into high-osmolar contrast medium (approximately 2000 mOsm/kg), low-osmolar contrast medium (600 to 800 mOsm/kg), and iso-osmolar contrast medium (290 mOsm/kg), and clinical studies suggest that the risk of nephrotoxicity increases with increasing osmolarity of the contrast medium. The higher cost of the iso-osmolality agents bars their universal use. The KDIGO AKI guidelines recommend the use of either iso-osmolar or low-osmolar iodinated contrast medium for patients at risk of CI-AKI.

The volume of contrast material administered is also a crucial risk factor and an independent predictor of CI-AKI and should be lowered as much as possible. Based on the volume of contrast given (V) and the creatinine clearance (CrCl), a V/CrCl ratio above 3.7 has been shown to be a significant and independent predictor of CI-AKI

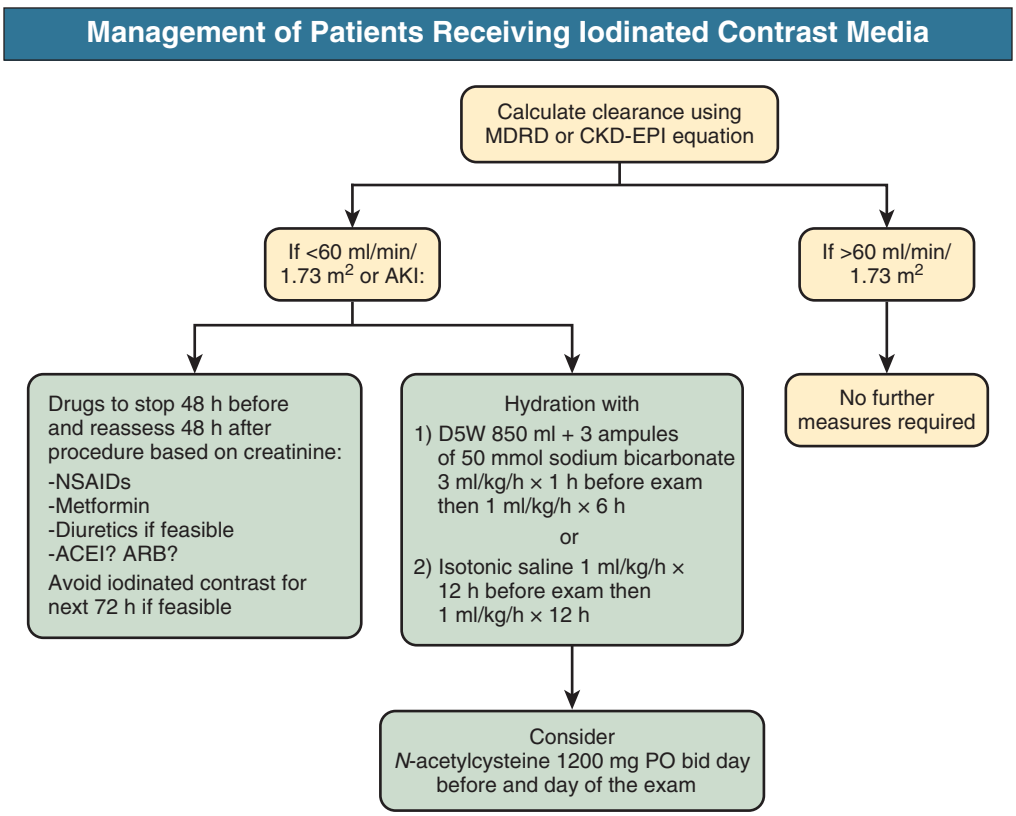

Figure 73-2 Management of patients receiving iodinated contrast media. *ACEI,* Angiotensin-converting enzyme inhibitor; *AKI,* acute kidney injury; *ARB,* angiotensin receptor blocker; *CKD-EPI,* Chronic Kidney Disease Epidemiology Collaboration; *D5W,* 5% dextrose in water; *MDRD,* Modification of Diet in Renal Disease; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

in the general population. Administration of contrast material more than once in a short period is another risk factor, and contrast studies should be postponed at least 48 to 72 hours after the last infusion of contrast medium if possible. The drugs used for CI-AKI prevention are included in the section on pharmacologic approaches.

Prevention of Drug- and Nephrotoxin-Induced Acute Kidney Injury

Drug-induced nephrotoxicity can often be predicted because it is more common in certain patients and in specific clinical situations. Prevention involves the knowledge of mechanisms of renal injury, patient-related risk factors, and drug-related risk factors. The most important patient-related factors associated with higher risk of nephrotoxicity are age older than 60 years, preexisting chronic kidney disease (CKD), volume depletion, diabetes, heart failure, and sepsis. A fundamental step in prevention includes drug monitoring of potential nephrotoxins in at-risk patients. Preventative measures include correctly estimating the GFR before initiation of therapy, adjusting the dosage, and monitoring renal function during therapy. Alternative non-nephrotoxic drugs should be used whenever possible, and nephrotoxic drug combinations should always be avoided if feasible.

Amphotericin

Amphotericin-associated nephrotoxicity can occur in as many as one third of treated patients, and the risk of AKI increases with higher cumulative doses. Lipid formulations cause less nephrotoxicity compared with the standard formulation, and therefore amphotericin deoxycholate is preferred over conventional amphotericin; however, it is significantly more expensive. Recently, alternative antifungal agents such as itraconazole, voriconazole, and caspofungin have been more commonly used in patients at high risk for AKI and should be used rather than conventional amphotericin.

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Nonsteroidal Anti-Inflammatory Drugs

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) cause vasodilation of the efferent glomerular arteriole, further reducing intraglomerular pressure already compromised by the BP-lowering effect of these agents. In patients with renal dysfunction, they can contribute to a reduction in GFR. In patients with an increase in serum creatinine higher than 30% after the initiation of ACE inhibitor and ARB treatment, bilateral renal artery stenosis, stenosis of the renal artery in a solitary kidney, diffuse intrarenal small-vessel disease, or generalized volume depletion should be suspected, and these drugs should be discontinued.

Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used with caution in patients with atherosclerotic cardiovascular diseases (CVDs). NSAIDs should be avoided in CKD and intravascular volume depletion because they inhibit cyclooxygenase, which blocks prostaglandin-induced vasodilation of the afferent arteriole, potentially reducing GFR and renal blood flow. In critically ill patients, renal hypoperfusion caused by decreased effective circulating volume is relatively common, and inhibition of prostaglandin-induced vasodilation may further compromise renal blood flow and exacerbate ischemic injury.

Aminoglycosides

Acute kidney injury caused by aminoglycoside nephrotoxicity usually occurs 5 to 10 days after initiation of the treatment; this type of AKI is typically nonoliguric and associated with decreased urine concentrating ability and urinary magnesium wasting. Because of nephrotoxicity, ototoxicity, and vestibular toxicity, the AKI KDIGO guidelines have recommended avoiding the use of aminoglycosides in patients with AKI and those at risk unless no other alternative is available. With multiple daily administration schedules, elevated aminoglycoside peak levels appear to correlate with nephrotoxicity. Because aminoglycoside uptake by proximal tubular cells is a saturable process, once-daily administration can decrease tubular cell toxicity by reducing drug taken up by proximal tubular cells. In the general population, extended intervals between doses maintains the target dose while decreasing the risk of nephrotoxicity compared with multiple daily doses; therefore, in patients with normal kidney function who are not at risk for AKI, aminoglycosides should be administered daily if needed.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is caused by uric acid and calcium-phosphate precipitation in the tubules. Correct identification of those at high risk is the first step toward preventing AKI in this setting. In patients with high-grade hematologic malignant neoplasms, risk factors for TLS are lactate dehydrogenase levels above 1500 IU, large tumor burden, extensive bone marrow involvement, CKD, and high tumor sensitivity to chemotherapeutic agents. In patients with low or intermediate risk of TLS, a xanthine oxidase inhibitor such as allopurinol can be used as a hypouricemic agent and should be started 2 days before chemotherapy. Aggressive hydration with isotonic saline is initiated 2 days before the chemotherapy to maintain a high urinary output, allowing the elimination of uric acid and phosphate. If urinary output decreases despite adequate fluid intake, a loop diuretic should be added, but RRT will be required if oliguria persists.[25] The use of urine alkalinization to promote elimination of urates is not recommended because it can induce calcium phosphate deposition and therefore aggravate TLS. In addition to the hydration, recombinant urate oxidase can reduce uric acid levels and the risk of uric acid deposition nephropathy.[26] Recombinant urate oxidase should be initiated in high-risk patients or for established TLS when hyperuricemia is severe.

SECONDARY PREVENTION

After the renal insult has occurred, secondary preventive measures should be directed to avoid further injury, to facilitate repair and recovery, and to prevent AKI complications. The timeliness of interventions is crucial to their effectiveness for secondary prevention. Various approaches have been applied but are best appreciated in the context of specific clinical scenarios.

Traumatic and Nontraumatic Rhabdomyolysis

In the prevention of myoglobin-induced nephropathy after crush syndrome, intravenous hydration should be initiated with isotonic saline before the crushed limb is relieved to prevent precipitation of the pigment in the tubular lumen. A solution with 2.7% sodium bicarbonate (50 mmol/l) should be given every second or third liter to maintain urinary pH above 6.5 and to prevent intratubular deposition of myoglobin and uric acid. The urine output should be maintained around 300 ml/h, which may require an infusion of up to 12 liters of fluid per day. The volume administered is generally much greater than the urinary output; the accumulation of fluid in the damaged muscles may exceed 4 liters. This protocol should be continued until clinical or biochemical evidence of myoglobinuria disappears, usually by day 3. It has also been suggested that mannitol

is beneficial because of its diuretic, antioxidant, and vasodilatory properties. Mannitol could prevent renal tubular cast deposition, expand extracellular volume, and reduce intracompartmental pressure, muscle edema, and pain.[15] However, mannitol may exacerbate CHF and nephrotoxicity, requires close monitoring, and is contraindicated in oliguria, hypervolemia, hypertension, and heart failure. Mannitol administration is considered, if urinary flow is sustained above 20 ml/h, given at a rate of 5 g/h added to each liter of infusate and not exceeding 1 to 2 g/kg/day.[27] Muscle damage induces stretch-activated ion channels, allowing for influx of calcium into cells after reperfusion. The resultant hypocalcemia is usually asymptomatic but can lead to cardiac dysrhythmias. Hence, care must be taken to avoid an $NaHCO_3$ (sodium bicarbonate)–induced decrease in ionized calcium (caused by metabolic alkalosis), which can trigger tetany, seizures, and cardiotoxicity and worsen existing muscle damage. During the AKI recovery phase, hypercalcemia is frequent, mainly in patients who received calcium infusion, as a result of the mobilization of previously precipitated calcium in muscles. Thus, hypocalcemia should be treated only if symptomatic. The importance of early fluid administration and the most important aspects of the treatment of crush victims have been recently summarized.[28]

In nontraumatic rhabdomyolysis, prevention of AKI involves vigorous fluid expansion to maintain renal perfusion pressure and to dilute myoglobin and other toxins. A urine output of 200 to 300 ml/h is desirable until myoglobinuria disappears. Urine alkalinization may help prevent tubular pigment cast formation; however, there is no clinical evidence that mannitol and bicarbonate are more effective than saline solution alone. Furthermore, there are potential risks to bicarbonate therapy, including precipitation of calcium phosphate and hypocalcemia.

In treating patients with rhabdomyolysis, it is important to consider when to stop aggressive fluid resuscitation. Although fluid expansion is the main therapeutic intervention to reduce the myoglobin precipitation in the tubular lumen, the risk of fluid accumulation and compartmental expansion should always be part of the clinical judgment. Frequent assessment of renal functional parameters (e.g., every 6 to 12 hours) associated with uric acid and creatine kinase levels help the clinician decide how intense the volume expansion should be.

Hyperglycemia

There have been conflicting results from studies of the effects of strict control of blood glucose concentration in reducing the incidence and mortality of AKI. In the Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study, a large multicenter randomized trial in critically ill patients, intensive glucose control (target blood glucose of 81 to 108 mg/dl [4.5 to 6.0 mmol/l]) increased the absolute risk of death at 90 days compared with conventional glucose control (target blood glucose of <180 mg/dl [<10 mmol/l]).[29] Intensive glucose control also increased the risk for severe hypoglycemia. There was no change in the incidence of AKI or need for RRT. Other studies have not found an increase in mortality with intensive glucose control. In summary, intensive glucose control in critically ill medical and surgical patients increased the incidence of severe hypoglycemia and either increased mortality or had no effect on mortality when compared with the more permissive blood glucose ranges of 140 to 180 mg/dl (7.8 to 10 mmol/l) and 180 to 200 mg/dl (10 to 11 mmol/l). Therefore, in critically ill patients, in concordance with the KDIGO AKI guidelines, we recommend maintaining appropriate control of blood glucose concentration in the range of 110 to 149 mg/dl (6.1 to 8.3 mmol/l) rather than intensive glucose control.

Pharmacologic Approaches

Because of the multiple different causes of AKI, various pathways have been targeted in studies to prevent or alter the course of AKI. These pathways include inhibition of inflammatory mediators, enhancement of renal perfusion by blocking vasoconstrictor mechanisms and intensifying vasodilator mechanisms, attenuation of leukocyte infiltration, inhibition of the coagulation cascade, and administration of growth factors to accelerate renal recovery.[30] Most of these preventive strategies were successful in animal models but did not translate into beneficial effects in patients. Only a few have consistently shown benefits (Table 73-3).

N-Acetylcysteine

N-acetylcysteine is a tripeptide analogous to glutathione and is able to cross cellular membranes. NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material. Because an increased production of free radicals by the kidneys is partly responsible for their cellular damage in postischemic and nephrotoxic AKI, several clinical studies have attempted to use NAC to prevent AKI, mainly in CI-AKI and during cardiac surgery.

In the first study, NAC at a dose of 600 mg orally twice daily the day before and the day of the procedure prevented AKI after radiocontrast dye administration. However, numerous further studies have shown conflicting results. Oral NAC is inexpensive and has an excellent side effect profile compared with intravenous NAC. A recent large study in patients undergoing coronary arteriography and peripheral vascular angiography did not show a benefit associated with oral NAC.[31] In addition, in an accompanying meta-analysis of the use of oral NAC, stratification of trials according to adequacy of methodologic characteristics (allocation concealment, double blinding, and intention-to-treat analysis) revealed a reduction in the pooled relative risk of CI-AKI with NAC treatment observed among low-quality studies, yet no effect of NAC in studies meeting all three methodologic criteria. If NAC is to be used, the preferred dose is 1200 mg administered orally twice daily on the day before and the day of the procedure in patients at risk for CI-AKI. Oral NAC should never replace intravenous fluids, which have a more substantial benefit.

Loop Diuretics and Natriuretics

Diuretics are often used to manage fluid in patients who develop AKI.[32,33] Although nonoliguric AKI has been associated with better outcomes than oliguric AKI, diuretics have been shown to be ineffective in the prevention of AKI or for improving outcomes once AKI occurs.[34] In addition, diuretics should be avoided when AKI is attributed to pre-renal causes. Meta-analyses have confirmed that the use of diuretics to prevent AKI did not reduce in-hospital mortality, the risk for requiring dialysis, the number of dialysis sessions required, or the proportion of oliguric patients.[34,35] An RCT, including 94 patients treated with prophylactic nesiritide undergoing high-risk cardiac surgery, did not show any effect on RRT requirement or lengths of stay, although AKI rates were lower with nesiritide.[36]

Vasoactive Agents

"Renal-dose" dopamine (0.5 to 3 μg/kg per minute) given as a renal vasodilator increases urine output but does not affect AKI outcome or mortality.[37] Dopexamine, a synthetic dopamine analogue, is a dopamine type-1 and less potent dopamine type-2 receptor agonist. Small studies performed in patients undergoing liver transplant surgery have not found a beneficial effect of dopexamine in preventing AKI.

Summary of Drugs Used in Prevention of Acute Kidney Injury (AKI)			
Drug	**Level of Evidence**	**Results**	**Comments**
Dopamine	RCTs	No effect on kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on kidney function Beneficial effect on kidney function	Further studies required
Loop diuretics	RCTs and meta-analysis	No effect on kidney function	
N-acetylcysteine	RCTs and meta-analysis	Variable effect in CI-AKI, mostly related to the quality of RCTs	1200 mg PO bid before and on the day of administration of iodinated contrast with saline or bicarbonate
Statins	Retrospective perioperative period One RCT in CI-AKI	Beneficial effect on kidney function No effect on kidney function	Further studies required
Insulin	Meta-analyses	Controversial effect	KDIGO recommends to target blood glucose 110-149 mg/dl (6.1-8.3 mmol/l)
Calcium channel blockers	RCT in peritransplant period	No effect on kidney function	Further studies required
Adenosine antagonists	RCTs	Controversial effect on kidney function	Further studies required
Nesiritide	RCT	Decreased incidence of AKI No effect on renal replacement therapy requirement	Further studies required
Erythropoietin	Animal models	Beneficial effect on kidney function	Human studies required*
Small interfering RNA targeting p53	Animal models	Beneficial effect on kidney function	Human studies required
Multipotent stem cells	Animal models	Beneficial effect on kidney function	Human studies required
Mesenchymal stem cells	Phase I clinical trials	Decreased incidence of AKI	Further studies required

Table 73-3 Summary of drugs used in prevention of AKI. *CI-AKI,* Contrast-induced acute kidney injury; *KDIGO,* Kidney Disease: Improving Global Outcomes (KDIGO); *PO,* by mouth; *RCTs,* randomized controlled trials; *RNA,* ribonucleic acid. *Current study results are conflicting and not definitive (see text for more information).

The effect of norepinephrine on prevention of AKI has not been assessed in RCTs. Fenoldopam is a pure dopamine type-1 receptor agonist with hemodynamic renal effects similar to those of low-dose dopamine, without systemic α- or β-adrenergic stimulation. In a meta-analysis, fenoldopam was shown to reduce the risk of AKI in postoperative or critically ill patients (odds ratio 0.43).[38] Intrarenal administration of fenoldopam allows the use of a substantial dose of fenoldopam mesylate while avoiding systemic adverse effects, such as hypotension. In a registry of 268 patients treated with intrarenal fenoldopam infused for at least 1 hour, the incidence of CI-AKI was less than 1%, compared with 27% based on historic rates in that population. Data from experimental models suggest that fenoldopam may have additional anti-inflammatory effects.[39] Currently, we do not recommend use of fenoldopam to prevent AKI because no high-quality trial has been performed with this agent.

Statins

Although the pathogenesis of CI-AKI is not completely known, multiple mechanisms may be involved. Statins induce downregulation of angiotensin receptors, decrease endothelin synthesis, decrease inflammation, improve endothelial function by inhibiting nuclear factor (NF) κB, decrease expression of endothelial adhesion molecules, increase nitric oxide (NO) bioavailability, attenuate production of reactive oxygen species, and protect against complement-mediated injury. Those mechanisms may be involved in the protective effect against CI-AKI. A number of observational publications support the potential for renal protection with statin administration.[40] However, the only RCT that included 304 patients with eGFR below 60 mL/min showed no benefit of atorvastatin compared with placebo.[41] Patients who are already receiving statin therapy or need it for other indications should be maintained on statins, but there is no basis to recommend the initiation of statin therapy specifically to prevent CI-AKI.

Statins may also reduce the risk of AKI after elective surgery.[42] A large retrospective study identified 213,347 patients who underwent surgery in Canada, among whom 32% were treated with a statin before surgery. AKI occurred in 1.9% of these patients. After multivariable adjustment, the use of statins was associated with a significantly decreased risk of AKI, of acute requirement for RRT, and 30-day mortality. There was no difference between groups in dialysis requirement 90 to 120 days after surgery. Because this was a retrospective study, there was likely residual confounding that could not be adjusted for. These results need to be validated before clinical recommendations can be made regarding the use of statins to prevent perioperative AKI.

Calcium Channel Blockers

Calcium channel blockers (CCBs) have been shown to reverse the afferent arteriolar vasoconstriction induced by a variety of stimuli and also have an independent natriuretic effect.[43] These drugs have been exhaustively evaluated in the prevention of AKI, especially in the context of transplant-associated nephropathy. Administered prophylactically, CCBs protected against post-transplantation delayed graft failure in some studies. However, a large multicenter RCT evaluating the effect of isradipine on renal function, incidence and severity of delayed graft function, and acute rejection after kidney transplantation did not find any benefit.[44] A systematic review evaluated the benefits and harms of using CCBs in the peritransplant period and did not find strong evidence for the routine use of CCBs to reduce the incidence of acute tubular necrosis (ATN) after transplantation.[42] Studies have shown improved long-term outcomes without any significant improvement in perioperative function. It is

possible that the use of CCBs during renal transplant surgery may be of benefit in extended donor criteria transplants (e.g., donors older than 60 years, predonation serum creatinine level higher than 1.5 mg/dl (132 µmol/l), cerebrovascular disease as the cause of death) or those with prolonged ischemia times.

Adenosine Antagonists

Theophylline, a nonselective adenosine receptor antagonist, prevents the adenosine-mediated vasoconstriction of the afferent arteriole. Adenosine is released in response to increased luminal chloride concentrations in the distal renal tubules, as part of the tubuloglomerular feedback. Small clinical studies evaluating the role of theophylline in the prevention of contrast nephropathy have shown discordant results. A meta-analysis including seven RCTs concluded that the prophylactic administration of theophylline or aminophylline appeared to protect against CI-AKI.[45] However, this meta-analysis included studies that did not control for hydration status. A recent RCT adding theophylline to NAC showed reduced incidence of CI-AKI. Currently, it remains unclear whether theophylline as a solo agent might be useful in preventing CI-AKI, and the KDIGO AKI guidelines do not suggest using theophylline to prevent CI-AKI.

Selective adenosine blocking agents, such as rolofylline, have been used in trials for prevention and treatment of cardiorenal syndrome. In a double-blind placebo-controlled trial of 63 patients with decompensated heart failure, whereas patients receiving furosemide presented a deterioration in GFR, the coadministration of adenosine A_1 antagonist with furosemide increased diuresis and prevented decrease in GFR.[46]

Emerging Agents

Multipotent mesenchymal stem cells (MSCs) were shown to prevent ischemia-reperfusion–induced AKI in rats. A Phase I clinical trial evaluated the feasibility and safety of suprarenal aorta infusion of allogeneic MSCs in patients undergoing on-pump cardiac surgery.[47] No adverse events were associated with the MSC infusion, and lengths of hospital stay and readmission rates were decreased by 40% compared with matched historical case controls. Postoperative kidney function remained at baseline levels, and no patients in the treatment group required hemodialysis (HD), whereas 20% of controls developed AKI. In addition, kidney function in the treatment group was stable for up to 16 months in patients with underlying CKD, whereas matched control patients showed progressive deterioration in kidney function.[47] The long-term safety of this approach is currently unknown.

From the results of animal and preliminary human studies, therapeutic use of erythropoietin (EPO) seems promising. EPO can prevent AKI and improve recovery through limitation of apoptosis, promotion of neovascularization, anti-inflammatory action, and tissue regeneration. In mice, EPO administered 30 minutes before the infusion of endotoxin significantly improved kidney function 16 hours after injury. EPO also seems to have a protective effect against ischemia-reperfusion injury in the rat kidney. A clinical trial of preoperative EPO in patients who underwent elective coronary artery bypass graft surgery showed a reduction in the incidence of AKI from 29% to 8% ($P = .035$) and improved postoperative renal function. In another trial, different doses of recombinant EPO administered to patients after cardiac surgery did not result in a difference in urine NGAL between 48 hours and randomization compared with placebo, and the incidence of AKI was similar.[48] In the intensive care setting, a recent study also failed to show therapeutic renoprotective benefits of EPO. Although the timing of treatment was not ideal—more than 6 hours after kidney injury had been detected by biomarkers—in this study, high-dose EPO did not alter outcome in AKI patients.[49] Another RCT comparing the effect of EPO or placebo in preventing AKI in patients receiving intravenous contrast material has finished, but the results are not yet available.

Small interfering ribonucleic acids were evaluated against placebo for prevention of AKI in a Phase I clinical trial. In an animal model of AKI, animals treated with small interfering ribonucleic acid targeting p53 presented a significant decrease in blood urea nitrogen (BUN) and creatinine levels 24 hours after ischemic injury, compared with those treated with a placebo. Because p53 has, among other activities, a tumor suppression function, one of the major drawbacks to the use of an inhibitor of p53 is its potential carcinogenic effect, and the study was stopped because of difficulties in enrolling patients.

TREATMENT OF ACUTE KIDNEY INJURY

Once measures to prevent AKI have failed, a key question is whether AKI can be managed with nondialytic therapy alone or if RRT is necessary (see Chapter 74). Management of AKI in the setting of cardiac failure and liver failure is discussed in Chapters 75 and 76, respectively.

General Management

Appropriate therapeutic management requires timely diagnosis of the clinical condition. Considerable effort and investment have been directed in the search for a more sensitive and specific biomarker to diagnose AKI. Because serum creatinine is a relatively late indicator of renal injury, significant AKI can occur without major increases in serum creatinine levels. Appropriate therapeutic interventions to reduce kidney function loss and for prevention and treatment of the associated complications of AKI need to be instituted even with minimal changes in serum creatinine. Initial management of established AKI includes careful assessment of the cause of renal dysfunction and the patient's volume status. The main goal includes maintenance of adequate hemodynamic status to ensure renal perfusion and avoidance of further kidney injury. Any potentially nephrotoxic agents should be avoided, including intravascular radiocontrast dye. Gadolinium-based contrast agents should be avoided because of the risk of development of nephrogenic systemic fibrosis (NSF). If gadolinium-based contrast agents need to be used in AKI, patients should be informed about the risk of NSF, and macrocyclic chelate (i.e., gadobutrol, gadoteridol, or gadoterate meglumine) should be preferred over linear chelates. The lowest dosage possible should be administered, and repeated exposures should be avoided. Antimicrobial agents such as aminoglycosides, amphotericin, acyclovir, and pentamidine should be avoided whenever possible, or their dose should be adjusted to prevent further insult. Any other medications associated with AKI (hemodynamic, nephrotoxic, immune mediated) should also be avoided if possible.

Fluid and Electrolyte Management

Whereas early and vigorous resuscitation with crystalloid solutions and aggressive infection control can reduce the incidence of AKI (see earlier discussion), the role of fluid resuscitation in established AKI is less clear. Volume status is one of the most difficult parameters to assess, and fluid resuscitation should target a predefined preload, stroke volume, or cardiac output rather than a set MAP. Nevertheless, many clinical studies have emphasized the poor value of right atrial pressure and pulmonary artery occlusion pressure in predicting volume expansion efficacy. Other bedside indicators of preload,

Summary of Drugs Used in Treatment of Acute Kidney Injury (AKI)			
Drug	**Level of Evidence**	**Results**	**Comments**
Dopamine	RCTs	No effect on mortality or kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on mortality or kidney function Beneficial effect on mortality and need for dialysis	Further studies required
Norepinephrine	Prospective observational studies	Possible beneficial effect on kidney function	Further studies required
Loop diuretics	RCTs and meta-analyses	No effect on kidney function	Further studies required; two RCTs ongoing
Atrial natriuretic peptide	RCTs	Possible beneficial effect on survival and kidney function	Further studies required
B-type natriuretic peptide	RCT in acute heart failure	No effect on kidney function	
Multipotent stem cells	Animal models	Beneficial effect on kidney function	Further studies required

such as the right ventricular end-diastolic volume (evaluated by thermodilution) and the left ventricular end-diastolic area (measured by echocardiography), have also been shown to be ineffective in differentiating volume responder from nonresponder patients.[50]

In critically ill patients receiving mechanical ventilation, respiratory changes in left ventricular stroke volume can predict fluid responsiveness. In hypovolemic patients, positive-pressure ventilation may induce a fall in the venous return and consequently in cardiac output. Based on the positive relationship between ventricular end-diastolic volume and stroke volume, the expected hemodynamic response to volume expansion is an increase in right ventricular end-diastolic volume, left ventricular end-diastolic volume, stroke volume, and cardiac output. Because a decrease in ventricular contractility decreases the slope of the relationship between end-diastolic volume and stroke volume, the increase in stroke volume as a result of end-diastolic volume increase depends on ventricular function.

Volume expansion in critically ill patients can frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body water in a short time. Studies have demonstrated an association between fluid accumulation and mortality in children and adults with AKI. A prospective multicenter observational study (Program to Improve Care in Acute Renal Disease [PICARD]) found that patients with fluid overload at AKI diagnosis, defined as an increase in body weight relative to baseline of more than 10%, had a threefold increase in mortality after multivariable adjustment. The risk of death was proportional to the magnitude and duration of fluid accumulation. The effect of fluid overload on renal recovery was inconsistent.[12] A second analysis from the FACTT trial in patients with AKI also confirmed that in patients with early AKI a positive fluid balance after AKI diagnosis is strongly associated with mortality.[51] The study showed a protective effect on mortality from furosemide, which disappeared after fluid balance was controlled for.[51] Other studies have shown a deleterious effect of fluid overload on kidney function. In summary, results from observational studies suggest that a conservative fluid approach may be beneficial in terms of mortality and kidney recovery in patients with severe AKI; however, RCTs are required to confirm these findings before any clear recommendation can be made.

In addition, increases in the total body water alter the volume of distribution of creatinine, resulting in underestimation of serum values. The resulting underestimation of the severity of renal dysfunction may delay recognition and adequate treatment of AKI. In AKI patients presenting with fluid overload, the evaluation of renal function should consider the effect of fluid balance to prevent underestimation of AKI severity, to modify drug dosage correctly, and to avoid use of nephrotoxic agents.

Drugs to Promote Recovery from Acute Kidney Injury

See Table 73-4 for a summary of drugs used in treatment of AKI.

Loop Diuretic Therapy

Although loop diuretics are often prescribed in established AKI,[52] a meta-analysis confirmed that their use is not associated with reduced mortality or better kidney recovery.[53] Two other meta-analyses have shown that loop diuretics do not affect mortality, need for dialysis, or number of dialysis sessions required.[35,54] With regard to morbidity, diuretics are associated with an increased risk of ototoxicity.[55] Concomitant prescription of aminoglycosides and diuretics should be avoided because of an increased risk of ototoxicity. Well-designed trials of diuretics are required to assess the benefits of these drugs and potential side effects in AKI, and RCTs are currently being performed in this field. In the meantime, we suggest avoiding diuretics to treat AKI, except for managing fluid overload.

Natriuretics

Atrial natriuretic peptide (ANP) has been studied as a treatment for AKI in four RCTs.[56-59] ANP was shown to reduce need for dialysis but not mortality.[56] In the largest study published so far, ANP improved overall dialysis-free survival in the subgroup of oliguric patients only.[57] Unfortunately, a subsequent trial including 222 oliguric patients did not confirm that ANP reduces mortality or dialysis-free survival.[40] Both trials delivered ANP for 24 hours and at high doses, which could have influenced the results. The most recent study included 61 patients who underwent cardiac surgery and were treated with ANP for a mean of 5.3 ± 0.8 days. In this small study the use of ANP decreased the probability of dialysis and improved dialysis-free survival.[58] Currently the KDIGO AKI guidelines do not suggest ANP to treat AKI. Larger studies are required to confirm the benefits of ANP in AKI. Nesiritide, a B-type natriuretic peptide, can be used for the treatment of heart failure. Nesiritide induces vasodilation and an indirect increase in cardiac output but has no inotropic effects and neutral effect on heart rate. In

addition, it inhibits adverse neurohormonal activation and can result in natriuresis and diuresis in some individuals. However, in a recent large RCT in patients with acute heart failure,[60] this drug did not decrease mortality or rehospitalization rates and had a nonsignificant effect on dyspnea. Nesiritide did not adversely affect renal function, but increased hypotension. Nesiritide has also been assessed in high-risk cardiovascular surgery, where it reduced AKI rates in the immediate postoperative period but did not improve long-term survival. The KDIGO AKI guidelines do not support the use of nesiritide to treat AKI.[13]

Vasoactive Agents

Dopamine use for the treatment of established AKI is no longer recommended (see earlier discussion).

Vasopressors are often considered to be detrimental for organ perfusion. In septic shock, a small prospective study including 14 patients showed that norepinephrine improved serum creatinine and creatinine clearance when MAP was raised above 70 mm Hg.[61] However, in a small RCT including 28 patients, increasing MAP from 65 to 85 mm Hg with norepinephrine did not improve renal function.[62]

In a meta-analysis, fenoldopam decreased the need for dialysis (7% vs. 10%) and in-hospital mortality (15% vs. 19%) in postoperative or critically ill patients.[38] Several limitations were present in this meta-analysis, such as no standardized criteria for initiation of dialysis, heterogeneity of populations and AKI definitions, and dosage and duration of treatments, and absence of an independent measure of GFR. In addition, fenoldopam has hypotensive properties and may be more dangerous in the "real world" outside of RCTs.[40,63] No single prospective study has shown that fenoldopam can reduce the need for dialysis. These results need to be confirmed with an adequately powered trial, and we do not suggest using fenoldopam to treat AKI in concordance with the KIDGO AKI guidelines.

Specific therapy for patients with the hepatorenal syndrome includes the use of terlipressin in combination with octreotide (see Chapter 76). In the United States, terlipressin is not available, and most centers use a combination of midodrine, octreotide, and albumin infusions. Norepinephrine has also been used in these settings with good response, equivalent to that of terlipressin.

Current ongoing clinical trials registered on www.clinicaltrials.gov have been recently summarized, and we expect that some will bring new preventive and therapeutic options for AKI.[30,64]

Other Agents

Other agents have been studied for treatment of established AKI. One promising therapy is the use of MSCs.[65] MSC are multipotent cells with anti-inflammatory and immunomodulatory properties proven to be beneficial in animal models of myocardial ischemia, sepsis, and AKI. In AKI models, infusion of MSCs improved recovery of renal function in cisplatin-induced, ischemia-reperfusion injury, and glycerol-induced AKI. A dose-escalating Phase I clinical trial was conducted to test the safety, feasibility, and preliminary efficacy of MSCs in patients at high risk of AKI.[47] An experimental study using a model of progressive mesangioproliferative nephritis evaluated the long-term effects of intrarenal, syngeneic MSC transplantation.[66] Although patients in the MSC-treated group had lower proteinuria and better kidney function on day 60, 20% of the glomeruli of MSC-treated rats contained single or clusters of large adipocytes with pronounced surrounding fibrosis.[66] Therefore the MSC benefit of maintaining kidney function in the short term needs to be balanced with a possible long-term effect of partial maldifferentiation of intraglomerular MSC into adipocytes and subsequent glomerular sclerosis.[66]

Erythropoietin might also be beneficial in the treatment of AKI, as shown in two animal models. A randomized trial including 71 patients scheduled for elective CABG EPO showed a beneficial effect on recovery after AKI.[66a] However, in a retrospective study including 187 patients with AKI, the use of EPO was not associated with renal recovery.[67]

In severe sepsis and septic shock, a study including 36 patients has shown that the infusion of alkaline phosphatase improves kidney function, possibly through reduced NO metabolite production and attenuated tubular enzymuria.[68]

Another potential agent is the endogenous antioxidative enzyme heme oxygenase-1 (HO-1), a stress inducible enzyme.[69] HO-1 has important antiapoptotic and anti-inflammatory functions, and the induction of HO-1 has been shown to be protective in several forms of injury, including AKI.[70]

Treatment of Acute Kidney Injury Complications

Fluid Overload

When fluid overload occurs in a patient with AKI, all intakes should be minimized and medical treatment should be attempted before dialysis initiation. In patients with positive fluid balance with large fluid intakes and inadequate urine output and in those presenting with symptomatic volume overload, loop diuretic therapy can be initiated in conjunction with measures to optimize systemic and renal perfusion. Intravenous bolus doses of diuretics may be necessary to optimize the response, especially in patients with CHF and nephrotic syndrome. If there is a response to an intravenous bolus, continuous infusion can be tried because they are less ototoxic.

In addition to diuretics, new drugs that selectively influence the excretion of water or sodium have been developed and can be used in specific clinical settings. Aquaretics act in the collecting duct of the kidney in the vasopressin-2 receptors, contributing to free water excretion. Vasopressin receptor antagonists require further studies to establish their role in the treatment of AKI with volume overload and hyponatremia. Natriuretic peptides inhibit sodium reabsorption in the nephron, resulting in net sodium excretion. There is currently no evidence to support the use of natriuretic peptides as an adjunctive treatment in AKI.

Morphine and nitrates can be used to alleviate the respiratory symptoms in urgent situations. Morphine reduces the patient's anxiety and decreases the work of breathing; it can be administered intravenously at an initial dose of 2 to 4 mg during a 3-minute period and can be repeated if necessary at 5- to 15-minute intervals. Nitrates are the most commonly used vasodilators in pulmonary edema. Nitroglycerin reduces left ventricular filling pressure through venodilation; an initial dose of 5 μg of intravenous nitroglycerin per minute can be used, commonly in addition to diuretic therapy. When fluid overload cannot be quickly treated with medical management, positive-pressure ventilation may need to be initiated with or without endotracheal intubation and dialysis, depending on the clinical situation (see Chapter 75).

Potassium Disorders

Hyperkalemia, covered in detail in Chapter 9, is a frequent complication of AKI. Its primary risk is its effect on cardiac conduction, and it may cause bradycardia or asystole. If electrocardiographic changes are present, the intravenous administration of calcium is urgently needed. Concomitantly, sources of oral or intravenous potassium should be identified and removed, including drugs with effect on potassium handling, such as β-adrenergic antagonists, potassium-sparing diuretics, ACE inhibitors, ARBs, and other drugs that inhibit renal potassium excretion.

The next step is to enhance the shift of potassium to the intracellular space by parenteral glucose and insulin infusions. The onset of action is within 20 to 30 minutes, and their effect lasts 2 to 6 hours. Continuous infusions of insulin and glucose-containing intravenous fluids can be used to prolong their effects. Sodium bicarbonate also promotes shift of K^+ into the intracellular space; the effect occurs in less than 15 minutes and has 1 to 2 hours of duration. This therapy can be started if there is no concern regarding fluid overload (50 mmol intravenously during 5 minutes), although the potassium-lowering effect of sodium bicarbonate is most prominent in patients with metabolic acidosis. β-Adrenergic agonists given as aerosols are effective but more likely to produce side effects and therefore are not often prescribed to treat hyperkalemia.

Potassium excretion should be increased by the administration of saline, loop diuretics, and cation exchange resins such as sodium polystyrene sulfonate or calcium resins. The resins can be administered orally or rectally as a retention enema. In patients with hyperkalemic emergencies, rectal administration is preferred, as the colon is the major site of action of this drug. There is concern that the risk of intestinal necrosis may be increased when sodium polystyrene sulfonate is administered with sorbitol. Sodium polystyrene sulfonate should be avoided postoperatively until normal bowel function resumes or in patients with stool impaction. If hyperkalemia is unresponsive to conservative measures, emergency HD is the treatment of choice. Continuous renal replacement therapy (CRRT) can also be used for hyperkalemia with higher volumes of replacement solution or dialysate with low or no potassium content if intermittent HD is unavailable. Because it may take some time to initiate RRT, medical management should always be used pending initiation of dialysis. Monitoring of potassium levels should continue after conservative or dialytic management to prevent and to treat rebound hyperkalemia from the underlying process.

Sodium Disorders

Hyponatremia is more common in AKI associated with heart failure, liver failure, or diuretics. In these settings, water restriction to below the level of output is mandatory. Sodium restriction is usually necessary to treat fluid overload and edema. In patients with true volume depletion with associated pre-renal AKI, isotonic saline will need to be administered to correct both disorders (see Chapters 7 and 8).

Intensive care patients with hypernatremia are more prone to AKI. In most patients, treatment of the underlying cause will be necessary and water deficit will need to be estimated. Water should be administered orally or intravenously as dextrose in water to correct serum sodium concentration at a maximum rate of 8 to 10 mmol/l/day. Dialysis and CRRT in particular may be required to optimally correct sodium disorders in AKI.

Calcium, Phosphorus, and Magnesium Disorders

Hyperphosphatemia and hypocalcemia are common in AKI. Hyperphosphatemia is usually caused by reduced excretion by the kidneys, although it can also be caused by a continuous release from rhabdomyolysis or TLS (see Chapters 10 and 69). As phosphorus levels increase, calcium levels decrease, resulting in hypocalcemia. The levels of reduction are usually mild to moderate, with total calcium levels dropping to 7 to 8 mg/dl (1.75 to 2.0 mmol/l). Other causes of hypocalcemia in AKI are skeletal resistance to parathyroid hormone (PTH) and low calcitriol production from the dysfunctional kidney. Hypocalcemia can also occur during rhabdomyolysis and pancreatitis, two conditions often associated with AKI. Hypocalcemia is also aggravated when bicarbonate is administered to correct acidosis. A high-calcium, high-phosphorus product could theoretically trigger tissue calcium deposition, which can cause cardiac arrhythmia. No randomized study has evaluated the benefits of treating these disorders. However, because hyperphosphatemia caused by oral phosphorus-containing medications and TLS can cause AKI,[71] severe hyperphosphatemia should be avoided to prevent further damage. Calcium-based phosphate binders and other phosphate binders can be used in this setting.[72] If there are symptoms of hypocalcemia or hemodynamic instability, a calcium gluconate infusion should be administered.

Hypercalcemia is rare in AKI and is usually seen in the recovery phase of rhabdomyolysis when calcium is released from calcium-containing complexes in muscle (see Chapters 10 and 69). In addition, when production of calcitriol is reestablished by the recovering kidney, an enhanced responsiveness to PTH can be seen. Hypercalcemia in this setting is rarely problematic and can be easily treated with medical management. Mild hypermagnesemia is frequent in AKI and usually does not have clinical consequences.

Acid-Base Disorders

In AKI, metabolic acidosis is the most common acid-base abnormality (see Chapter 12) and is caused by reduced regeneration of bicarbonate and failure to excrete ammonium ions. Accumulation of phosphate and unexcreted unmeasured anions, such as sulfate, urate, hippurate, hydroxypropionate, furanpropionate, and oxalate, is contributory. Hypoalbuminemia can attenuate this acidification process, and it is exacerbated by lactic acidosis. Despite retention of unmeasured anions, the anion gap remains within normal limits in 50% of patients. Whereas metabolic acidosis is frequent, triple acid-base disturbances can also occur.

The approach to acid-base disturbances in AKI needs to be adjusted according to the underlying causes.

There is controversy surrounding the optimal treatment of acute metabolic acidosis. When metabolic acidosis is simply a complication of AKI, sodium bicarbonate can be administered if the serum bicarbonate concentrations fall below 15 to 18 mmol/l. Volume overload can occur after the administration of bicarbonate. Bicarbonate administration in lactic acidosis caused by an underlying shock is controversial, given the possibility of an increase in carbon dioxide generation, worsening of the intracellular acidosis, and volume overload. Rapid improvement in the metabolic status may also enhance hypocalcemia, which may lower cardiac output. Therefore, in patients with lactic acidosis, most physicians would restrict the administration of sodium bicarbonate to patients with severe metabolic acidosis (arterial pH below 7.10 to 7.15) to maintain the pH above 7.15 to 7.20 until the primary process could be reversed. Alternative forms of base treatment have not been studied extensively in patients with AKI. Tris(hydroxymethyl)aminomethane (THAM) is excreted in the urine, and its clinical efficacy compared with that of sodium bicarbonate remains unproven.[47] We do not recommend its use in patients with AKI, especially in patients with hyperkalemia, because, in contrast to bicarbonate, THAM does not decrease serum potassium and can even cause hyperkalemia. Restriction of protein intake has also been suggested as a method of acidosis control because protein breakdown has been associated with worsening acidosis, such as in CKD.[73] However, protein restriction is not recommended in AKI (see later discussion of nutritional considerations).

Nutrition

Patients with AKI have an increased risk of protein-energy malnutrition because of poor nutrient intake and high catabolic rate. Nutritional support should be directed toward ensuring adequate

nutrition, preventing protein-energy wasting with its concomitant metabolic complications, promoting wound healing and tissue repair, supporting immune system function, and reducing mortality.

Nutritional assessment is difficult, especially in AKI patients with high metabolic demands. Subjective global assessment evaluates nutritional status, requires no additional laboratory testing, and is highly predictive of outcome.[74]

Patients with AKI should receive a basic intake of 0.8 to 1.0 g of protein per kilogram per day if not catabolic and a total energy intake of 20 to 30 kcal/kg/day, as recommended in the KDIGO AKI guidelines. In addition, in patients on RRT, 1.0 to 1.5 g of protein per kilogram per day should be administered up to a maximum of 1.7 g/kg/day in patients on CRRT and in hypercatabolic patients. Protein catabolism can be ascertained by the urea nitrogen appearance rate over a set interval with appropriate adjustments for dialysis sessions and CRRT.[75]

Monitoring of nitrogen balance to assess the effectiveness of supplemental nutritional therapy is determined by measuring protein intake during 12 or 24 hours and urinary excretion of urea nitrogen during the same time interval. A positive or negative protein balance is used to determine the adequacy of protein intake of the patient. It is calculated as follows:

$$\text{Nitrogen balance} = (\text{Protein intake}/6.25) - (\text{UUN} + 4)$$

Protein intake and urinary urea nitrogen (UUN) are each expressed in grams. The enteral route should be the first choice for nutritional support if the gastrointestinal tract is functioning; parenteral nutrition should be reserved for when the gastrointestinal tract cannot be used or when the enteral route appears inadequate to reach nutrient intake goals.[76] AKI itself and other factors commonly present in critically ill patients, such as medication use, hyperglycemia, and electrolyte disorders, can impair gastrointestinal motility.

CHAPTER 74

Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology

Mark R. Marshall and Luis A. Juncos

Intensive care unit (ICU) nephrology can be defined as a subspecialty that focuses on abnormalities of fluid, electrolyte, and pH homeostasis in ICU patients, and the prevention and management of functional renal impairment relative to physiologic demand. This chapter describes agreed-on best practices with respect to acute renal replacement therapy (ARRT) and provides strategies for avoiding common treatment-related complications. The chapter uses appropriate clinical practice guidelines as starting points for discussion and summarizes their recommendations (Box 74-1).[1-8]

When the Acute Kidney Injury Network (AKIN) criteria are applied, approximately 40% of ICU patients develop evidence of acute kidney injury (AKI), an independent risk factor for death. The nondialytic therapy of AKI is discussed in Chapter 73. Approximately 5% of ICU patients require ARRT, and mortality in this population is improving over time despite a higher degree of illness severity.[9] Death attributable to AKI appears to result from nonresolving infection, hemorrhage, or nonresolving shock, despite optimal care. Such conditions may therefore be considered a systemic "acute uremic syndrome" that is specific to AKI and a possible target for modulation with ARRT—analogous to the traditional uremic syndrome in the setting of maintenance dialysis.

ORGANIZATIONAL ASPECTS OF ACUTE RENAL REPLACEMENT THERAPY PROGRAMS

Intensive care units can be described as open (patient care remains under the attending physician of record), closed (patient care is transferred to an intensivist), or comanaged (an open ICU, as defined earlier, in which patients receive mandatory consultation from an intensivist). Most ICUs in the United States are open, whereas most in Australia and New Zealand are closed. Those in Europe are approximately equally split. When AKI and ARRT are considered, advantages of intensivist-based management include immediate availability of service and decreased fragmentation of care. This model of care is supported by ecologic studies that suggest improved overall patient outcomes in health care systems with closed ICUs. Alternatively, advantages of nephrology-based management include greater understanding of the dialysis process and underlying AKI. This model of care is supported by studies that show improved outcomes in ICU patients with AKI associated with earlier referral to nephrology. All of these studies have disparate definitions and analyses that make interpretation difficult. Clinical governance over ARRT is therefore likely to remain contentious, although the expertise of staff providing care probably influences patient outcomes more than the specialty to which they belong. Specific training in ICU nephrology and exposure to ARRT is inadequate in many critical care and nephrology training schemes and should be a component of both core curricula.

In many parts of the world, ICU nursing staff members deliver all modalities of ARRT; in other countries, support from nephrology staff is required. As machinery platforms become universal for continuous renal replacement therapy (CRRT) and intermittent hemodialysis (HD), it is likely that ICU expertise in all modalities will grow, provided in-service education and support are adequate to develop and maintain the skill base.

OVERVIEW OF ACUTE RENAL REPLACEMENT THERAPIES

The main modalities of ARRT are acute intermittent HD and its variants, CRRT, and acute peritoneal dialysis (PD). Acute intermittent HD and CRRT are most popular, although practice patterns vary regionally because of cost, availability of technology, and reimbursement policies. Recently, intermittent HD has undergone resurgence through variants that provide slower fluid removal over longer periods of time, resulting in improved hemodynamic stability and increased solute clearance. These variants are most commonly referred to as *sustained low-efficiency dialysis* (SLED). Collectively, however, they are best referred to with the umbrella term *prolonged intermittent renal replacement therapy* (PIRRT), a term more aligned to nomenclature endorsed by the Acute Dialysis Quality Initiative (www.adqi.net) (Fig. 74-1). *Acute PD* is mostly used in the developed world for pediatric patients, and it is not considered further in this chapter.

Therapeutic goals for ARRT are not well defined. The usual minimum recommendation is to correct acidosis or hyperkalemia, refractory hypervolemia, and uremic features such as pericarditis or coma. Serum electrolyte and bicarbonate concentrations should be maintained in the normal range. Although specific laboratory thresholds for starting and stopping therapy are unknown, dialysis dose should be measured and adjusted to meet minimum targets, which are discussed later. It is important to note that the process of ARRT itself should not jeopardize the patient by exacerbating hemodynamic instability, increasing end-organ damage, or delaying renal recovery.

Determining goals with respect to a patient's extracellular volume status is not straightforward. Assessment itself is difficult; physical signs such as jugular venous distention are generally not informative, especially for mechanically ventilated patients. Moreover, baseline values of central venous pressure, pulmonary capillary wedge pressure, and echocardiographic left ventricular diastolic dimensions may be inaccurate surrogates for intravascular volume status, especially for patients with sepsis. An alternative approach is to use the effect of therapeutic maneuvers such as fluid challenge on blood pressure, stroke volume, or vena cava collapsibility. Even after fluid status has been adequately assessed, determining the therapeutic

goal is also difficult; patients with extracellular fluid excess in the absence of intravascular hypervolemia may benefit from fluid removal if they develop abdominal compartment syndrome, impairment of lung compliance and oxygenation, or poor wound healing. In particular, patients with acute lung injury require a shorter period of ventilation with less fluid loading (guided by central filling pressures).

Variations of ARRT have been used to enhance removal of cytokines. Cytokines are medium (300 to 12,000 d) and large (>12,000 d) molecules that are essential in modulating the immune response. However, their production is increased with acute illness, and their clearance decreased during AKI, resulting in excessive levels that have cardiodepressant, vasodilatory, and immunosuppressive properties.[10] Consequently, this has sparked interest in enhancing cytokine clearance during acute illness or AKI. Differing degrees of cytokine removal can be achieved through the use of high-flux or super-high-flux membranes (molecular weight cutoff of approximately 60 to 150 kd), bioadsorption and coupled plasma filtration–adsorption filters, and high levels of convective clearance. The last is achieved by ultrafiltering large amounts of plasma through a standard hemofilter and replacing the ultrafiltrate with a physiologic replacement fluid, thus diluting the remaining solutes in the body. It should be noted, however, that ARRT will remove both proinflammatory and anti-inflammatory cytokines, with potential to inadvertently exacerbate the inflammatory milieu. Notwithstanding, a promising technique is high-volume hemofiltration, supported by observations of improved outcomes in ICU patients with sepsis with higher doses of hemofiltration (≥45 ml/kg/h), and improved hemodynamic stability with even higher doses (60 to 100 ml/kg/h) applied either as a "pulse" or continuous maneuver. At present, only preliminary outcome data support the approach, although clinical trials are under way.[11]

Timing of ARRT initiation is controversial. Proponents of early initiation argue that it is in the patients' interest to prevent rather than treat the acute uremic syndrome and recommend initiation once kidney injury or failure is present. Indeed, this view is supported by observational studies suggesting that earlier initiation might achieve better outcomes (none suggest more harm). However, there is no high-quality evidence, and the single clinical trial designed to answer the question was inadequately powered.[12] Currently, timing of initiation is variable; a large multinational cohort study showed ARRT was initiated when the median (interquartile range [IQR]) serum creatinine and urine output were 309 (202 to 442) µmol/l and 576 (192 to 1272) ml/day, respectively.[13]

INTERMITTENT ACUTE RENAL REPLACEMENT THERAPY

Techniques for Acute Intermittent Hemodialysis

Acute intermittent HD is categorized according to hemodialyzer membrane and mechanism of solute removal. High-flux membranes allow greater convective removal of middle and larger solutes, but limited clinical data do not show obvious advantages in the ICU setting. Biocompatibility is a membrane characteristic that includes a low capacity for activating complement and leukocytes. After complement activation, there is stasis of leukocytes in the lungs, renal parenchyma, and other organs and the release of products of leukocyte activation. Although studies have been inconsistent, the use of biocompatible membranes should in principle favorably affect mortality and recovery of renal function in ICU patients with AKI, and are recommended.

Hemodiafiltration (HDF) is usually performed in the ICU as a continuous modality. However, acute intermittent HDF can be performed with use of sterile replacement fluid generated from ultrapure dialysate ("online"), which is infused directly into the extracorporeal blood circuit. As with high-flux dialysis, limited clinical data do not show obvious advantages.

Dialysate for intermittent ARRT can either be delivered by a batch system or generated online by a single-pass system. The latter uses concentrate and tap water that is purified by reverse osmosis in a central water purification plant or portable unit. Most ICUs do not have a central plant, although this is increasingly common in units in which on-line HDF is performed. There is concern about the possibility of backfiltration of bacterial contaminants, specifically endotoxin, which could exacerbate cytokine-mediated injury. At this time, the reference standards for water purity in the ICU setting are the same as those for the end-stage renal disease (ESRD) setting (www.iso.org; see Box 74-1). Online replacement fluid for HDF is sterilized with ultrafilters in the dialysate pathway and does not differ from commercial preparations in terms of microbial counts, endotoxin concentration, and cytokine-inducing activity. Sterile dialysate is suggested by some for all acute intermittent HD, although there are insufficient data to support a strong recommendation.

Strategies to Reduce Intradialytic Hemodynamic Instability During Intermittent Hemodialysis

Intradialytic hypotension is detrimental for end-organ function and recovery. Fresh ischemic lesions in kidney biopsy specimens can be found in patients on ARRT of longer than 3 weeks' duration. The relatively high ultrafiltration rate (UFR) with acute intermittent HD often leads to intradialytic hypotension, which reduces residual renal function. Increasing the frequency and treatment time of intermittent HD minimizes ultrafiltration goals and is the most effective measure to minimize intradialytic hypotension. Certain technical features on dialysis machinery are also helpful. Hemodynamic stability is facilitated by precise and predictable fluid removal, especially when the fluid removal is greater than that required for the restoration of euvolemia, such as for HDF. Hence, machines with computerized flow or volumetric ultrafiltration control are preferred.

Bicarbonate-buffered dialysate should be used routinely in critically ill AKI patients. It is associated with less hypotension than acetate dialysate, which has a peripheral vasodilating and myocardial depressant effect.

Hemodynamic stability is also facilitated by sodium profiling during intermittent HD. The rapid reduction in serum osmolality with intermittent HD promotes water movement into cells, thus reducing effective circulating volume. Dialysate sodium concentration can vary from approximately 130 to 150 mmol/l. The default for intermittent HD and PIRRT is approximately 145 mmol/l and avoids changes in sodium mass balance that can lead to marked fluid shifts and therefore intradialytic hypotension. Sodium profiling further ameliorates this process by inducing water flux into the vascular compartment, although an alternative and simpler approach of use of a high-sodium dialysate (e.g., 145 to 150 mmol/l) may also work and needs to be tested. A randomized study showed that intermittent HD with sodium profiling (starting at 160 mmol/l, reducing to 140 mmol/l) combined with ultrafiltration profiling (50% of ultrafiltration volume removed in first third of treatment) improved hemodynamic stability.[14] Profiling seems to be effective, although it should be used carefully in patients with dysnatremias, in whom serum sodium concentrations should be corrected slowly to minimize the risk of neurologic complications.

Online blood temperature and blood volume monitoring involves biofeedback systems that automatically adjust intermittent HD operating parameters. Blood volume monitoring adjusts UFR and dialysate sodium content in response to a fall in circulating blood volume, and blood temperature monitoring maintains blood temperature at a target value by controlling thermal transfer to and from dialysate to avoid vasodilation and decreased vascular resistance. Although helpful in the ESRD setting, neither technique has been shown to prevent intradialytic hypotension in the ICU setting.[15,16] The likely reasons pertain to different causes and compensatory mechanisms for hypotension that probably differ in the two settings.[17]

High dialysate calcium (1.75 mmol/l) has been used to improve hemodynamic stability during intermittent HD in ESRD patients with cardiomyopathy. This technique is limited by the development of hypercalcemia, however, and has not been studied in the ICU setting.

A number of early observational studies demonstrated less intradialytic hypotension during intermittent HDF in the ESRD setting, although prospective controlled trials, such as the Convective Transport Study (CONTRAST), have not supported this finding.[18] It is unlikely that intermittent HDF reduces intradialytic hypotension in critically ill AKI patients.

Extensive cumulative clinical experience shows that lower-efficiency modalities of ARRT provide better hemodynamic stability because of slower fluid and solute removal. This is supported by meta-analyses showing better preservation of blood pressure and lower vasopressor requirements in those treated with CRRT rather than intermittent HD.[1,19] Several prospective clinical trials and many observational studies have also shown comparable hemodynamic stability between CRRT and PIRRT.[20-23] Lower-efficiency prescriptions of PIRRT and CRRT are therefore suitable for ameliorating intradialytic hypotension, and the first choice of ARRT modality for hemodynamically unstable patients.

Prolonged Intermittent Renal Replacement Therapy

Prolonged intermittent renal replacement therapy uses standard intermittent HD equipment and consumables, but with lower solute clearances and UFR maintained for prolonged periods of time.[24] Typically, treatment duration is 6 to 18 hours. Dialysate flow rate *(Qd)* is usually 200 to 300 ml/min, and urea clearances are therefore lower and higher than in intermittent HD and CRRT, respectively, allowing for scheduled downtime without compromising dialysis

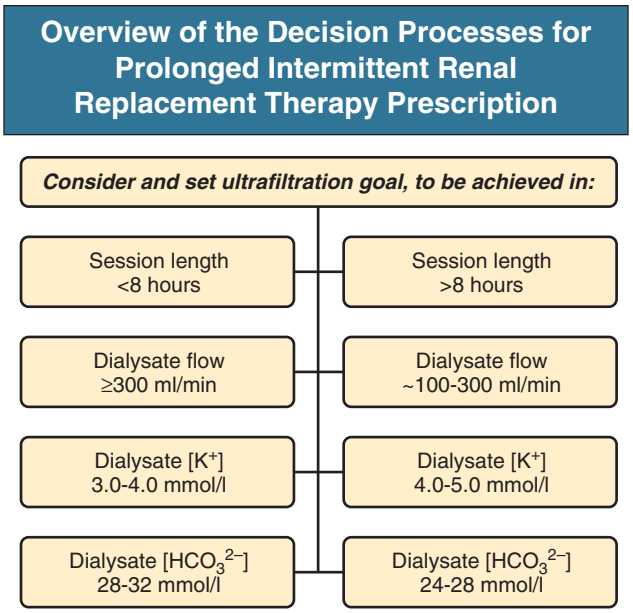

Figure 74-2 Overview of the decision processes for prolonged intermittent renal replacement therapy prescription.

dose. With longer treatments, phosphate replacement may be required at 0.1 to 0.2 mmol/kg or by adding 30 to 45 ml of a bowel preparation containing sodium dihydrogen phosphate dihydrate and disodium phosphate (e.g., Fleet Phospho-Soda) to dialysate. In addition, dietary protein should be supplemented by 0.2 g of protein per kilogram per day. A prescription algorithm is shown in Figure 74-2.

Prolonged intermittent renal replacement therapy provides a high dose of dialysis with minimal urea disequilibrium, excellent control of electrolytes, and good tolerance to ultrafiltration.[20] PIRRT is usually delivered as a diffusive therapy, although there is increasing experience with combined diffusive and convective clearance.

Dosage of Acute Intermittent Renal Replacement Therapy

The relationship between small-solute clearance and the outcomes of critically ill AKI patients is now established. A key study from 20 years ago showed that delivered single-pool *Kt/V (spKt/V)* above 1.0 per intermittent HD treatment was associated with improved survival in patients with intermediate illness severity, although the study did not relate outcomes to frequency of treatments.[25] Most recently, a well-conceived and executed prospective, randomized controlled trial showed that delivered *spKt/V* of 1.2 to 1.4 per intermittent HD or PIRRT treatment five to six times per week did not improve survival compared with this dose thrice weekly.[26] There are consistent data restricted to PIRRT from the Hannover Dialysis Outcome Study, a smaller but well-executed randomized clinical trial (see later).[27]

Optimal intermittent HD dose therefore appears to be related to small-solute clearance, although there appears to be a dose above which survival becomes dose independent. The minimum recommended intermittent HD and PIRRT dose in ICU patients with AKI is a delivered *spKt/V* of at least 1.3 per treatment at least thrice weekly.[1] Because routine dialysis regimens used in the United States in this setting have been reported to deliver a dose of *spKt/V* that is less than 1, routine measurement of dose should be undertaken to guide appropriate adjustment of operating parameters as summarized in Box 74-2. If this dosage target cannot be achieved, dose should be maintained as high as possible and treatment frequency

Measures to Increase Intermittent Hemodialysis Dose

- **Maximize hemodialyzer surface area** (up to 2 to 2.2 m^2)
- **Maximize hemodialyzer porosity** (high flux)
- **Maximize blood flow rate** by:
  - Maximizing internal lumen diameter of catheter (up to 2.0 to 2.2 mm)
  - Titrating blood flow to maximum arterial and venous pressure (up to − and + 300 to 350 mm Hg, respectively)
  - Correcting position of catheter tip in SVC and IVC as appropriate
  - Use right-sided IJ and SC in preference to left-sided IJ and SC
- **Minimize access recirculation** by correcting position of catheter tip in superior or inferior vena cava as appropriate using internal jugular and subclavian, rather than femoral, catheters
- **Maximize dialysate flow** (up to 800 to 1000 ml/min)
- **Add postdilution HDF**
- **Optimize anticoagulation** to reduce hemodialyzer fiber bundle clotting
- **Optimize circulation** to reduce compartmental urea sequestration
- **Increased treatment frequency** (up to daily)
- **Increased treatment duration** (up to 6 to 8 hours, then consider PIRRT [SLED] or CRRT)

increased. The required number of treatments per week and administration interval can be established from the nomogram in Figure 74-3, expressing combinations of intermittent HD dose and treatment frequency as a continuous small-solute clearance (expressed as the corrected equivalent renal urea clearance [EKRc]), aiming for a value of 13 ml/min or higher.[28,29] This expression of dose is useful to frame interpretation of outcomes in the Hannover Dialysis Outcome Study: patients treated with daily PIRRT to keep plasma urea at 11.3 ± 4 mmol/l (EKRc equal to 20 ml/min, assuming urea generation of 20 mg/min) had outcomes indistinguishable from those of patients treated to keep plasma urea at 19 ± 6 mmol/l (EKRc equal to 13 ml/min).[27] In both arms, the doses expressed as EKRc were above the value that defines adequate intermittent HD delivering an *spKt/V* of 1.3 or higher at least thrice weekly (EKRc ≥ 13 ml/min in Fig. 74-3).

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapy involves the application of lower UFR and solute clearances for substantial periods every day. The lower UFR provides comparatively better hemodynamic stability than intermittent HD, especially during ultrafiltration of large obligatory fluid loads, and the lower solute clearances result in single-pool solute kinetics despite disparities between regional blood flows resulting from pressor use. The longer treatment duration results in better and more consistent control of uremic solutes, especially for severely catabolic patients.

Interruptions to CRRT because of circuit clotting or out-of-unit procedures lead to a reduction in dose from downtime as well as expense related to blood circuitry changes. Mean operating time for

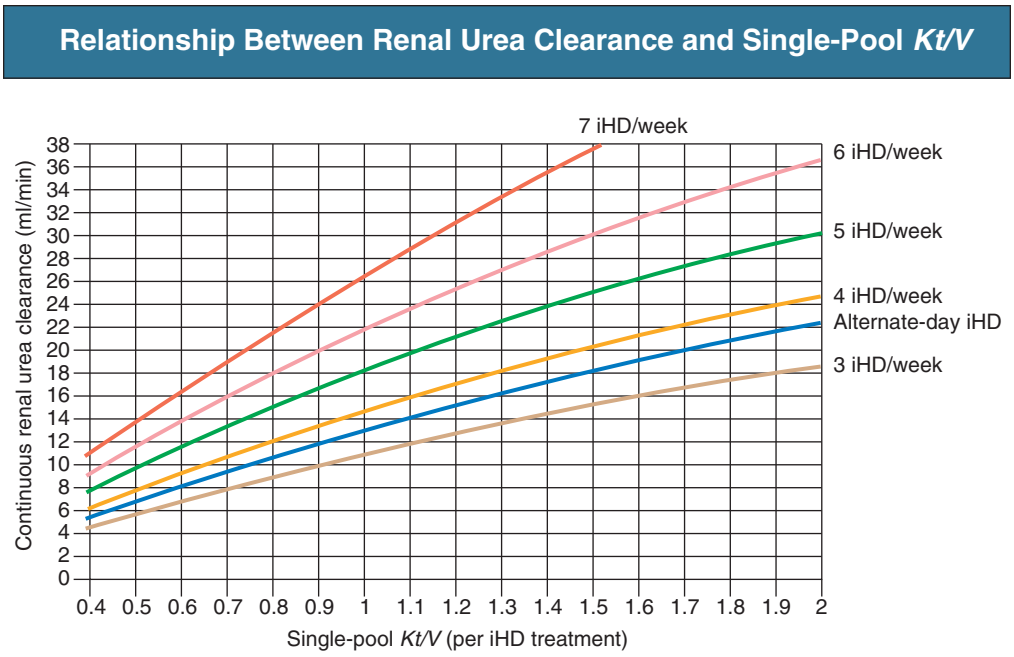

Figure 74-3 Relationship between corrected continuous renal urea clearance and single-pool *Kt/V* (weekly urea clearance/volume of distribution of urea) per treatment for a frequency of three to seven treatments per week. *iHD,* Intermittent hemodialysis. *(From reference 56.)*

CRRT has been reported to be between 17 and 22 h/day.[30] It is therefore important to apply rigorous protocols, including proper catheter tip positioning and anticoagulation, to ensure adequate delivery of CRRT.

Techniques for Continuous Renal Replacement Therapy

The Acute Dialysis Quality Initiative (www.adqi.net) classification of CRRT is accepted as standard and uses nomenclature based on the type of vascular access and the method of solute removal.

Venovenous (VV) denotes a circuit with a central venous catheter, achieving more reliable and rapid blood flow rate *(Qb)* of approximately 250 ml/min by a mechanical pump. Pumped VV circuits are more complex and costly and have the disadvantage of potential inadvertent disconnection of lines, resulting in hemorrhage or air embolism with continued pump operation; this risk is minimized by monitors and alarms. *Arteriovenous* (AV) denotes an extracorporeal blood circuit in which an arterial catheter allows blood to circulate by systemic blood pressure. A venous catheter is placed for return. AV circuits are simple but involve arterial puncture, which can lead to distal embolization, hemorrhage, and vessel damage. A *Qb* of 90 to 150 ml/min is typical in patients with mean arterial pressure above 80 mm Hg, although flow can be erratic, predisposing to clotting.

Mechanisms of Solute Removal

Hemodialysis

Continuous HD provides diffusive small-solute transport. *Qb* and *Qd* during CRRT are usually relatively low (approximately 150 ml/min and approximately 2 l/h, respectively). Under these conditions, the ratio of dialysate-urea nitrogen to blood urea nitrogen (DUN/BUN) is 1.0, indicating complete saturation. Urea clearance therefore equals *Qd* and is unaffected by *Qb* until it decreases to below 50 ml/min.

With increasing *Qd*, there are proportionally decreasing gains in small-solute clearance as the DUN/BUN progressively decreases.

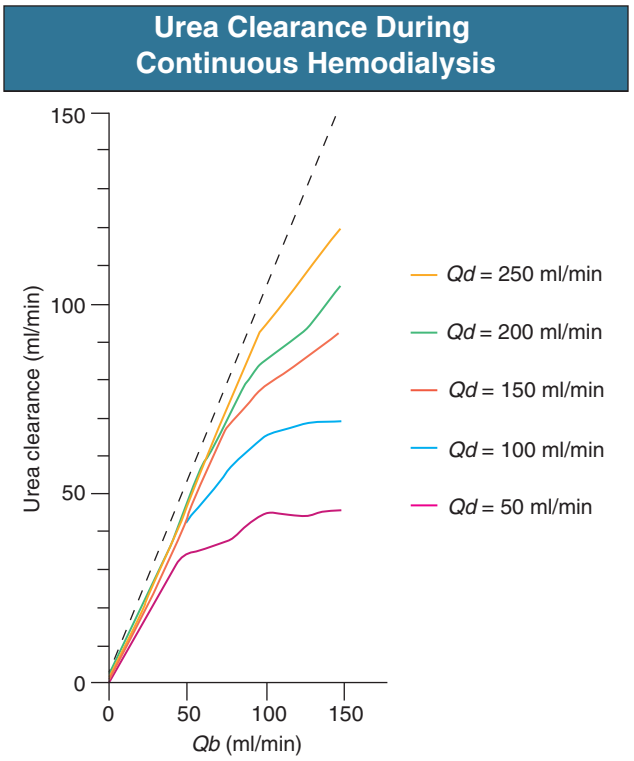

Figure 74-4 Determinants of urea clearance during continuous hemodialysis. Relationship among urea clearance, *Qb* (blood flow), and *Qd* (dialysate flow) during continuous hemodialysis. The flattening of the urea clearance curves describes the conditions in which increases in *Qb* do not enhance clearance. *(From reference 31.)*

Figure 74-4 illustrates this principle.[31] The flattening of the curves describes the conditions where increasing *Qb* does not enhance clearance. At a *Qb* of 200 ml/min, urea clearance will correspond to *Qd* at a rate of 2 l/h (or less) and will not increase with increased *Qb*. If *Qd* is increased to 4 l/h, this will correspond to a urea clearance

of approximately 3 l/h that will progressively increase with increasing *Qb*.

Hemofiltration

Continuous HF provides convective small- and medium-sized–solute transport. An important determinant of clearance is the site of fluid replacement, which can be infused either into the arterial blood line leading to the hemofilter (predilution) or into the venous blood line leaving the hemofilter (postdilution). The standard method is postdilution. However, higher UFR can lead to hemoconcentration in the hemofilter, increased resistance in the blood flow pathway, reductions in *Qb*, and ultimately increased risk for clotting of the hemofilter. In practice, UFR should not exceed 30% of the plasma water flow rate (i.e., filtration fraction should be below 0.30). The problem can be resolved by increasing *Qb* to at least 200 to 250 ml/min or by diluting the blood and clotting factors with replacement fluid before it reaches the hemofilter (predilution), thereby improving filter patency and decreasing anticoagulant requirements.

The disadvantage of predilution is that filtrate is generated from blood diluted with replacement fluid and therefore contains a lower concentration of uremic solutes. Small-solute clearance is reduced by approximately 15% at low UFR, although this figure increases to approximately 40% with a higher UFR.[32,33] Clearance of any given solute during continuous HF is calculated as follows:

$$K\,(\text{postdilution}) = \text{UFR} \times S$$

$$K\,(\text{predilution}) = \text{UFR} \times S \times [\text{Qbw}/(\text{Qbw} + \text{Qr})]$$

where *K* is clearance (ml/min), *S* is the sieving coefficient of the solute, *Qbw* is blood water flow rate equal to the product of *Qb* and (1 – hematocrit), and *Qr* is the replacement fluid rate.

Hemodiafiltration

Continuous HDF refers to a combination of the preceding techniques. With large enough membranes, the small-solute clearances obtained approach the sum of the individual techniques.[32]

Specific Techniques

Continuous renal replacement therapy techniques are shown in Figure 74-5. The choice of technique is dependent on equipment availability, clinician expertise, prospects for vascular access, and whether the primary need is for fluid and/or solute removal. This last factor is often the most important because each technique provides different rates of fluid and solute removal. Most clinicians avoid AV circuits because of higher vascular complication rates.

For isolated fluid removal, slow continuous ultrafiltration (SCUF) can be used. Given its minimal solute clearance (equal to the UFR at generally 4 to 5 ml/min), SCUF has primarily proven useful for treatment of the cardiorenal syndrome.

Most ICU patients require removal of solute in addition to that of fluid. For this, most clinicians prefer pumped VV rather than AV circuits because of higher and more reliable *Qb*, allowing for greater solute clearance. It should be noted that the benefit of larger-solute clearance is uncertain in this population, whereas the benefits of small-solute clearance are more evident (see later). It should also be

Continuous Renal Replacement Therapies

	Slow continuous ultrafiltration	Continuous hemofiltration	Continuous hemodialysis	Continuous hemodiafiltration
				Arteriovenous (AV) or venovenous (VV)	AV or VV	AV or VV	AV or VV	AV or VV
Blood flow (ml/min)	50–100	50–200	50–200	50–200
Dialysate flow (ml/min)	–	–	10–20	10–20
Clearance (l/24 h)	–	12–36	14–36	20–40
Ultrafiltration rate (ml/min)	2–5	8–25	2–4	8–12
Blood filter	Highly permeable filter	Highly permeable filter	Low-permeability dialyzer with countercurrent flow through the dialyzer compartment	High-permeability dialyzer with countercurrent flow through the dialyzer compartment
Ultrafiltrate	Corresponds exactly to the patient's weight loss	Replaced in part or completely to achieve purification and volume control	Corresponds to patient's weight loss; solute clearance by diffusion	In excess of patient's weight loss; solute clearance by both diffusion and convection
Replacement fluid	None	Yes	None	Yes, to achieve fluid balance
Efficiency	Used only for fluid control in overhydrated states	Clearance for all solutes equals ultrafiltration	Limited to small molecules	Extends from small to large molecules

Figure 74-5 Continuous renal replacement therapy modalities. The pump *(P)* is used only in venovenous modes. *(Modified from reference 57.)*

noted that the practice of treating lactic acidosis with CRRT should be discarded. The only effective treatment for lactic acidosis is addressing the cause of lactate formation (improving tissue oxygenation, removing dead gut, and so on); extracorporeal lactate clearance is 10-fold to 100-fold lower than plasma clearance through hepatic metabolism.

Dosage of Continuous Renal Replacement Therapy

Continuous renal replacement therapy dose is expressed as effluent volume flow rate per unit of premorbid or pre-ICU weight (ml/kg/h). Despite mixed results in earlier single-center studies, the relationship between CRRT dose and mortality has been established in several well-powered and definitive clinical trials, the most important of which are the Acute Renal Failure Trial Network Study and the Randomised Evaluation of Normal Versus Augmented Level of Replacement Therapy (RENAL) trial. As with intermittent HD, there appears to be a dose of CRRT above which survival becomes dose independent. This "break point" in the CRRT dose-response curve varies by study, although taken together the data show no benefit of increasing CRRT doses above an effluent volume flow rate of 20 to 25 ml/kg/h. In clinical practice, interruptions to CRRT will compromise dose, and it is generally necessary to prescribe in the range of 25 to 30 ml/kg/h while minimizing downtime. As for intermittent HD, quality assurance mandates routine measurement of dose to guide appropriate adjustment of operating parameters. Of note, optimal CRRT dose appears to be related more to small- than larger-solute clearance, although several clinical trials of increased convection through high-volume hemofiltration are awaited.

Technical Aspects of Continuous Renal Replacement Therapy

Equipment

Machines are commercially available that are dedicated to VV CRRT, with an integrated blood pump, arterial and venous pressure monitors, an air detection system, a method for removing air bubbles, and computerized volumetric or gravimetric systems to balance dialysate inflow and replacement fluid with dialysate outflow/filtrate.

Hemofilters

Specific devices for CRRT are usually referred to as *hemofilters*. However, conventional inexpensive hemodialyzers can serve as hemofilters. For adequate UFR to be achieved, the surface area must be large (approximately 2 m^2) for low-flux or, alternatively, more modest (approximately 0.5 m^2) for high-flux hemodialyzers. Some CRRT machines use a specific hemofilter because of a unique cartridge system. Sieving coefficients of small solutes are maintained throughout the life of hemofilters only in the absence of fiber bundle clotting, and a progressive decrease in DUN/BUN or filtrate urea nitrogen–BUN ratio may be noted throughout treatments. Monitoring of this parameter is recommended by some to guide prophylactic changes of hemofilters, thereby avoiding the advent of total extracorporeal circuit clotting and wastage of blood, as well as any associated compromise of CRRT dose from declining saturation of effluent.

There is promise in the use of superflux hemofilters as discussed previously, and studies are under way to determine effects on clinical outcomes. Albumin losses may prevent the prolonged use of such filters.

Replacement Fluids and Dialysate

Continuous renal replacement therapy requires sterile replacement fluid or dialysate for blood purification, with composition that is determined by the clinical requirements for acid-base control and electrolyte management. Fluids are available commercially or can be prepared aseptically in hospital pharmacies.

Buffer choice is between bicarbonate and lactate, the latter being metabolized in the liver to bicarbonate in a 1 : 1 ratio. Although many patients tolerate lactate solutions, bicarbonate solutions are superior in terms of acid-base control, hemodynamic stability, urea generation, cerebral dysfunction, and possibly survival in patients with a history of cardiac failure. Overall, bicarbonate has become the buffer of choice and is preferred in patients with lactic acidosis and/or liver failure. If lactate-buffered fluids are used, the development of lactate intolerance (>5 mmol/l increase in serum lactate during CRRT) may require a switch to bicarbonate-based fluid. Bicarbonate concentrations in fluid are typically 25 to 35 mmol/l: concentrations in the lower part of this range are indicated during high-dose or prolonged CRRT and during regional citrate anticoagulation therapy to prevent metabolic alkalosis.

Glucose concentrations in fluids range from 0.1% in commercially prepared fluids to 1.5% to 4.25% in PD fluids adapted for use with CRRT. Up to 3600 kcal/day may be derived from these latter solutions, although hyperglycemia may supervene to the detriment of patient outcomes. It is recommended that glucose intake be less than 5 g/kg/day and that glucose concentration in fluid be approximately 100 to 180 mg/dl (approximately 5.5 to 10 mmol/l) to maintain zero glucose balance.

Intravenous phosphate supplementation is often required during CRRT and is usually administered separately because of the potential for precipitation with calcium and magnesium in dialysate or replacement fluid. This concern may have been overstated in the past, and phosphate has been safely supplemented by injecting phosphate into these solutions. Moreover, replacement solutions containing up to 1.2 mmol/l of phosphate are commercially available or will soon become available.

VASCULAR ACCESS

A prerequisite for all ARRT modalities is reliable vascular access characterized by low resistance to flow and minimal access recirculation. AV fistulas and prosthetic bridge grafts should be used in patients who have them. However, access is usually via uncuffed untunnelled (temporary) double-lumen polyurethane or silicone catheters in the internal jugular, femoral veins, or less frequently subclavian catheters because they are associated with a higher incidence of procedural complications, venous stenosis, and thrombosis.

For CRRT and PIRRT, *Qb* below 250 ml/min is usually sufficient. For acute intermittent HD, higher *Qb* is sometimes required to allow sufficient solute clearance within a clinically or logistically appropriate dialysis schedule. Flows can be safely increased until venous and arterial pressures are plus and minus 350 mm Hg, respectively, after which hemolysis can occur. Left-sided internal jugular and subclavian catheters provide flows that are more erratic and up to 100 ml/min lower than elsewhere. Femoral and right-sided internal jugular or subclavian catheters provide the best *Qb*.[34]

Access recirculation for all sites is approximately 10% at *Qb* 250 to 350 ml/min and may increase to as much as 35% at *Qb* above 500 ml/min. It is least in internal jugular catheters and highest in femoral catheters less than 20 cm in length. Up to half of acute intermittent HD treatments will require catheters to be used in

reversed configuration, such that the original venous line is used as for blood inflow (relative to dialyzer) and the original arterial line for outflow. Access recirculation in this situation doubles to approximately 20% at 250 to 350 ml/min.[34] It also affects dialysis dose, and several studies have shown lower dialysis dose with femoral catheters despite identical operating parameters. Recent advances in catheter design minimize access recirculation through the use of symmetric (nonstepped) bias-cut spiraled ports on their tips. In both animal and preliminary human studies, this design results in minimal or acceptable access recirculation in both normal and reversed configuration. Overall, the data support a recommendation for right-sided internal jugular catheters with bias-cut spiraled ports as the first choice for intermittent HD and PIRRT, with femoral and left-sided internal jugular catheters as the second and third choices, respectively.

In the ICU setting, catheter associated bloodstream infection is common and is associated with a mortality risk estimated at 10% to 50%. There is ongoing controversy around the risk of infection with different insertion sites, but on balance the internal jugular site is preferred—although it is likely that the way the catheter is handled is more important at preventing infection than the site in which it is inserted.

Low rates of infection require both adherence to specific clinical guidelines and grounding of activities within a formal quality improvement framework.[35] There is strong evidence that standardizing catheter insertion techniques and adhering to the previously mentioned quality initiatives result in a close to zero catheter-related infection rate.[36] The relevant guidelines in choosing interventional bundles are those contained in the position statements of the Institute for Healthcare Improvement (IHI) and the Center for Disease Control and Prevention (CDC) Healthcare Infection Control Practices Advisory Committee (HICPAC).[3,4] The core elements in these guidelines appropriate for dialysis catheters are listed in Box 74-3.

Best Practices to Minimize Catheter-Associated Bloodstream Infection

Insertion

- Hand hygiene and aseptic technique (including early replacement of catheters inserted in uncontrolled settings if adherence to these measures cannot be ensured)
- Maximum barrier precautions (hat, mask, sterile gloves, sterile gown, and full patient drape)
- Appropriate skin preparation (2% chlorhexidine in 70% alcohol)
- Avoidance of the femoral site for catheter placement, especially in obese patients
- Avoidance of catheter placement near open wounds

Maintenance

- Daily review of the need for the line, with prompt removal of unnecessary lines
- Appropriate dressing with sterile gauze or a sterile, transparent, semipermeable dressing
- Appropriate schedule for dressing changes according to condition and type of dressing
- Daily review of the catheter exit site by inspection or palpation with minimal disturbance to the dressing unless clinically indicated
- Appropriate skin preparation before ports are accessed
- Daily cleansing of patients with a 2% chlorhexidine wash
- Use of a sutureless securing device for catheter stabilization

Box 74-3 Best practices to minimize catheter-associated bloodstream infection.

Antibiotic- or antiseptic-impregnated lines are recommended by the CDC for patients whose catheters are expected to remain in place for a prolonged period (longer than 5 days), when there is optimal adherence to measures to reduce infection, and also in patients at high risk for infection (patients with extensive burn injury, neutropenia, and arguably AKI). A potential downside of these impregnated lines is anaphylaxis.[37] Topical antibiotic ointments are not recommended because of their potential to promote fungal infections and antimicrobial resistance. Catheter-restricted locking solutions are effective at reducing catheter-associated infections in chronic intermittent HD.[3,5] However, their efficacy in critically ill AKI patients is unresolved and warrants further study.

ANTICOAGULATION IN ACUTE RENAL REPLACEMENT THERAPY

Most ICU patients can successfully avoid any anticoagulation during intermittent HD because of the short treatment duration. Only a minority can do so during PIRRT or CRRT, however, and anticoagulation is required to prevent clotting in the extracorporeal circuit without producing significant bleeding. Most commonly, unfractionated heparin is infused into the most proximal part of the extracorporeal circuit, keeping the activated partial thromboplastin time (APTT) in the venous blood line 1.5 to 2 times the control value and the systemic APTT below 50 seconds. This typically requires an initial bolus dose of approximately 2000 U and a maintenance infusion of approximately 500 U/h. Advantages of unfractionated heparin include low cost, relative safety, and ease of monitoring. Risks include bleeding, hyperkalemia, elevated hepatic transaminases, and heparin-induced thrombocytopenia (HIT) in 3% to 5% of patients.

Low-molecular-weight heparin (LMWH) is theoretically advantageous because of increased antithrombotic activity and decreased hemorrhagic risk. However, disadvantages include a prolonged half-life (approximately doubled in AKIN stage 3, with no significant clearance during ARRT), incomplete reversal with protamine, and limited availability of appropriate monitoring by serial anti–factor Xa determinations (recommended level 0.25 to 0.35 U/ml). Meta-analyses and the American College of Chest Physicians (ACCP) guidelines conclude that the use of LMWH is associated with major bleeding in patients with a creatinine clearance below 30 ml/min, and recommend either unfractionated heparin or a reduction in LMWH dose by 50% for such patients.[6,38] LMWH dosage is not interchangeable between different drugs. If LMWH is used, most experience is with dalteparin administered as a single bolus of approximately 20 to 30 U/kg for intermittent HD, followed by an infusion of approximately 10 U/kg/h for PIRRT. Overall, evidence does not support a recommendation of LMWH over unfractionated heparin in terms of safety and efficacy in the critically ill AKI setting, although it is not contraindicated in those with a low risk of bleeding.

Other approaches to anticoagulation include direct thrombin inhibitors (e.g., argatroban), antithrombin-dependent factor Xa inhibitors (e.g., fondaparinux), and serine protease inhibitors (nafamostat mesilate). Their roles are usually limited to anticoagulation of patients with HIT. Argatroban does not cross-react with heparin antibodies and is the preferred approach because of its hepatic clearance (half-life approximately 35 minutes, no significant clearance during intermittent HD or PIRRT[39]) and ease of monitoring with APTT. It is administered as a 0.1-mg/kg bolus before intermittent HD or an infusion of 0.1 to 0.2 mg/kg/h during PIRRT, titrated according to APPT. Further management of HIT is provided in

guidelines from the ACCP and the European Best Practice Guidelines.[6,8]

For those receiving systemic anticoagulation with heparin, the incidence of significant bleeding complications is up to 25% to 30%. Alternatives to systemic anticoagulation include regional citrate anticoagulation, regional heparin anticoagulation, and prostacyclin (epoprostenol). The lowest rates of hemorrhage and greatest prolongation of filter life are associated with regional citrate anticoagulation, and it is the preferred regional technique.

Regional citrate anticoagulation involves calcium chelation in the extracorporeal blood circuit with calcium reversal. For intermittent HD and PIRRT, this most commonly involves an infusion of 4% trisodium citrate into the proximal circuit, with zero- or low-calcium dialysate and an infusion of calcium chloride into the venous blood line. A simpler approach has been described in which the citrate infusion is combined with normal calcium dialysate and no calcium infusion. The positive calcium flux through the hemodialyzer maintains calcium balance without the need for a separate infusion and provides partial chelation of the undialyzed citrate.

For CRRT, regional citrate anticoagulation may be performed with 4% trisodium citrate or with anticoagulant citrate dextrose A. The latter is preferred over sodium citrate because it is less hypertonic, potentially reducing complications from overinfusion and mixing errors. For continuous HD, a prefilter infusion of 3% to 7% of *Qb* with a postfilter infusion of calcium chloride is used. This requires dialysate that is hyponatremic and devoid of alkali because citrate metabolizes to bicarbonate in the liver in a 1:3 ratio. For continuous HF, a prefilter infusion of substitution fluid can be used that contains no calcium but citrate as buffer (Table 74-1). Frequent monitoring and titration of citrate dose have usually been advocated to keep the ionized calcium within a therapeutic range. Many centers now use a simplified fixed-dose anticoagulant citrate dextrose A protocol that minimizes the need to measure postfilter calcium or adjust the citrate infusions. Major complications of regional citrate anticoagulation include systemic hypocalcemia and metabolic alkalosis from citrate toxicity, particularly in patients with liver dysfunction.

Regional heparin anticoagulation involves neutralization of heparin by infusion of protamine into the venous blood-line. It may be complicated by rebound bleeding, occurring when neutralization with protamine wears off faster than the anticoagulation from heparin. Furthermore, protamine may cause sudden hypotension, bradycardia, or anaphylactoid reactions.

Prostacyclin is an effective alternative anticoagulant. However, it is a vasodilator, causing a variable but occasionally marked decrease in blood pressure. Moreover, there is a risk of worsening ventilation-perfusion mismatch and lactic acidosis in patients with multiorgan dysfunction, and a risk of increasing intracranial pressure in patients with combined liver and kidney failure.

MODALITY CHOICE AND OUTCOMES IN ACUTE RENAL REPLACEMENT THERAPY

On the basis of current evidence, the use of one modality of ARRT over another is unlikely to translate to overall clinical benefit if applied to all patients.[1,19] The relationship between modality choice and outcomes is being studied in specific clinical situations such as acute lung injury, sepsis, and acute cardiac decompensation. Such studies may yet yield definitive data, but in the interim, modality choice depends on the most clinically appropriate rate of solute and fluid removal for the given clinical situation. Certain patients are best treated with a lower-efficiency modality, such as those who are hemodynamically unstable, including those with cardiogenic shock.[40] Although tolerance to ultrafiltration during intermittent HD can be improved, patients still often require a change to a lower-efficiency modality as evidenced by contamination between the arms in the Continuous Venovenous Haemodiafiltration Versus Intermittent Haemodialysis for Acute Renal Failure in Patients with Multiple-Organ Dysfunction Syndrome (Hemodiafe) study.[41] Given the risks of hypotension and subsequent fresh ischemic injury, PIRRT and CRRT are more desirable for such patients. The same applies to those who are at risk for dialysis disequilibrium syndrome. Solute disequilibrium should be minimized to avoid water influx into the brain in

Comparison of Regional Citrate Anticoagulation Protocols

	Modality	Blood Flow (ml/min)	Replacement Fluid Composition (mmol/l)	Dialysis Fluid Composition (mmol/l)	Citrate Source
Mehta et al[47] (1990)	CAV-HD	52-125	Normal saline	Na 117, Cl 122.5, Mg 0.75, K 4, dextrose 2.5%	4% Trisodium citrate
Hoffmann et al[49] (1995)	CVV-HD	125	Prefilter: normal saline + KCl 4, alternate with 0.45% saline + KCl 4 Postfilter: 0.45% saline + $MgSO_4$ + $CaCl_2$	—	4% Trisodium citrate

those with cerebral edema or high intracranial pressure, and influx into the abdomen in those with compartment syndrome.[40]

An important determinant of modality choice is cost, and the complex extracorporeal circuits and requirement for replacement fluids generally make CRRT more expensive than intermittent HD or PIRRT. Pharmacoeconomic studies comparing ARRT modalities are all limited by wide variation in ICU cost and reimbursement structures. The modality that is the easiest to organize and least expensive to perform will be the most successful, if all outcomes are equivalent. Ultimately, the skill and experience of the staff providing ARRT probably influence patient outcomes as much as the choice of modality itself.

ACUTE RENAL REPLACEMENT THERAPY DURING MECHANICAL CIRCULATORY SUPPORT

There has recently been an increase in the use of mechanical circulatory support devices. Two are particularly important to ARRT providers: extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs). ECMO is used for refractory acute cardiac and/or respiratory support. Its use was largely limited to pediatrics, but recent advances have resulted in renewed interest in adults. ECMO can be either venoarterial, in which the blood is drawn from the venous system, oxygenated, and returned into the arterial circulation (providing cardiorespiratory support), or VV, in which the oxygenated blood is returned into the venous circulation (providing only respiratory support).

Ventricular assist devices are blood pumps that assist the left and/or right ventricles in patients with refractory heart failure or cardiogenic shock. They are used as a bridge to recovery, as a bridge to transplantation, or for long-term therapy in patients ineligible for transplant. Early VADs had pulsatile flow, but the limitations of these pumps led to the development of axial and centrifugal pump VADs that create nonpulsatile flow.[42] The improved reliability and results obtained with VADs, together with the increasing prevalence of severe heart failure, have caused a rapid increase in their use.

Acute kidney injury is common in patients with circulatory and/or respiratory failure. If the cause of AKI is simply hypoperfusion, initiating mechanical circulatory support may improve the renal

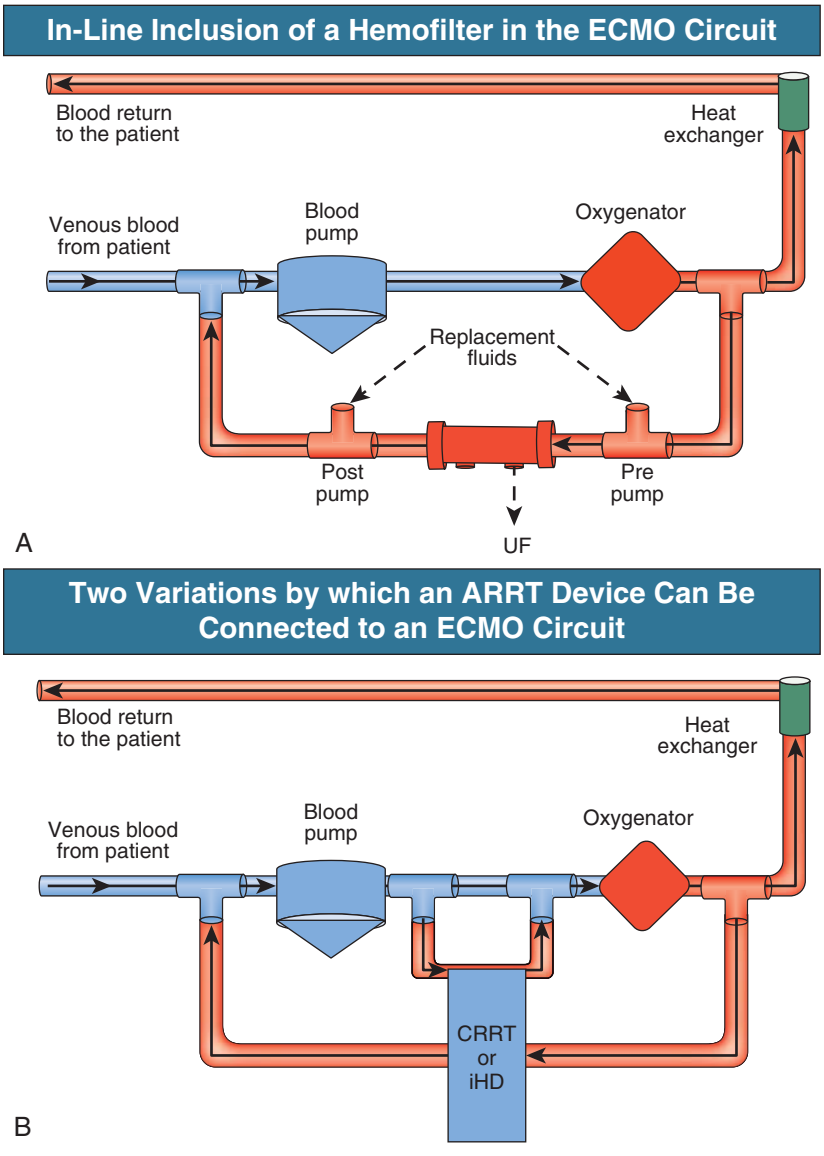

Figure 74-6 Techniques used to incorporate AART into ECMO and VAD circuits. A, In-line inclusion of a hemofilter in the ECMO circuit. Note that inclusion into an RVAD circuit would be similar except simplified in that blood comes from the body to the pump and then goes back to the body without passing through an oxygenator. **B,** Two variations by which an ARRT device can be connected to an ECMO circuit. Note that flow in the mechanical circulatory support circuit is high enough that recirculation is not a concern even when the arterial access port is distal to the venous return port. *ARRT,* Acute renal replacement therapy; *CRRT,* continuous renal replacement therapy; *ECMO,* extracorporeal membrane oxygenation; *iHD,* intermittent hemodialysis; *RVAD,* right ventricular assist device; *UF,* ultrafiltration.

function.[43] However, it can also be associated with mechanisms that induce AKI, including periprocedural hypotension, inflammation, thromboembolism, hemolysis, and medications. Consequently, AKI remains a common complication of mechanical circulatory support and frequently requires ARRT. Although few data are available to guide the use of ARRT in this situation, the general principles are similar to those for other ICU patients. However, special consideration should be given to volume management in these patients, not only because volume overload is associated with worse outcomes, but also because volume management facilitates weaning of mechanical circulatory support and allows for better delivery of nutrition.[44,45] Consequently, even though all forms of ARRT have been successfully used in patients with mechanical circulatory support, prolonged or continuous modalities are generally advantageous. Monitoring volume status in patients on continuous flow mechanical circulatory support devices can be particularly challenging. Patients have minimal pulses, so specialized blood pressure cuffs with low pulsatility modes are needed, or blood flow is monitored with flowmeters or Doppler. Because continuous flow pumps are dependent on preload, hypovolemia leads to left ventricular collapse with subsequent fall in mechanical circulatory support flow, pump overdrive, hypotension, and ventricular arrhythmias. This should be corrected by gentle volume administration while other causes of preload reduction (e.g., bleeding, sepsis) are considered. Decreasing the pump speed and treating arrhythmias should usually be performed only after detailed consultation. Chest compressions should not be performed.

Technical Aspects of Acute Renal Replacement Therapy During Mechanical Circulatory Support

Patients on mechanical circulatory support present several access options. The first is via standard HD catheters, which have the advantage of maintaining the two circuits independent of each other. The risks are the same as in other patients, but infections are especially hazardous as they are an important cause of death.

An alternative method of accessing the circulation is directly via the mechanical circulatory support circuit. This method is only for ECMO or right ventricular assist device (RVAD) circuits, not left ventricular assist devices (LVADs), because of the unacceptable risk of thromboembolism. Two three-way taps are placed along the mechanical circulatory support circuit to create a shunt for ARRT. The placement sites depend on the type of ARRT that will be used. In the first method, a hemofilter is directly placed in the circuit shunt. Blood flow through the filter is determined by the pressure gradient between the arterial port (located postpump, where the pressure is positive) and the venous port (located prepump, where the pressure is negative). The ultrafiltrate, dialysate, and/or replacement fluid volumes are regulated via infusion pumps (Fig. 74-6, *A*). This method is simple, adds little expense, and does not require another specialized machine. However, the infusion pumps are a source of errors; thus the accuracy of the infused and removed volumes should be confirmed (especially in infants).

In the second method, the three-way taps are used to connect a dialysis or CRRT machine to the mechanical circulatory support circuit. Modern ARRT machines can accommodate positive arterial access pressures; thus numerous access sites have been successfully used (Fig. 74-6, *B*).[46] This setup uses commercially available ARRT machines that control the renal replacement therapy procedure. It requires the use of an ARRT machine and can be labor intensive. The technique used should be determined by the availability of appropriate equipment and the skill and experience of the staff.

DRUG DOSAGE IN ACUTE RENAL REPLACEMENT THERAPY

For patients undergoing CRRT, 20 liters of daily filtrate correspond to a glomerular filtration rate (GFR) of approximately 14 ml/min, and the dose of drugs should be calculated accordingly. Any drug with a low therapeutic index that can be readily measured should be measured frequently early in the course of ARRT, until a stable pattern appears. One day of CRRT is in general comparable to one intermittent HD treatment with regard to drug removal.

CHAPTER 75

Management of Refractory Heart Failure

Edward A. Ross and Kevin Damman

Nephrologists are being increasingly consulted regarding fluid management in patients with refractory heart failure. Renal expertise extends beyond diuretics and electrolyte homeostasis and now includes recent advances in acute and chronic fluid removal by extracorporeal dialysis machines or isolated ultrafiltration (UF) devices, as well as peritoneal modalities.

DEFINITION AND SCOPE OF THE PROBLEM

Heart failure and renal dysfunction may coexist, but each disease can also cause or exacerbate the other. Poor cardiac output results in reduced renal perfusion and may result in kidney ischemia and progressive chronic kidney disease (CKD).[1] Conversely, CKD may result in salt and water retention with subsequent venous congestion, hypertension, activation of the renin-angiotensin-aldosterone system (RAAS), and vascular calcification that cause cardiac dysfunction, accelerated atherosclerosis, and left ventricular hypertrophy and remodeling. These conditions subsequently may exacerbate heart failure, which results in a vicious cycle of reduced cardiac output and kidney dysfunction.

Of the 100,000 patients in the Acute Decompensated Heart Failure National Registry (ADHERE) 57% had CKD stages 3 or 4, 7% were at stage 5 (68% receiving dialysis), and only 9% had normal kidney function. In patients with heart failure who presented with CKD at the time of admission, there was greater use of diuretics and inotropes, less angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) administration, and a 5% higher in-hospital mortality rate.[2]

The cardiorenal syndrome has been classified[3] into several categories, including cardiorenal (heart causing kidney disease), renocardiac (CKD leading to heart failure), and syndromes in which both are primary disorders or secondary to systemic conditions, although the significance of this classification for treatment strategies is unclear.

PATHOGENESIS

Figure 75-1 illustrates the pathogenesis of refractory heart failure.

In the cardiorenal syndrome low cardiac output is the most important aspect of heart failure. Low cardiac output worsens renal perfusion and function, activating the RAAS and other systems, leading to salt and water retention with a subsequent and paradoxical further worsening of cardiac function. Central to this vicious cycle is tubuloglomerular feedback (TGF; described in Chapter 2), which is maladaptive in heart failure and in the case of some drugs that alter tubular sodium delivery. Secondary (hyper)aldosteronism (resulting in increased sodium retention), increased systemic vascular resistance (thereby putting more strain on the heart), and higher cardiac filling pressures may reduce cardiac output as described by the Frank-Starling mechanism, wherein further increase in preload reduces stroke volume. This further activates the sympathetic nervous system (SNS), which in turn worsens vasoconstriction, cardiac function, and renal perfusion. Excessive activation of both the RAAS and SNS pathways has long been considered the hallmark of worsened heart failure. However, other pathophysiologic mechanisms that could have important therapeutic implications have now been elucidated and are discussed in the following paragraphs.

Venous Congestion

There has been a growing appreciation that through multiple pathways right-sided congestion and renal venous hypertension cause kidney dysfunction.[4] In this regard, heart failure would be analogous to such disorders as the abdominal compartment syndrome, portal hypertension, or renal venous thrombosis; however, some of these conditions differ in whether there is extravascular versus intravascular hydrostatic pressure transmitted to the kidneys. Venous hypertension is thought to trigger neuromyogenic changes that decrease renal perfusion, raise kidney interstitial pressure, narrow the arterial-to-venous pressure gradient, lower renal blood flow and glomerular filtration rate (GFR), trigger maladaptive autoregulatory responses, and exacerbate neurohumoral pathways already problematic in heart failure. Furthermore, there is also a direct effect of higher renal venous pressure that transmits to the renal parenchyma. This higher pressure directly opposes filtration in the Bowman capsule, causes collapsing of tubules, and may be the first initiating trigger for tubulointerstitial fibrosis.[5] These mechanisms are consistent with a critical role of the adrenergic system in modulating venous tone and thus capacity. In that veins contain 70% of the circulatory volume, changes to venous capacitance (and pressure) can decompensate or ameliorate heart failure, without changes to total body salt, fluid, or weight.[6] This variation in the venous reservoir volume reconciles how approximately a third of outpatients have heart failure decompensation with minimal change in weight, and how 16% of heart failure inpatients can symptomatically improve despite no weight loss. If validated, this pathway could potentially lead to pharmacologic treatments based on modulation of adrenergic tone. Changes in reservoir capacity would also confound interpretation of simultaneous changes in volume by extracorporeal UF. The importance of congestive renal failure is highlighted by studies in which kidney function in decompensated heart failure correlated better with right-sided pressures than the ejection fraction or cardiac index. In addition, elevated central venous pressures correlated with mortality.[7] Better kidney function resulted when central venous pressures below 8 mm Hg were achieved.[8]

Adenosine Mediators

Adenosine receptors are involved with TGF signaling and maintain intrarenal vascular tone via a number of complex pathways; these

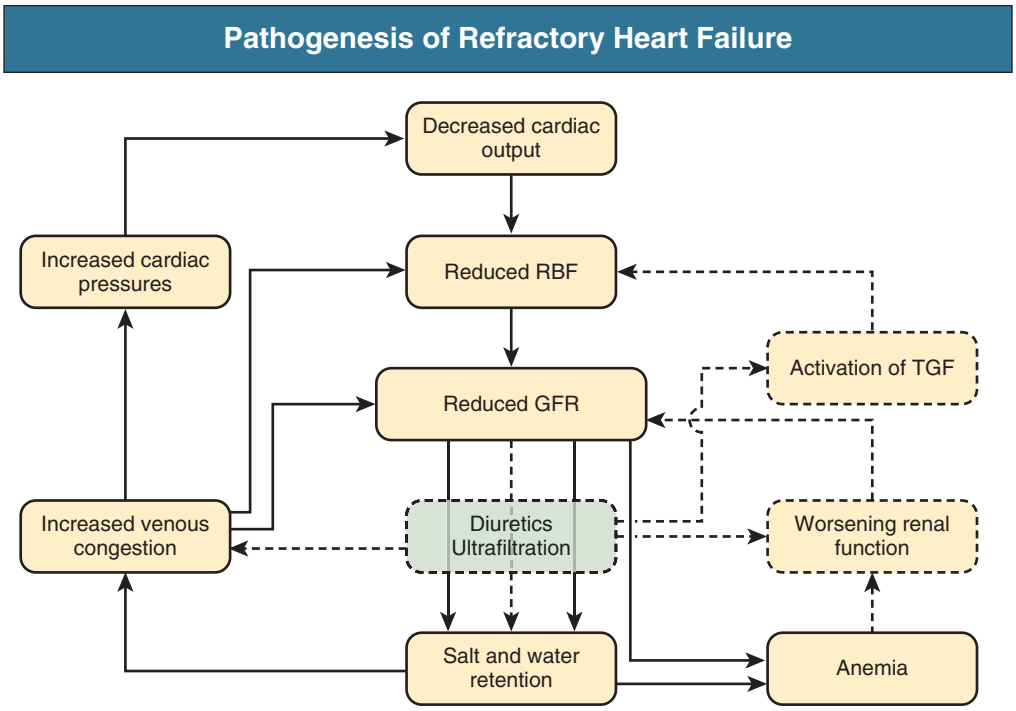

Figure 75-1 Pathogenesis of refractory heart failure. *GFR,* Glomerular filtration rate; *RBF,* renal blood flow; *TGF,* tubuloglomerular feedback. Dashed lines indicate treatment and its effects.

include A_1 receptors (A_1Rs), which cause afferent arteriolar vasoconstriction, and A_2 receptors, which induce efferent vessel dilation. Actions of adenosine at the macula densa and mesangium depend on angiotensin, renin, nitric oxide, and prostaglandin levels. A_1R antagonists could thereby not only restore diuretic sensitivity but also allow appropriate aquaresis in severe heart failure.

Inflammatory Cytokines

Chronic as well as acute exacerbations of heart failure are associated with widespread inflammation and high levels of proinflammatory cytokines, which may further boost cardiac, renal, and other tissue dysfunction.

Anemia

Anemia may be caused by chronic disease or coexistent CKD, or it may be the consequence of hemodilution by venous congestion. The term *cardiorenal anemia syndrome* emphasizes this pharmacologically remediable aspect of heart failure.

Diuretic Tolerance and Adverse Effects

Many patients with heart failure develop tolerance to chronic diuretic therapy, fail to have appropriate natriuresis despite escalating doses, and have worsening of neurohumoral mediator levels—that is, diuretic resistance.[9] Thus some of the cardiac benefits from ACE inhibitors might be from blocking diuretic-induced RAAS activation. Consistent with this paradigm and data from the ADHERE registry, morbidity and mortality in advanced heart failure increased up to fourfold with higher doses of diuretics, despite the fact that there were no clinical or echocardiographic parameters to suggest that the high-dose group had any worse cardiac function.[10] However, when differences in baseline characteristics were controlled for, outcomes with respect to diuretic therapy were similar in a large French registry of patients with acute heart failure.[11] In a multicenter analysis, patients on high-dose diuretics had worsening of GFR compared with the control group on alternative medications, despite equivalent fluid losses.[12] Finally, in the Diuretic Optimization Strategies Evaluation (DOSE) trial (see later), there was no difference in outcome in high- versus low-dose diuretic therapy, despite a higher incidence of (transiently) worsening GFR in the high-dose diuretic group.[13]

TREATMENT

General Approach and Limitations

A pragmatic approach is to first address potentially treatable problems such as valvular disease, conduction disorders and arrhythmias, pericardial effusion, or coronary ischemia (e.g., by angioplasty and stenting) (Box 75-1). The clinician can then approximate the volume of excess fluid and can craft a daily therapeutic goal concurrent with salt restriction. Medication-naive patients can then be cautiously treated as described in the following sections, with serial monitoring because hypotension or renal dysfunction commonly limits the use of pharmaceuticals. Determining to what degree a particular patient may be able to tolerate drug-induced hypotension (e.g., from afterload-reducing agents) is clinically challenging. If there is marked sensitivity of the blood pressure or GFR to low doses of RAAS blockade, bilateral renal artery stenosis should be considered (see Chapter 39).

Pharmacologic Therapeutic Strategies

The pharmacologic management of heart failure is summarized in Box 75-1 and includes traditional approaches for arrhythmias (e.g., for atrial fibrillation) and afterload reduction, SNS blockade, and mineralocorticoid receptor antagonism. Although diuretics remain the front-line treatment for heart failure patients, adequate salt and water clearance in acute heart failure is often difficult; registry data

Treatment Modalities for Refractory Heart Failure

Traditional Treatment
Diuretics: loop diuretics, long-acting thiazides
Digoxin
ACE inhibitors and ARBs
Mineralocorticoid receptor antagonists
β-Blockers
Vasodilators
Blood transfusions

Pharmaceuticals
Inotropes—for example, milrinone, dobutamine*
Synthetic natriuretic peptides*
Aquaretics: vasopressin antagonists*
Erythropoietic-stimulating agents*
Adenosine receptor blockade*

Mechanical Treatment
Biventricular pacing
Ventricular assist devices

Ultrafiltration
Peritoneal dialysis
  Manual (CAPD) and automated using a cycler (APD)
Extracorporeal therapies
  Intermittent short-duration ultrafiltration
  Slow continuous ultrafiltration (SCUF)

Box 75-1 Treatment modalities for refractory heart failure. *ACE,* Angiotensin-converting enzyme; *APD,* automated peritoneal dialysis; *ARB,* angiotensin receptor blocker; *CAPD,* continuous ambulatory peritoneal dialysis. *No clinical benefit established.

indicated that of patients admitted with acute heart failure, approximately 16% were discharged at a higher body weight.[14]

Diuretics

Despite the concerns described previously, most patients initially respond to escalating doses of diuretics. Loop diuretics need to be administered at frequent intervals at a high enough dose to achieve adequate drug levels within the glomerular filtrate. Coadministering a long-acting thiazide diuretic may help maintain natriuresis. In severe heart failure, continuous low-dose infusion of a loop diuretic may be required. In the DOSE study,[13] high versus low doses and continuous versus bolus infusion of loop diuretics were tested in acute heart failure. None of the dosage regimens was associated with superior outcome. Although higher dosages of diuretics resulted in more frequent transient decreases in GFR, this did not affect the long-term outcomes. Based on the recently completed Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) trial, in which there was worsened renal function in decompensated heart failure, efficacious and safe algorithms can be crafted for stepped pharmacologic care wherein inotropes are added to diuretics.[15]

Renin-Angiotensin-Aldosterone System Antagonists

Although low GFR is a marker for increased mortality with heart failure, a further fall in GFR after initiation of RAAS blockade does not necessarily portend a worsened outcome.[16] ACE inhibitors and ARBs, however, may worsen GFR in patients undergoing diuresis or in those with advanced CKD to the extent that there needs to be a temporary decrease in dose or withdrawal. Alternatively, diuretic dosage may need to be reduced before the ACE inhibitor dose is adjusted. Hyperkalemia may also limit the use of RAAS blockers.

Adenosine Receptor Antagonists

Despite encouraging findings in an early study of the selective A_1R antagonist rolofylline for acute heart failure with renal dysfunction, no clinical benefits were noted in the more than 2000 patients in the PROTECT investigation (Placebo-Controlled Randomized Study of the Selective Adenosine A_1 Receptor Antagonist Rolofylline for Patients Hospitalized with Acute Decompensated Heart Failure and Volume Overload to Assess Treatment Effect on Congestion and Renal Function).[17]

Erythropoiesis-Stimulating Agents

In a large registry 25% of patients with heart failure exhibited hemoglobins of 5 to 10.7 g/dl, and anemia (hemoglobin < 12.1 g/d,) was associated with higher in-hospital mortality, longer length of stay, and more readmissions at 90 days.[18] In small series, correction of severe anemia (hemoglobin < 10 g/dl) improved heart failure and clinical outcomes. However, in a recent large randomized controlled trial studying the Reduction of Events by Darbepoetin Alfa in Heart Failure (RED-HF) in 2278 patients, there was no benefit from raising the hemoglobin from as low as 9.0 to a target of 13.0 g/dl. We believe the most prudent course for pharmacologic anemia correction is to follow guidelines based on coexistent chronic kidney disease (see Chapter 83).[18a]

Antidiuretic Hormone Antagonists

Release of vasopressin by (nonosmotic) low cardiac output results in water retention and hyponatremia. Vasopressin (V_2) selective antagonists, such as tolvaptan and lixivaptan, or a nonselective oral V_{1a}/V_2 antagonist increased urine output and serum sodium. However, in the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST), in which tolvaptan was used for a minimum of 60 days, there was no effect at 10 months on all-cause mortality or heart failure–related morbidity.[19] For now, vasopressin antagonists are not indicated in patients with cardiorenal failure.

Natriuretic Peptides

Early clinical trials were encouraging for a cardiac benefit, but there was no improvement in renal function. The Acute Study of Clinical Effectiveness of Nesiritide and Decompensated Heart Failure (ASCEND-HF), including more than 7000 acute heart failure patients, showed no beneficial effect of nesiritide when compared with placebo.[20]

Nonrenal Salt and Water Removal

Nonrenal methods for salt and water removal have been proposed to be advantageous because they avoid TGF-mediated neurohumoral pathway activation and are effective in patients whose condition is refractory to pharmaceutical treatment. However, establishing their outcome benefits and determining the optimal use (as summarized in Box 75-2) have been controversial.

Paracentesis

In a subset of patients, intra-abdominal hypertension may cause renal venous hypertension and kidney congestion. In five patients, removal of approximately 3 liters of ascites decreased intra-abdominal pressure and improved GFR.[21] Repeated paracentesis, however, causes significant protein losses, often the need for albumin repletion, and the possibility of subsequent fluid leakage and/or infection. Nevertheless, the role for this approach in selected patients needs to

Stepwise Treatment Approach for Symptomatic Heart Failure (HF) and the Cardiorenal Syndrome

Step 1

1. Compliance: Optimize adherence to medication regimen and salt restriction.
2. Electromechanical: Evaluate and treat arrhythmias and dyssynchrony
3. Anatomic, with imaging (cardiac catheterization, echocardiogram) as appropriate for:
   a. Ischemic: Angioplasty, stents, or surgery when appropriate for coronary artery stenoses
   b. Other remediable disorders such as valvular heart disease, pericardial effusions, constrictive pericarditis
4. Anemia control, following CKD guidelines (see Chapter 83)
5. Pharmacologic, with dose reductions for hypotension:
   a. ACE inhibitors and ARBs
   b. β-Blocker therapy
   c. Mineralocorticoid receptor antagonists
   d. Diuretics if volume overloaded, congestion, symptoms are present
   e. Other agents: Afterload-reducing medications (e.g., hydralazine), digoxin

Step 2: For Worsened Renal Function, Ineffective Diuresis, Persistent HF

1. Begin stepped approach to escalate pharmacologic treatment, preferably algorithm-based. Focus on dose adjustments to avoid hypotension and further renal impairment
2. Reevaluate for concurrent renal disease (i.e., renocardiac syndrome)
   a. Consider primary nephrologic disorders (e.g., parenchymal, obstruction)
   b. Consider evaluation for unilateral or bilateral renal artery stenosis
   c. If necessary, paracentesis or other specific therapies to reduce intra-abdominal hypertension, relieve renal venous hypertension and renal congestion

Step 3: For Persistent Hypotension, Renal Dysfunction and Acute Decompensated HF

1. Reassess to further optimize pharmacologic care with diuretics and inotropes.
2. Consider ultrafiltration but acknowledge risks of renal deterioration, catheter- and/or anticoagulation-related complications.
3. Begin cautious extracorporeal ultrafiltration, especially if patient's condition is refractory to pressors:
   a. Intermittent slow ultrafiltration, when hypotension does not preclude adequate fluid removal over typically 4- to 6-hour sessions
   b. Continuous ultrafiltration, when equipment is available and patient becomes hypotensive or has worsening renal function with intermittent treatment sessions

Box 75-2 Stepwise treatment approach for symptomatic heart failure and the cardiorenal syndrome. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker.

be better defined, especially in those settings in which the more elaborate and costly nonpharmacologic methodologies are not available.

Ultrafiltration: Peritoneal Dialysis

Most of the experience with using peritoneal dialysis (PD)–based UF to treat heart failure has been in small series.[22] There are specific issues with regard to PD use for heart failure. Apart from volume and sodium clearance, other potential advantages include the removal of heart failure–induced ascites (thereby lowering the risk of spontaneous bacterial peritonitis and intra-abdominal hypertension). Compared with rigorous PD exchange prescriptions in end-stage renal disease (ESRD) patients, there can be simplified lower-frequency regimens crafted for just fluid removal using nonabsorbable osmotic agents such as icodextrin. The literature is, however, confounded by a wide range in patients' underlying CKD, as well as the fact that many individuals have had initial care with hemofiltration, and in these patients it has been difficult to prove improved heart failure survival. In practice, PD for heart failure is most commonly advocated as a chronic treatment, with advanced pharmaceutical and extracorporeal methods used as initial strategies for acute decompensation.

Concerning potential adverse outcomes, as with any rapid use of newly placed PD catheters, acute heart failure patients have increased risk of early fluid leaks and peritoneal infection. In addition, PD-induced electrolyte disturbances (e.g., hypokalemia or hypomagnesemia) may worsen rhythm control. Notably, approximately half of PD ultrafiltrate occurs through aquaporins. Thus, fluid losses are hypotonic and accomplish less sodium removal than the isotonic extracorporeal blood-based hemofiltration modalities. Large peritoneal fluid volumes can also potentially compromise respiration, which might already be tenuous in heart failure; this could be avoided by frequent lower-volume exchanges via automated cyclers. The albeit limited literature has described efficacy of PD in cardiorenal (apart from renocardiac) patients for fluid removal; its use has restored diuretic responsiveness, reduced body weight, resulted in better echocardiographic or other objective cardiac hemodynamic parameters, improved heart failure biomarkers (e.g., brain natriuretic peptide and aldosterone), improved New York Heart Association (NYHA) class, increased 6-minute walk capacity, provided a bridge to cardiac transplantation, decreased hospitalization days, and improved quality of life.[23] Several of these studies used simple PD regimens such as one to three exchanges per day[24] or treatments performed in-center (thrice weekly for 12-hour sessions).[24] Overall the studies have shown that chronic PD in heart failure has had an acceptably low rate of complications and has been well tolerated, but PD has to date not been associated with improved mortality in heart failure patients.[24]

Extracorporeal Ultrafiltration: Conventional Hemodialysis or Hemofiltration

There is extensive experience with intermittent hemodialysis techniques for fluid removal in heart failure. Acute temporary or tunneled dual-lumen catheters are inserted (see Chapter 91). Permanent vascular access (as used for ESRD patients) is often precluded because these arteriovenous fistulas or grafts may shunt a liter or more of blood per minute. Technical approaches include "isolated UF" (see Chapter 93) or traditional dialysis techniques when electrolyte disorders are already present. Even with careful setting of the UF rate, many unstable heart failure patients will not tolerate removal of 2 or more liters during typical 2- to 4-hour treatment times. It is important to note that episodes of hypotension will not only prevent further fluid removal but can also induce acute kidney injury (AKI) and potentially make the patient dialysis dependent.

The key to hemodynamic stability may be to dramatically slow the UF rate (see later), and this approach has led to longer and then continuous treatment modalities: slow extended-duration isolated UF, and continuous venovenous hemofiltration (CVVH). However, the literature lacks larger groups of patients treated with such techniques, homogenous patient populations, appropriate control groups, well-defined outcome measures, and strict treatment protocols.

Ultrafiltration: Setting the Rate of Fluid Removal

The key concept is to avoid intravascular fluid depletion by ensuring that the UF rate does not exceed the rate at which the vascular plasma compartment is being refilled from interstitial spaces. The plasma refill rate can vary over the course of fluid removal, as it is dependent on Starling forces (generated by the plasma oncotic pressure and the gradient between interstitial and vascular hydrostatic pressures) and the permeability of vascular basement membranes. If the UF rate exceeds the plasma refill rate, hemoconcentration, hypovolemia, hypotension, and decreased renal function develop. Equipment has been developed for hemodialysis machines that optically monitors hemoconcentration, and this approach can also be used as a guide for UF in patients with refractory heart failure. In addition, body fluid determination can be done by bioimpedance vector analysis, although its role in guiding heart failure treatment has yet to be established.

Effect of Extracorporeal Ultrafiltration on the Pathophysiology of Heart Failure

In a report of 24 patients with refractory heart failure, removal of up to 4 liters of fluid in a few hours[25] did not affect plasma volume—that is, UF matched the plasma refill rate. Even at 24 hours postprocedure the patients had reduced right atrial, pulmonary artery, and wedge pressures; increased stroke volume; stable heart rates and systemic vascular resistance; and improved responsiveness to diuretics.

Ultrafiltration in heart failure patients decreases levels of norepinephrine, aldosterone, and renin.[26] In contrast to diuretics alone, UF also reduced systemic levels of inflammatory cytokines. Some patients reportedly also have improved exercise capacity and pulmonary function. Last, when comparing UF with diuretics, it is important to appreciate that salt losses vary between these therapies. Part of the benefit from UF may be a result of the convection of isotonic fluid, compared with less sodium being removed in the diuretic-induced hypotonic urine.

Effect of Extracorporeal Ultrafiltration on Renal Function

It has been proposed that the benefits of UF for renal function occur predominantly in patients with low urine output (<1 l/day), in whom UF reverses the RAAS and SNS activation, thereby improving renal perfusion and GFR and restoring sensitivity to diuretics.[27] In contrast, in heart failure patients with a mean baseline GFR of 48 ml/min and preserved diuretic sensitivity, there were no significant differences in the kidney parameters before or after 2 days of either UF or intravenous diuretic therapy.[28]

Although there are encouraging (but not unanimous) reports of renal function improving with UF when compared with diuretics, it is important that cautious fluid removal be accomplished without a significant fall in GFR or in a manner that is detriment to renal hemodynamics.[29,30] Determining a safe rate of UF, however, can be difficult, and excessive fluid removal can unquestionably lead to a rise in serum creatinine in more patients.[31]

Ultrafiltration: Recent Advances in Extracorporeal Techniques

The barriers of extended treatment times and the need for 1 : 1 supervision by nurses have been overcome with commercially available modern devices dedicated to isolated UF. These now have small extracorporeal blood volumes (<100 ml), allow blood flows low enough (<50 ml/min) to permit use of temporary peripheral vein catheters, and have preassembled tubing for one-step loading, computerized simple user interfaces with embedded help screens, remote monitoring capabilities, and miniaturization for portability. Treatment times range from 6 h/day to continuous treatment over multiple days. A first feasibility study[32] demonstrated that 16- to 18-gauge catheters could deliver blood at up to 40 ml/min, resulting in 2.6 ± 1.0 liters (up to 3.7 liters) of UF over approximately 7 hours. In another study[29] of 20 patients with decompensated heart failure and serum creatinine levels of at least 1.5 mg/dl (132 µmol/l) and/or diuretic resistance, more than 8 liters fluid were removed. Patients were discharged earlier without changes in GFR and had improved heart failure scores; some had resolution of hyponatremia and fewer readmissions. In the Relief for Acutely Fluid-Overloaded Patients with Decompensated Congestive Heart Failure (RAPID-CHF) trial on 40 patients, UF did not significantly affect weight loss but did improve fluid removal and symptoms compared with usual care.[33]

Two large prospective studies, however, subsequently had opposite conclusions. In the UNLOAD trial (Ultrafiltration Versus Intravenous Loop Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure), 200 heart failure patients were randomized to early UF or intravenous diuretics and followed for 90 days.[30] The UF achieved by the study was 241 ml/h for 12.3 ± 12 hours, which led to a weight reduction of 5.0 ± 3.1 kg over the 2 days, approximately 2 kg more than those in the control diuretic group. Although dyspnea was improved in those undergoing UF at 8 hours, this was not different at 48 hours. Renal end points also were not different. At 90 days the UF group had fewer total rehospitalizations (18% vs. 32%), rehospitalization days (1.4 vs. 3.8 days), and unscheduled office and emergency room visits (21% vs. 44%), but the study was not powered to allow conclusions on these clinical endpoints. Potential weaknesses of the study design included sponsorship by the manufacturer, submaximal medical therapy in the diuretic group, and uncertainties regarding posthospitalization care and readmission. In the CARRESS-HF trial[34] 188 patients were compared at 96 hours after randomization to a protocol of stepped drug therapy (diuretics with intravenous inotropes) or extracorporeal UF at 200 ml/h. There was no difference in weight loss (approximately 5.6 kg), dyspnea, or well-being scale scores, or diuretic dose; however, the UF group but not the pharmacologic group experienced a decline in GFR. At 60 days there were no differences in mortality, emergency visits, or rehospitalizations for heart failure or any cause. It remains unclear whether these disappointing findings for UF can be extrapolated to all such patients and methodologies. This trial had limitations in that the inclusion criteria necessitated that patients were in acutely decompensated heart failure and already had AKI with a rise in creatinine of at least 0.3 mg/dL, which could indicate that the initial renal injury had already occurred. Notably, most UF was accomplished early in the protocol, with a mean duration of only 40 hours compared with the pharmacologic care over 96 hours. Thus it remains unknown whether alternative protocols with slower or more prolonged UF might have had different heart failure or renal function outcomes. Furthermore, a large proportion of patients in the UF group (10%) did not receive the randomized treatment for various reasons, and 30% in this group also received intravenous diuretics after UF had ceased. Thus, crossover between therapies was

an important confounder, and it is unclear what the implications of these limitations are.

Safety and Risks to Extracorporeal Therapies

Although newer simplified devices for isolated UF have improved the ease of patient care, these modalities are not risk free. In a small, outpatient, 1-year study of 14 patients, two deaths were attributed to complications of the UF procedure.[35] In the CARRESS-HF trial,[34] such UF-related complications included catheter exit-site hemorrhage and systemic infection. In the UNLOAD trial,[30] however, the UF therapy proved very safe. The recently developed machines dedicated to isolated UF have an added margin of safety conferred by low rates of filtration and blood flow, as well as more robust automated monitoring software. Nevertheless, all complications that can occur in hemodialysis therapies are of course also relevant for heart failure patients receiving isolated UF (see Chapter 95).

SUMMARY

Despite longstanding evidence concerning the pathophysiology of fluid overload in heart failure and adverse neurohumoral effects from diuretics, it has been difficult to reach a consensus on the benefits or techniques of UF or diuretic therapy. PD appears to have a role in chronic heart failure care, especially for individuals whose management is complicated by CKD. For acutely decompensated heart failure, recent evidence suggests that protocolized stepped pharmacologic care can be efficacious and safer than rapid UF; however, it remains to be determined whether there can be benefits from alternative extracorporeal protocols.

CHAPTER 76

Hepatorenal Syndrome

Javier Fernández and Vicente Arroyo

DEFINITION

Hepatorenal syndrome (HRS) is a potentially reversible functional renal failure that occurs in patients with acute or chronic liver disease, advanced hepatic failure, and portal hypertension. Although it may occur in patients with acute liver failure or severe acute alcoholic hepatitis, it is mainly observed in patients with advanced cirrhosis. HRS is characterized by impaired renal function and marked abnormalities in the arterial circulation and endogenous vasoactive systems. In the kidney, there is pronounced vasoconstriction resulting in low glomerular filtration rate (GFR). In the splanchnic circulation, there is marked arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.[1-3] Two forms of HRS can be identified on the basis of the progression of the disease (Box 76-1). The acute form (type 1 HRS) is characterized by an acute and rapid deterioration in renal function that occurs in the setting of multiorgan failure (acute-on-chronic liver failure), whereas the chronic form (type 2) has an insidious onset and is characterized by moderate renal failure that follows a steady or slowly progressive course.[1-3]

PSEUDOHEPATORENAL SYNDROME

Pseudohepatorenal syndrome describes concurrent hepatic and renal dysfunction secondary to a wide variety of infectious, systemic, circulatory, genetic, and other diseases and after exposure to a variety of drugs and toxins (Table 76-1).[4] All these entities must be excluded before the diagnosis of HRS can be established. In all these conditions, the liver does not play a causative role in the pathogenesis of renal failure. Pseudohepatorenal syndrome is usually easy to exclude because the causative agent is frequently known and both renal and liver functional abnormalities are often found at first clinical presentation, when there is no evidence of advanced liver failure and portal hypertension. In contrast, HRS invariably occurs after liver failure and portal hypertension are fully established and frequently develops when the patient is undergoing treatment for these conditions or their complications.

PATHOPHYSIOLOGY AND PATHOGENESIS

Circulatory Dysfunction: Renal and Systemic Hemodynamic Changes

In HRS, reduction in GFR occurs mainly as a result of renal cortical hypoperfusion after intense cortical renal vasoconstriction, which can be demonstrated angiographically as marked beading and tortuosity of the interlobular and proximal arcuate arteries and the absence of a distinct cortical nephrogram and vascular filling of the cortical vessels (Fig. 76-1).[5] Intense renal vasoconstriction is the final consequence of marked systemic circulatory dysfunction, characterized by progressive splanchnic arterial vasodilation, reduction of the effective arterial blood volume, hypotension, and homeostatic activation of the vasoconstrictor systems.[3] This further compromises renal perfusion because intense renal vasoconstriction results in blunting of the autoregulation of renal blood flow, so that renal perfusion becomes more pressure dependent. In HRS, filtration fraction is also reduced, reflecting a dominant increase in afferent arteriolar tone and a decrease in the ultrafiltration coefficient. Serial systemic hemodynamic studies showed that HRS occurs in the setting of reduced mean arterial pressure (MAP), cardiac output, and wedge pulmonary pressure without change in systemic vascular resistance. These findings suggest that the inability of the heart to increase its output to compensate for a decrease in cardiac preload (secondary to the accentuation of splanchnic arterial vasodilation) also contributes to the pathogenesis of HRS.[6] Vasoconstriction is not confined to the renal vascular bed. In HRS it is also observed in other extrasplanchnic territories, including the liver, brain, muscle, and skin.[2,3]

Neurohumoral Abnormalities

The renal and systemic hemodynamic changes that characterize HRS are a direct consequence of neurohumoral disturbances.[2,3] Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system [RAAS], the sympathetic nervous system, and vasopressin) is the cause of renal vasoconstriction; meanwhile, activation of the vasodilator systems occurs mainly in the splanchnic circulation and leads to splanchnic vasodilation. Increases in the serum and urinary levels of vasoconstrictors and in the plasma level of vasodilators are observed in patients with HRS. The vasoconstrictors include renin, norepinephrine, neuropeptide Y, arginine vasopressin, endothelin and F_2 isoprostanes, and urinary cysteinyl leukotrienes; the vasodilators include plasma endotoxin, nitrite and nitrate (end product of nitric oxide metabolism), and glucagon. The sympathetic discharges through the renal nerves are also markedly increased.

In contrast to increased plasma and urinary levels of vasoconstrictors and plasma level of vasodilators, decreased levels of urinary vasodilators have been observed in HRS. These include prostaglandin E_2, 6-keto-prostaglandin F_1 (a stable metabolite of renal prostacyclin), and kallikrein. Because the level of these urinary vasodilators is normal in compensated cirrhosis and higher than normal in decompensated cirrhosis with ascites and normal renal function, it is postulated that a reduction in the renal synthesis of renal vasodilators is the final event that leads to the development of HRS.[3]

Most of these neurohumoral abnormalities found in HRS are also detected, albeit to a lesser extent, in decompensated cirrhosis (with ascites) with normal renal function and in compensated cirrhosis (without ascites). These findings support the hypothesis that HRS most likely represents one end of the spectrum of homeostatic abnormalities that occur in liver failure and portal hypertension.

Causes of Pseudohepatorenal Syndrome		
Potential Causes	**Predominantly Tubulointerstitial Involvement**	**Predominantly Glomerular Involvement**
Infections	Sepsis, leptospirosis, brucellosis, tuberculosis, Epstein-Barr virus, hepatitis A virus	Hepatitis B and C viruses, HIV infection, *Schistosoma mansoni,* liver abscess
Drugs	Tetracycline, rifampin, sulfonamide, phenytoin, allopurinol, fluroxene, methotrexate (high dose), acetaminophen overdose	
Toxins	Carbon tetrachloride, trichloroethylene, chloroform, elemental phosphorus, arsenic, copper, chromium, barium, amatoxins,* raw carp bile toxins†	
Systemic diseases	Sarcoidosis, Sjögren syndrome	Systemic lupus erythematosus, vasculitis, cryoglobulinemia, amyloidosis
Circulatory failure	Hypovolemic or cardiogenic shock	
Malignancy	Lymphoma, leukemia	
Congenital and genetic disorders	Polycystic liver and kidney disease, nephronophthisis, congenital hepatic fibrosis	
Miscellaneous	Fatty liver of pregnancy, Reye syndrome	Eclampsia, HELLP syndrome,‡ cirrhotic glomerulopathy

Main Clinical Characteristics of Type 1 and Type 2 Hepatorenal Syndrome (HRS)

Type 1 HRS

- Acute and rapid deterioration in renal function (serum creatinine ≥ 2.5 mg/dl or 220 μmol/l in less than 2 weeks)
- Occurs in parallel with the failure of other organs or systems (e.g., coagulopathy, hepatic encephalopathy)
- In cirrhosis, is a form of acute-on-chronic liver failure
- Frequently follows a precipitating event, mainly bacterial infection
- Rapidly fatal without treatment: mean survival 2 to 3 weeks

Type 2 HRS

- Moderate stable renal impairment (average serum creatinine 2 mg/dl [176 μmol/l])
- Mainly causes refractory ascites
- Mean survival without treatment: 6 months

Box 76-1 Main clinical characteristics of type 1 and type 2 hepatorenal syndrome.

Summary of Pathogenetic Events

Figure 76-2 shows the pathogenetic events that lead to HRS. Liver failure and portal hypertension through endotoxemia and increased shear stress increase vascular production of vasodilators, including nitric oxide, carbon monoxide, and glucagon in the splanchnic circulation, leading to the initiating event of splanchnic arteriolar vasodilation (the peripheral arterial vasodilation hypothesis). Splanchnic vasodilation leads to a decrease in systemic vascular resistance, but MAP is initially maintained by an increase in cardiac output, resulting in a hyperdynamic circulation. Splanchnic vasodilation also decreases arterial filling and reduces the effective arterial blood volume. The subsequent stimulation of the central volume baroreceptors leads to compensatory activation of the vasoconstrictor systems, in particular the arginine vasopressin system, RAAS, and sympathetic nervous system (including its hormones norepinephrine and neuropeptide Y), which help restore effective arterial blood volume. This restoration is achieved in patients with compensated cirrhosis but not in patients with decompensated cirrhosis, in whom progressive splanchnic arteriolar vasodilation leads to increased splanchnic capillary pressure, resulting in an increase in lymph formation that exceeds reabsorption capacity. In parallel, further contraction of the effective arterial blood volume leads to reduction of systemic MAP and further stimulation of the vasoconstrictor systems, resulting in sodium and water retention. The net result of these combined effects is continuous ascites formation (the forward theory of ascites formation).[2,3]

The splanchnic circulation is resistant to the effects of vasoconstrictors because of local release of vasodilators; progressive splanchnic vasodilation continues to occur as liver failure and portal hypertension progress. This leads to continued contraction of effective arterial blood volume, which, in combination with the progressive inability of the cirrhotic heart to respond to reduced preload consequent to splanchnic vasodilation, results in further reduction of MAP and more intense stimulation of the vasoconstrictor systems. Normally, the effect of vasoconstrictors on the renal circulation is counterbalanced by the reactive production of intrarenal vasodilators. It is postulated that HRS develops when the balance of activities between the renal vasoconstrictors and intrarenal vasodilators finally breaks down. The likelihood that this will occur increases with progressive or acute deterioration in liver function or increasing severity of portal hypertension (e.g., after acute alcoholic hepatitis) and is precipitated by events that lead to further volume contraction and reduction of the effective arterial blood volume (e.g., spontaneous bacterial peritonitis; see later discussion).

EPIDEMIOLOGY

The possibility for development of HRS in the cirrhotic patient is estimated to be 18% at 1 year and 39% at 5 years.[7] Neither the cause nor the Child-Pugh score or the model for end-stage liver disease (MELD) score (http://www.mdcalc.com/child-pugh-score-for-cirrhosis-mortality/) predicts the incidence of HRS. Rather, independent predictors of HRS include dilutional hyponatremia, impairment in systemic hemodynamics (high plasma renin activity and noradrenaline concentration and low cardiac output),[6,7]

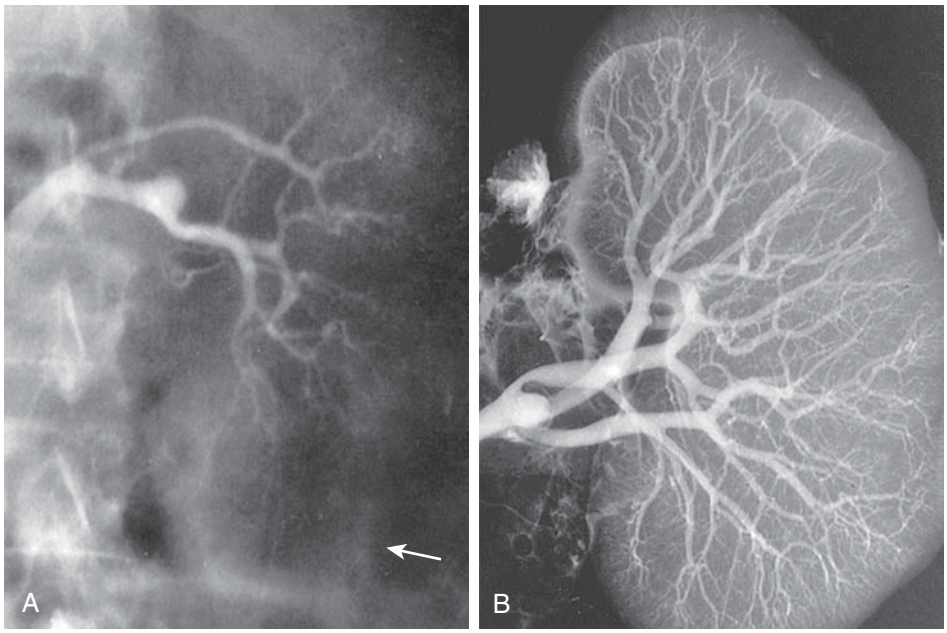

Figure 76-1 Renal arteriography of a patient with hepatorenal syndrome (HRS). A, Renal angiogram (the arrow marks the edge of the kidney). **B,** The angiogram carried out in the same kidney at autopsy. Note complete filling of the renal arterial system throughout the vascular bed to the periphery of the cortex. The vascular attenuation and tortuosity seen previously **(A)** are no longer present. The vessels are also histologically normal. This indicates the functional nature of the vascular abnormality in HRS.[4]

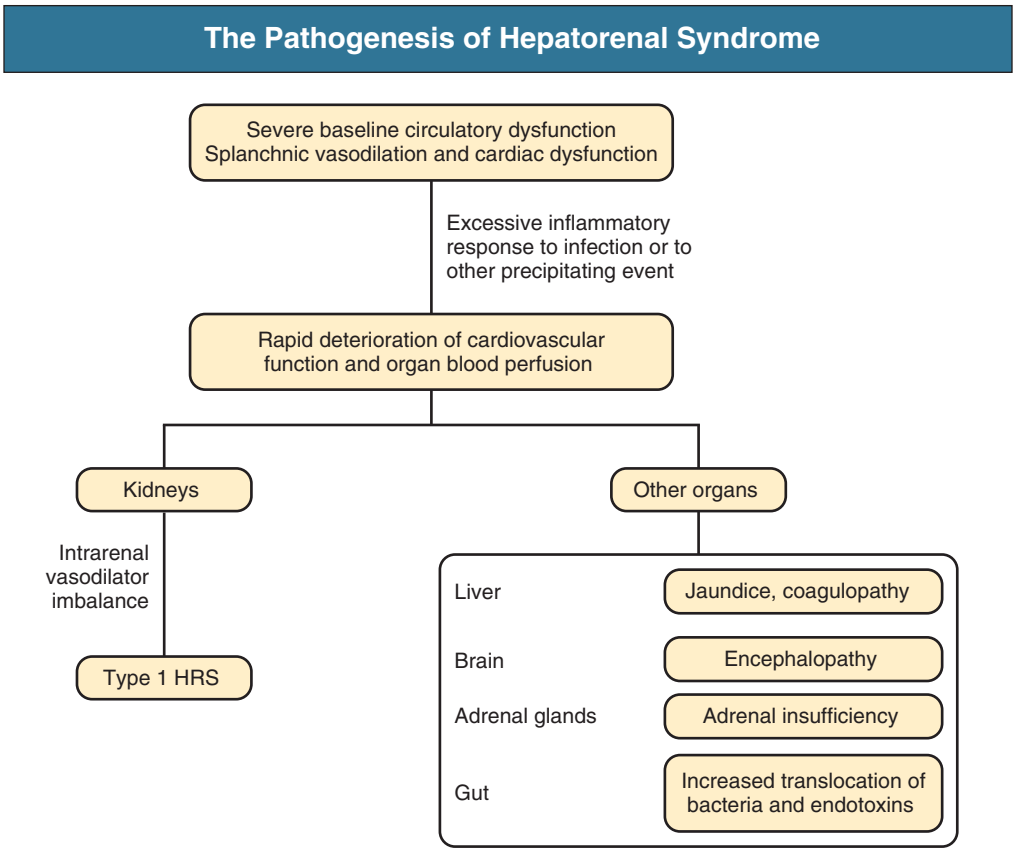

Figure 76-2 The pathogenesis of hepatorenal syndrome (HRS). Mechanisms leading to type 1 HRS and multiorgan failure. Patients with cirrhosis and ascites present a severe cardiocirculatory dysfunction that may be further aggravated by infection. Although circulatory dysfunction predominantly affects the kidneys and leads to the development of type 1 HRS, it also decreases the perfusion of other organs and systems such as the liver, with marked impairment in hepatic function and aggravation of portal hypertension; the brain, with the development of hepatic encephalopathy; the adrenal glands, with the development of relative adrenal dysfunction; and the gut, decreasing intestinal motility and promoting intestinal bacterial overgrowth and bacterial translocation.[2,3]

abnormal renal duplex Doppler ultrasound study findings (resistive index >0.7),[8] and low GFR.[3]

CLINICAL MANIFESTATIONS

Type 1 and type 2 HRS are considered to be different syndromes rather than different expressions of a common underlying disorder.[2,3] Type 1 HRS is characterized by a rapid decline in renal function (see Box 76-1) and is observed in patients with acute decompensation of advanced cirrhosis, severe acute alcoholic hepatitis, or acute liver failure. In addition to developing a rapidly progressive acute kidney injury (AKI), patients also develop multiorgan dysfunction including severe hepatic failure (jaundice, coagulopathy), brain failure (hepatic encephalopathy), and frequently relative adrenal insufficiency. Hyponatremia is almost always present, and arterial blood pressure is usually low. Type 1 HRS may be precipitated by bacterial infections (especially spontaneous bacterial peritonitis), gastrointestinal bleeding, or total paracentesis without albumin administration. Left untreated, type 1 HRS tends to run a rapid and progressive downhill course, resulting in death of the patient within 2 to 3 weeks.[7]

Type 2 HRS is characterized by insidious onset and slowly progressive deterioration of renal function. This is most often observed in patients with cirrhosis and portal hypertension. These patients tend to be less severely jaundiced and mainly present with refractory ascites caused by poor response to diuretics. Low-normal arterial blood pressure, modest prolongation of prothrombin time, and moderate or marked hypoalbuminemia and hyponatremia are usually present. Type 2 HRS tends to run a slowly progressive downhill course over months, which most likely reflects the natural course of the disease because additional precipitating factors are not usually identified.[2,3,7] Mean survival time after onset of type 2 HRS is 6 months.

PATHOLOGY

Hepatorenal syndrome is, by definition, a functional renal disorder, and the presence of significant glomerular and/or tubular disease excludes the diagnosis. However, glomerular abnormalities, including mesangial expansion, capillary wall thickening, mesangial and capillary wall electron-dense deposits, and immune deposits of C3 and IgA, IgM, and IgG, are frequently found in cirrhotic patients with normal renal function and minimal urinary abnormalities. The presence of such glomerular abnormalities in a cirrhotic patient, therefore, does not exclude the diagnosis of HRS. Protrusion of the proximal tubular epithelium into the Bowman space (glomerulotubular reflux) is not specific for HRS and is found in other conditions associated with profound renal ischemia and terminal hypotension. Although early autopsy studies demonstrated normal tubular morphology in patients who had died of HRS, detailed light and electron microscopic studies have documented proximal tubular lesions consistent with ischemic injury. However, these lesions do not explain the renal failure and reduction in GFR observed in patients with HRS.[3]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic criteria for HRS were established by the International Ascites Club in 1996[1] and have recently been revised (Box 76-2).[9] The main differences between the new and old criteria include the exclusion of creatinine clearance as a measure of renal function because of the difficulty in obtaining accurate urine collection data, the removal of ongoing bacterial infection as an exclusion criterion so that treatment of HRS is not delayed in these patients, the substitution of saline with albumin as the preferred fluid for plasma volume expansion, and the removal of the minor criteria because they are not thought to be essential.

Diagnostic Criteria of Hepatorenal Syndrome According to the International Ascites Club

- Cirrhosis with ascites
- Serum creatinine >1.5 mg/dl (133 μmol/l).
- No improvement in serum creatinine (decrease to a level of 1.5 mg/dl or less) after at least 2 days of diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/day.
- Absence of shock.
- No current or recent treatment with nephrotoxic drugs.
- Absence of parenchymal kidney disease as indicated by proteinuria >500 mg/day, microhematuria, and/or abnormal renal ultrasound findings.

Box 76-2 Diagnostic criteria of hepatorenal syndrome according to the International Ascites Club.[9]

The diagnosis of HRS is mainly one of exclusion and should be suspected in any patient with acute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive renal impairment. Serum creatinine concentration and blood urea nitrogen are poor markers of GFR in cirrhosis.[3] Cirrhotic patients may have significant renal impairment despite normal serum creatinine or blood urea nitrogen concentration values because they are frequently malnourished, with reduced lean body mass, and often have a low urea generation rate because of liver failure and low protein intake. Severe hyperbilirubinemia, which is often present in patients with HRS, interferes with the Jaffe reaction for creatinine quantification and may cause falsely low results. Enzymatic creatinine assays are less susceptible to high bilirubin levels. In cases of uncertainty, GFR may be assessed with use of ^{125}I-iothalamate or chromium 51–labeled ethylenediaminetetraacetic acid (^{51}Cr-labeled EDTA). Studies involving a low number of patients suggest that serum cystatin C could be an accurate GFR marker in the cirrhotic population.[10] However, the real usefulness of serum cystatin C in the assessment of GFR in cirrhosis needs to be confirmed.

In patients with preexisting liver failure, portal hypertension, and renal failure, the use of nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] and aminoglycosides) must be stopped, and conditions leading to renal failure must be excluded by careful history, physical examination, urine examination, and ultrasound study before the diagnosis of HRS can be considered. The absence of shock or gastrointestinal bleeding, and excess gastrointestinal, peritoneal, or renal fluid loss must also be documented. Prerenal AKI must be excluded by withdrawal of diuretics and fluid challenge either with 1.5 liters of normal saline or preferably with albumin, 1 g/kg body weight per day up to the maximum of 100 g/day for 2 days. Absence of microhematuria and proteinuria of less than 500 mg/day help exclude significant coexisting glomerular or tubulointerstitial disease leading to renal failure and support the diagnosis of HRS.

The most important differential diagnosis for renal failure in cirrhosis is between type 1 HRS and "true" AKI with tubular damage,

because they require rapid therapeutic decisions with different treatments. The parameters traditionally used to differentiate AKI with tubular damage from functional renal failure (urinary sodium excretion and urinary-plasma osmolality ratio) are of no value in patients with cirrhosis and ascites.[3] Granular casts may be found in the urinary sediment in both HRS and AKI with tubular damage. Recent data suggest that the determination of the neutrophil gelatinase–associated lipocalin (NGAL) level, a urinary biomarker of tubular damage, could be of help to differentiate these two entities.[11] However, further studies are needed to confirm this finding because biomarkers of AKI can also be increased in pre-renal acute injury[12] and HRS can progress to AKI in final stages.

NATURAL HISTORY

The prognosis of HRS is poor. Without treatment, the median survival rate for type 1 HRS is about 2 weeks; that of type 2 HRS is about 4 to 6 months.[3,7] Patients with type 1 HRS usually die in the setting of multiple organ failure and are now considered to have acute-on-chronic liver failure, a syndrome recently redefined as characterized by the presence not only of organ failure(s) and high mortality rate but also of systemic inflammation.[13] Severe hepatic encephalopathy, gastrointestinal bleeding, and sepsis are common final events in these patients. Patients with type 2 HRS are at a higher risk of type 1 HRS after the development of a precipitating event.[3]

PREVENTION AND TREATMENT

General Principles in the Prevention of Renal Failure

In patients with cirrhosis and ascites excessive diuretic therapy results in volume contraction and renal failure. To avoid the latter, a stepwise approach to the treatment of ascites is recommended. All patients are advised to have bed rest and to follow a low-sodium diet (60 to 90 mmol/day, equivalent to about 1.5 to 2 g of salt per day). After this, spironolactone is prescribed at increasing doses (100 mg/day as initial dose; if there is no response within 4 days, 200 mg/day). When there is no response to this dose of spironolactone, furosemide is added at increasing doses every 2 days (40 to 80 mg/day). Maximum doses of spironolactone and furosemide are 400 and 160 mg/day, respectively. In patients with diuretic resistance, therapeutic paracentesis is indicated but must be combined with plasma volume expansion with use of albumin (8 g/l of ascites removed) to decrease the incidence of circulatory dysfunction after treatment and to prevent the development of HRS. The use of renin-angiotensin system (RAS) blockers as well as potentially nephrotoxic agents, including NSAIDs, aminoglycosides, and radiocontrast media, should be avoided as much as possible.[2,3] β-Blockers, used for primary or secondary prophylaxis of variceal bleeding, reduce MAP and GFR and must be used cautiously in patients with cirrhosis and ascites. Close monitoring of renal function is recommended, especially in patients with refractory ascites. β-Blockers may increase short-term mortality in this specific cirrhotic subpopulation and should therefore be replaced by band ligation of varices.[14]

Preventive Measures

Accepting the hypothesis that HRS represents one end of the spectrum of the homeostatic abnormalities in liver failure and portal hypertension and that it is precipitated by clinical events as volume contraction or bacterial infection, it follows that a major focus of treatment must be to prevent such events and to treat them promptly when they occur. There should be a low threshold for antibiotic therapy for suspected infection in cirrhosis. Spontaneous bacterial peritonitis must be excluded by regular examination of ascites whenever a patient is admitted to the hospital or clinically deteriorates. This infection must be treated not only with broad-spectrum antibiotics but also with albumin infusion (1.5 g/kg at diagnosis and 1 g/kg at day 3) because the latter has been shown to prevent the subsequent development of HRS and improves short-term survival.[15] Primary prophylaxis of spontaneous bacterial peritonitis with norfloxacin has recently been shown not only to prevent its development but also to delay the development of HRS and to improve patient survival in cirrhotic patients at high risk for complications (low ascitic protein level <15 g/l; advanced liver failure with Child-Pugh score ≥9 and serum bilirubin ≥3 mg/dl; or impaired renal function with serum creatinine ≥1.2 mg/dl or serum sodium ≤130 mmol/l).[16] Norfloxacin is thought to exert its renoprotective effect by reducing bacterial translocation from the intestine, endotoxemia, and nitric oxide generation, which in turn leads to improved hemodynamics. Prophylactic use of pentoxifylline (400 mg orally three times per day) also prevents the development of HRS in patients with acute alcoholic hepatitis, probably by inhibiting the synthesis of tumor necrosis factor α.[17]

General Approach to Treatment

As mentioned before, in patients with preexisting liver failure, portal hypertension, and renal failure, the use of nephrotoxic agents must be stopped. The absence of shock or gastrointestinal bleeding, and excess gastrointestinal, peritoneal, or renal fluid loss must also be documented. Pre-renal AKI must be excluded by withdrawal of diuretics and fluid challenge either with normal saline or preferably with albumin. Absence of microhematuria and proteinuria should also be confirmed.

Once the diagnosis of HRS has been made, patients should be assessed for orthotopic liver transplantation (OLT). Suitable candidates should be placed on the waiting list for deceased donor or if possible living donor liver transplantation. Bridge treatments are also needed. Pharmacotherapy, transjugular intrahepatic portosystemic shunt, extracorporeal liver support therapy, and, in patients with advanced uremia, renal replacement therapy are treatments that can be used in patients with HRS. They can improve renal function and the clinical condition of the patient before OLT and in some patients who are not transplant candidates can prolong survival by months.

Pharmacotherapy

At present, the most promising pharmacotherapy appears to be vasoconstrictor therapy targeted at reversal of splanchnic arteriolar vasodilation and restoration of the effective arterial blood volume with use of albumin (Box 76-3). Vasodilator therapy, which aims at reversal of renal vasoconstriction, is contraindicated in HRS because it is ineffective and can induce marked hypotension.

Vasopressin analogues exhibit preferential vasoconstrictor action on the splanchnic versus the renal vascular bed. Terlipressin (triglycyllysine vasopressin) is a synthetic analogue of vasopressin that, in addition to having a greater effect on the vascular vasopressin receptors (V_1) than the renal vasopressin receptors (V_2), is a prodrug requiring transformation to the active form, lysine vasopressin. Because of this, terlipressin has a prolonged half-life and can be given as an intravenous bolus or as continuous intravenous infusion. Continuous administration improves the probability of HRS reversal and reduces the incidence of systemic ischemic side effects.[3] Long-term

Pharmacologic Options in the Treatment of Hepatorenal Syndrome

Terlipressin + albumin*: Terlipressin: 1 mg/4-6 h to start,† increasing to a maximum of 2 mg/4-6 h if serum creatinine decreases <25% at day 3. Treatment is maintained until serum creatinine has decreased below 1.5 mg/dl (133 μmol/l). Maximum duration of treatment: 14 days.

Norepinephrine + albumin*: Norepinephrine: IV infusion at 0.5 mg/h to start, increasing the dose by 0.25 to 0.5 mg/h every 4 hours up to a maximum of 3 mg/h to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 14 days.

Vasopressin + albumin*: Vasopressin: IV infusion at 0.01 U/min to start, increasing the dose upward to a maximum of 0.8 U/min to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 11 days.

Midodrine + octreotide + albumin*: Oral midodrine 2.5 to 7.5 mg/8 h + subcutaneous octreotide 100 μg/8 h to start, increasing midodrine dose to a maximum of 12.5-15 mg/8 h and octreotide dose to a maximum of 200 μg/8 h to achieve an increase in MAP of at least 15 mm Hg. Maximum duration is not defined.

Box 76-3 Pharmacologic options in the treatment of hepatorenal syndrome. *IV,* Intravenous; *MAP,* mean arterial pressure. *Albumin dose: 1 g/kg on day 1 (up to 100 g) followed by 20 to 40 g/day. Central venous pressure monitoring is advised (but not mandatory) to achieve a value of 10 to 15 mm Hg. †Terlipressin can also be administered as continuous infusion.

prospective studies[18-22] and a large retrospective study[23] in patients with type 1 and type 2 HRS have shown that terlipressin combined with daily albumin infusion improved renal function in 60% of the treated patients, with 37% surviving beyond 1 month, 60% without OLT. Reversal of HRS was associated with improved survival.[21,23] The efficacy of terlipressin in the treatment of HRS has been confirmed in four randomized trials (Table 76-2).[24-27] Terlipressin was given at a starting dose of 2 to 6 mg/day, and in two studies the dose was titrated upward on the basis of response to a maximum dose of 12 mg daily. Both treated patients and controls were given daily albumin infusion of 20 to 40 g/day. Reversal of HRS was associated with improved survival in only one study.[26] The inclusion of patients with more severe renal failure in the treated group[25] and the unexpected high response and survival rate in controls[27] may explain the inability of some of these studies to show a survival benefit of treatment despite success in reversing HRS. The latter is likely a result of the more aggressive use of albumin infusion in these studies because such an approach has been shown to reverse HRS in a high proportion of patients.[28] A meta-analysis recently published confirms that terlipressin plus albumin prolongs short-term survival in patients with type-1 HRS.[29] Response to therapy is characterized by a slowly and sustained reduction in serum creatinine and improvement in systemic hemodynamics (marked suppression of the plasma levels of renin and norepinephrine, increase in MAP), urine volume, and serum sodium concentration. Median time to reversal of HRS is 7 days and depends on pretreatment serum creatinine.[3]

Recurrence rates of HRS after successful treatment are variable and tend to be more common in type 2 (around 50%) than in type 1 HRS (20%).* Re-treatment with terlipressin is successful in most patients.[19,21,25] Younger age,[23,26] lower baseline serum creatinine level,[27] Child-Pugh score of 12 or lower,[23,26] administration of albumin,[21] serum bilirubin below 10 mg/dl, and increase in MAP over 5 mm Hg after initiation of terlipressin[30] are independent predictors for a successful response to treatment. In patients with severe alcoholic hepatitis, the absence of underlying cirrhosis increases the probability of response to medical treatment. Child-Pugh score (<12)[21,23,25,26] and MELD score[27] are independent predictors for survival. Transient abdominal pain and diarrhea after the first dose of terlipressin treatment are common. Significant ischemic side effects attributed to terlipressin occurred in an average of 4% to 12% of patients.[18-27]

Intravenous vasopressin has been used as an alternative to terlipressin in the treatment of HRS in countries where this drug is not available and was successful in reversing type 1 and type 2 HRS in 42% of patients in a retrospective study.[31] Responders had significantly lower mortality and a higher liver transplantation rate than nonresponders did. No adverse effect related to therapy was observed.

Intravenous norepinephrine combined with intravenous albumin and furosemide reversed type 1 HRS in 10 of 12 patients; three survived with OLT, and four survived for a median of 332 days without OLT.[32] With use of a similar dosage regimen, two randomized comparative studies showed that norepinephrine is as effective as terlipressin in the treatment of type 1 and type 2 HRS (see Table 76-2).[33,34] All recurrences were successfully re-treated with the original

regimen. Significant treatment-related side effects were low, and the cost of treatment with norepinephrine was 3 and 15 times lower, respectively, than with terlipressin.

Administration of midodrine (an oral vasoconstrictor with α-adrenergic effect), subcutaneous octreotide, and albumin infusion has been demonstrated to improve renal function in patients with HRS in studies with low numbers of patients.[35-38] However, this treatment is less effective than the combination of terlipressin plus albumin.[3]

Transjugular Intrahepatic Portosystemic Shunt

Portal hypertension is central in the pathogenesis of the homeostatic abnormalities in HRS. The high operative mortality precludes side-to-side portacaval shunts in HRS patients. The transjugular intrahepatic portosystemic shunt (TIPS) creates a parenchymal track between branches of the hepatic and portal vein (Fig. 76-3). In experienced hands, operative mortality rates are 1% to 2%, and the morbidity rate is 10%. Procedure-related complications include intra-abdominal bleeding, cardiac arrhythmia, shunt migration and thrombosis, hemolytic anemia, fever, infection, and reactions to radiocontrast media (including nephrotoxicity). The resultant diversion of portal blood flow from the liver to the systemic circulation may result in transient deterioration of liver function. Shunt stenosis and hepatic encephalopathy are the main long-term complications of TIPS. Exceptionally, TIPS induces disabling encephalopathy. In these cases closure of the shunt should be performed.[39] In an earlier study, TIPS improved renal function in six of seven HRS patients (all with Child-Pugh score <12) and achieved a mean survival of 4.7 (0.3 to 17) months.[40] A long-term study of 31 cirrhotic patients with HRS (14 type 1 and 17 type 2) who were not transplant candidates and did not have severe liver failure confirmed that TIPS improved renal function and survival compared with controls.[41] Shunt stenosis and occlusion occurred in seven patients and could be treated in six by balloon dilation or stent prolongation, and 11 developed hepatic encephalopathy during follow-up. TIPS, therefore, could be an alternative treatment of type 1 HRS in patients without response to terlipressin/norepinephine plus albumin.

Combined TIPS and intravenous terlipressin therapy was performed in nine patients with type 2 HRS.[22] All seven patients who responded to terlipressin and relapsed after treatment cessation responded to TIPS. In another study, TIPS was performed in five patients with type 1 HRS after successful treatment with midodrine, octreotide, and albumin.[37] Complete normalization of renal function was observed in all patients 12 months after TIPS. In both studies, improvement or elimination of ascites was an added benefit.

Extracorporeal Liver Support Therapy

Extracorporeal liver support therapy, as a bridge to OLT, relies on biologic (hepatocytes from human or animal source in an *ex vivo* perfusion system) or nonbiologic methods, including plasma exchange and albumin dialysis systems. Numerous studies have suggested that albumin dialysis (molecular adsorbent recirculating system [MARS] or fractionated plasma separation and adsorption [FPSA]) may have beneficial effects in patients with type 1 HRS. In a small prospective randomized controlled trial, a mean of five treatments with MARS effectively removed albumin-bound toxic metabolites (i.e., bilirubin and bile acids), improved renal function, and prolonged survival in eight patients (mean survival, 25 ± 5 days) with type 1 HRS and severe liver failure compared with five control patients treated only with hemodiafiltration (mean survival, 5 ± 2 days).[42] In another study of eight encephalopathic patients with acute

alcoholic hepatitis (five with type 1 and two with type 2 HRS), MARS improved renal function, bilirubin, prothrombin time, grade of encephalopathy, MAP, systemic vascular resistance, and cardiac output, with four patients still alive without OLT at 3 months.[43] Three large randomized controlled trials have so far been performed evaluating albumin dialysis in patients with acute-on-chronic liver failure.[44-46] In the first study, albumin dialysis with MARS was found to be more effective than standard medical therapy in the management of patients with grade III or IV hepatic encephalopathy. Most patients had HRS, and the treatment was found to be safe.[44] The two other trials compared albumin dialysis with standard medical therapy in patients with type 1 HRS (MARS) or with type 1 and 2 HRS (FPSA). Significant beneficial effect on hepatic encephalopathy was observed in the MARS study but not on survival.[45] In the FPSA trial no effect on survival was observed in the whole group or in patients with type 1 HRS, but a significant improvement was observed in patients with high MELD score (>30 points). The administered dosage of dialysis was very low in both studies (six sessions of 6 hours in 21 days). In these studies, therapy was well tolerated.[45,46] Further studies are clearly needed to ascertain the potential role of albumin dialysis in type 1 HRS. Patients with type 2 HRS are usually treated by total paracentesis or TIPS.

Renal Replacement Therapy

Hemodialysis and peritoneal dialysis in HRS patients with advancing uremia are both difficult. Conventional hemodialysis is hampered by the invariable systemic hypotension, and the efficacy and safety of peritoneal dialysis have not been well evaluated in these patients. Continuous venovenous hemofiltration (CVVH) or continuous venovenous hemodiafiltration (CVVHDF) has been advocated for the treatment of advancing uremia in HRS.[47] This is particularly true for patients with fulminant hepatic failure in whom intermittent dialysis can increase intracranial pressure. Anticoagulation should be minimized or may be avoided totally, especially in patients with preexisting coagulopathy, by giving the replacement fluid in the predilutional mode. When anticoagulation is needed, conventional heparin is generally recommended. Regional citrate anticoagulation is not recommended in advanced cirrhosis because the liver plays a significant role in its metabolism. If used, dose adaptation and close metabolic monitoring would be required, especially after prolonged use. Close plasma calcium monitoring is mandatory because hypocalcemia is common as a result of the impaired citrate clearance. Bicarbonate should be used instead of lactate as the buffer for the replacement solution to minimize metabolic acidosis. MARS may be combined with either CVVH or hemodialysis for the treatment of HRS. This approach may be most desirable in patients who also have severe hepatic encephalopathy. In patients who could require venovenous bypass for liver transplantation, the site of dialysis catheter placement should be carefully chosen so that the right jugular and right femoral vein may be preserved for cannulation.

Liver Transplantation

Liver transplantation is the treatment of choice in patients with advanced cirrhosis, including those with type 1 and type 2 HRS.[48-51] The hemodynamic and neurohormonal abnormalities associated with HRS disappear within the first month after liver transplantation. For this reason, calcineurin inhibitors should be withheld in the first few days after OLT to give the ischemic kidney a chance to recover, thus avoiding the nephrotoxicity of these immunosuppressants. Patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than transplantation patients without HRS. The long-term survival of patients with HRS who undergo liver transplantation, however, is good (3-year survival 60%) compared with transplantation in patients without HRS (70% to 80%).[48,49] Although renal function improves after transplantation in HRS patients, it never reaches that observed in non-HRS patients.[52] The incidence of end-stage renal disease in patients with HRS is slightly higher than that observed in transplantation patients without HRS (7% vs. 2%). Thus, OLT is associated with comparable liver outcome but inferior renal outcome in patients with HRS. This problem cannot be overcome by performing combined kidney and liver transplantation in HRS, which overall produces outcomes no better than with OLT alone.[53] However, in the very infrequent subgroup of patients with HRS who required prolonged pretransplant dialysis for more than 2 months (probably patients with combined functional and organic renal failure), combined kidney and liver transplantation did confer an advantage in patient survival and use of hospital resources. These infrequent patients usually have normal kidney size and morphology at ultrasound but develop some additional indications of organic nephropathy during follow-up (mild proteinuria or microhematuria).[54]

The main problem with liver transplantation in type 1 HRS is that because of their extremely short survival, most patients die before transplantation. The introduction of the MELD score for listing has partially solved the problem because patients with HRS are generally allocated in the first places of the waiting list. As mentioned earlier, treatment of HRS with vasoconstrictors and albumin improves survival in the group of patients with response to treatment, increasing the number of patients reaching liver transplantation. In addition, reversal of HRS before transplantation may decrease early morbidity and mortality after transplantation and prolong survival.[51]

Therapeutic Algorithm

Figure 76-4 shows the recommended algorithm for the management of HRS. Recent recommendations have also been published by the International Ascites Club.[9,55] OLT is undoubtedly the treatment of choice for patients with HRS, but other treatments described earlier must be used as a bridge to OLT, and they may improve the renal outcome after successful OLT. In patients who are not transplantation candidates, these treatments are their only chance for increased survival and in some cases may improve their condition to an extent that may allow them to be reconsidered for transplantation. The choice of therapeutic modalities depends on the availability of resources and expertise on the one hand and the severity of underlying renal and liver failure and the general condition of the patient on the other. All patients should be considered for vasoconstrictor therapy combined with albumin infusion. Among the vasoconstrictor therapies, intravenous terlipressin, combined with daily albumin infusion, is most established and is the preferred therapy.[55] In countries where terlipressin is not available, continuous intravenous norepinephrine or vasopressin may be used as alternative. Patients with a history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine plus albumin. Oral midodrine combined with subcutaneous octreotide and albumin is another alternative in the treatment of HRS, especially in patients with type 2 HRS. In patients with relatively well-preserved liver function (serum bilirubin <5 mg/dl or 85.5 µmol/l and Child-Pugh score <12) without severe hepatic encephalopathy (grade <2) or history of recurrent encephalopathy, concurrent severe bacterial infection, or serious cardiovascular or pulmonary disease, TIPS should be considered, especially in patients with recurrence after vasoconstrictor therapy, a situation more commonly observed in HRS type 2

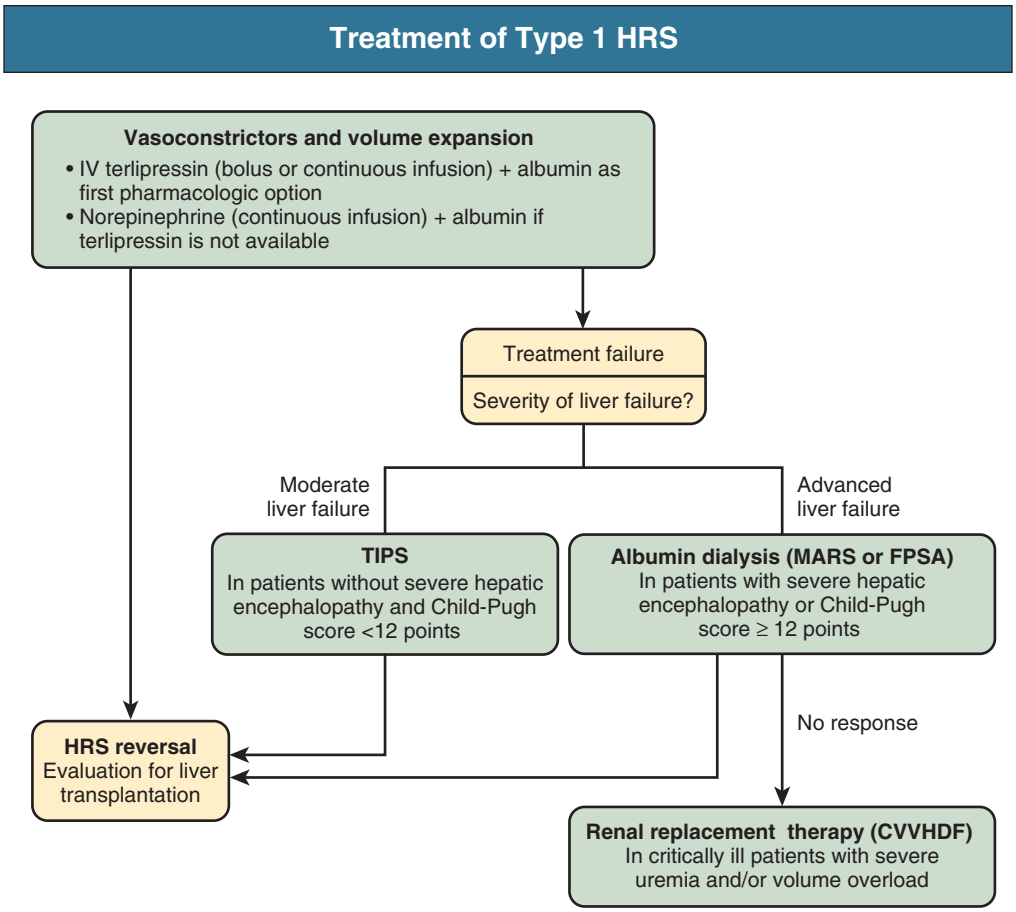

Figure 76-4 Algorithm for the management of type 1 hepatorenal syndrome (HRS). Initial treatment is based on the use of vasoconstrictor therapies plus albumin. Intravenous terlipressin is the most established and is the preferred therapy.[55] If terlipressin is not available, continuous intravenous norepinephrine should be used. Patients with history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine. If pharmacologic therapy fails, the severity of liver failure should be assessed. In patients with less severe liver dysfunction (bilirubin <5 mg/dl or 85.5 µmol/l and Child-Pugh score <12) without severe hepatic encephalopathy (grade ≤2) or history of recurrent encephalopathy, transjugular intrahepatic portosystemic shunt (TIPS) should be considered.[3] In patients with more severe liver failure (Child-Pugh score ≥12) and/or severe hepatic encephalopathy (grade >2), albumin dialysis (molecular adsorbent recirculating system [MARS] or fractionated plasma separation and adsorption [FPSA]) should be considered. In critically ill cirrhotic patients with advancing renal failure, continuous venovenous hemodiafiltration (CVVHDF) is the treatment of choice.

patients.[3] In these patients, TIPS may have the added benefit of relieving refractory ascites. TIPS also appears to achieve complete normalization of renal function in selected patients after an initial successful response to vasoconstrictor therapy. In patients with severe liver failure (Child-Pugh score ≥12) and severe hepatic encephalopathy (grade >2), MARS should be considered. In critically ill cirrhotic patients with advancing renal failure, CVVH is the treatment of choice and may be combined with other therapeutic modalities, especially MARS or FPSA.

SECTION XV

Drug Therapy in Kidney Disease

CHAPTER 77

Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy

Matthew J. Cervelli and Graeme R. Russ

Renal impairment can alter drug pharmacokinetics and pharmacodynamics, and consequently patients with renal impairment are at risk of adverse effects. In addition, these patients take multiple drugs and are at high risk of drug interactions and drug-related problems.[1] To prescribe safely and effectively, clinicians should be familiar with the pharmacokinetics of drugs in varying stages of renal impairment and renal replacement therapy (RRT) and ideally rely on data from these populations. Unfortunately, such information is not always available, and exclusion of these patients from clinical studies can lead to restrictive licensed recommendations. This chapter describes pharmacokinetic principles and highlights common prescribing issues in patients with renal impairment, dialysis, and transplantation. Specific dose recommendations and pharmacokinetic data are not included but can be obtained from references developed specifically to provide concise, reliable, and practical information for prescribing the settings of renal impairment, dialysis, and transplantation.[2-5]

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics describes the behavior of a drug (or metabolite) with regard to absorption, distribution, metabolism, and elimination (Fig. 77-1 and Table 77-1).[6,7]

Absorption: Bioavailability

Bioavailability *(F)* is the portion of a drug dose that appears in the systemic circulation after administration by a nonintravenous route. Whereas drugs given intravenously have 100% bioavailability, drugs given by alternative routes pass through a series of biologic membranes before entering the systemic circulation so that only a fraction may reach the circulation.

After oral administration, the liver can metabolize a drug during "first pass" when it is absorbed or later when it is delivered through systemic blood flow. First-pass metabolism can significantly reduce absorption. The gastrointestinal mucosa also acts as a barrier to absorption by metabolizing drugs or retarding absorption.[8] Renal impairment can influence absorption, although the effect is difficult to quantify and clinical examples are limited. Gastrointestinal edema can limit oral absorption, for example, of furosemide. Nausea and vomiting from uremia can impair absorption and contact time between the drug and gastrointestinal mucosa. In patients with advanced uremia, the alkalinizing effect of salivary urea may decrease absorption of drugs optimally absorbed in an acid milieu. Commonly prescribed metallic ion phosphate binders can decrease drug absorption by forming nonabsorbable complexes with drugs (Table 77-2).[9] Changes in cardiac output in renal failure can reduce the rate and extent of absorption for drugs with significant first-pass metabolism. Increased absorption in patients with renal impairment from reduced first-pass metabolism is seen with some β-blockers, dextropropoxyphene, and dihydrocodeine. Comorbidities in renal patients also have an effect; for example, absorption can be erratic because of diabetic gastrointestinal neuropathy.

Distribution

Volume of Distribution

After absorption, drugs may distribute from plasma to an extravascular compartment. Each drug has a characteristic volume of distribution (V_D), which is really an apparent V_D because it does not correspond to an anatomic space but instead relates the amount of drug in the body to its plasma concentration. V_D is used to calculate the loading dose to achieve a desired plasma concentration (V_D = dose/plasma). Water-soluble drugs tend to be restricted to the extracellular fluid space and have a relatively small V_D. Lipid-soluble drugs penetrate body tissues and have a large V_D. Increased V_D can occur with edema, ascites, or infection, particularly for water-soluble drugs. If usual doses are given, low concentrations result. Conversely, muscle wasting or volume depletion can decrease the V_D of water-soluble drugs, and usual doses produce high concentrations.

Plasma Protein Binding

Drugs can bind extensively to plasma proteins.[10] The free (unbound) fraction of a drug is usually the portion that exerts a pharmacologic effect. If protein binding is reduced, a greater free fraction is available for any given total drug concentration, which may increase drug activity. Organic acids usually have a single binding site on albumin, whereas organic bases have multiple binding sites on glycoproteins. Protein binding can be altered in patients with renal impairment, especially when serum albumin is low (e.g., nephrotic syndrome) or when uremic toxins displace drugs from binding sites (Table 77-3). Predicting the effect of changes in protein binding is difficult because even though more free drug is available at the site of action, more is available for metabolism or renal excretion. Hence, lower plasma concentrations can occur and drug half-life may decrease rather than increase. Phenytoin, for example, has marked decreases in protein binding in patients with renal impairment, and toxicity can occur despite normal or low total plasma concentrations because of an increase in free fraction. With albuminuria, bound drug may also be lost, which may partially explain the refractoriness of nephrotic patients to diuretics. In patients with chronic kidney disease (CKD), high plasma levels of α_1-acid glycoprotein are induced in acute and chronic inflammation, which can increase drug binding.

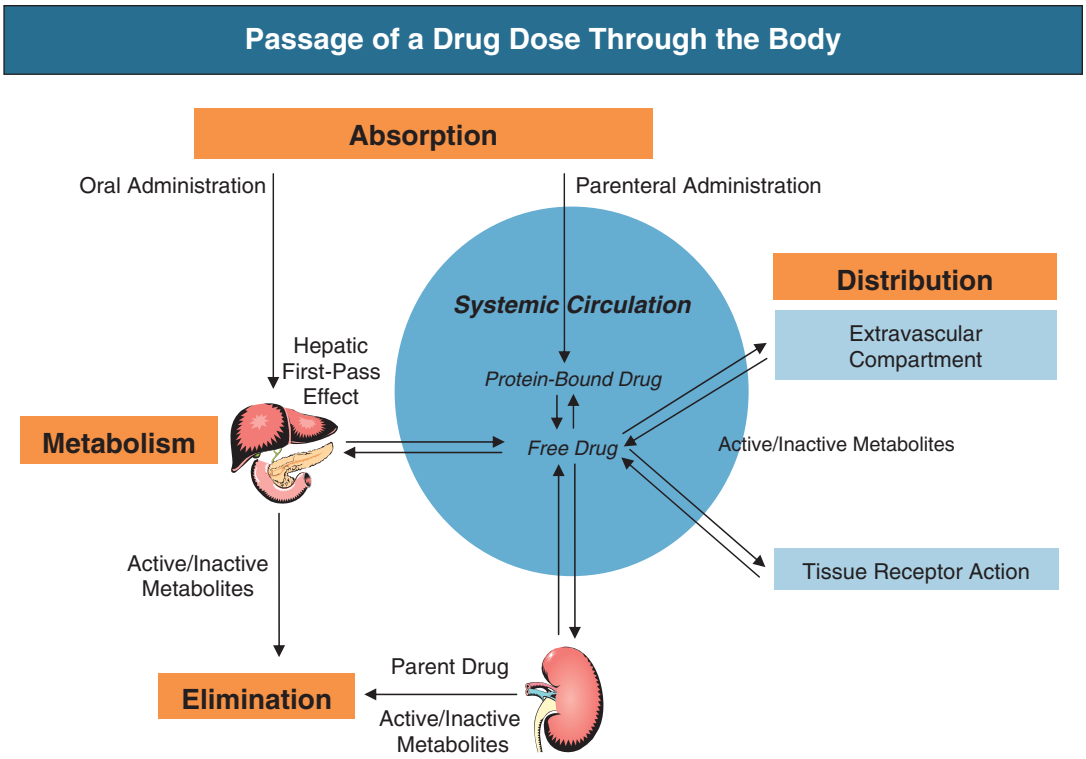

Figure 77-1 Passage of a drug dose through the body.

Pharmacokinetic Parameters

Parameter	Definition	Application
Bioavailability (*F*)	Percentage of a dose that appears in the systemic circulation after administration by a nonintravenous route	Determines the amount of drug reaching the systemic circulation
Volume of distribution (V_D)	Proportionality constant relating the amount of drug in the body at a given time to a simultaneously occurring drug concentration in plasma, blood, or other reference fluid at an identical time	Determines the size of loading doses
Clearance (Cl)	Proportionality constant between rate of drug elimination from the body (units = mass/unit time) and the concentration of the drug in plasma or blood at the same point in time	Determines the maintenance dose
Half-life ($t_{1/2}$)	Time taken for the drug concentration in plasma to fall to half its current value	Determines frequency of administration and time to steady state

Table 77-1 Pharmacokinetic parameters.

Effect of Food and Phosphate Binders on Oral Drug Absorption

Drug	Effect of Food
Captopril	Decreases serum drug levels
Bisphosphonates (oral)	Significantly reduces drug absorption
Cinacalcet	Significantly increases drug absorption
Iron (oral)	Decreases absorption
Ketoconazole or itraconazole	Increases absorption with reduced pH
Sirolimus	High-fat meals increase absorption
Tacrolimus	Reduces drug absorption
Drug	**Effect of Metallic Phosphate Binders**
Bisphosphonates (oral)	Calcium-containing binders significantly reduce absorption
Fluoroquinolones	Reduction in absorption
Tetracycline	Reduction in absorption
Thyroid hormones	Reduction in absorption

Table 77-2 Effect of food and phosphate binders on oral drug absorption.

Metabolism

Drug metabolism is primarily a hepatic function by which drugs are converted to more water-soluble entities to promote elimination by the kidneys and bile. Despite the assumption that nonrenal clearance is unchanged, renal impairment can alter and slow drug metabolism.[11] It is important to note that some drugs have renally cleared active or toxic metabolites that, although insignificant in normal renal function, can accumulate in patients with renal impairment.

Elimination

The kidney is the most important organ for drug and metabolite elimination. Terms to describe drug clearance are shown in Box 77-1. Total drug clearance equals the apparent volume of blood or plasma from which the drug is cleared per unit of time and is expressed as the dose divided by the area under the drug concentration curve (AUC). *Half-life* describes the time taken for plasma

Protein Binding of Drugs in Renal Disease	
Major Effects	**Minor Effects**
Albumin: Binding Sites for Acidic Compounds	
Barbiturates (↓)	Ascorbic acid
Benzodiazepine	Valproate (↓)
Carbamazepine	Fatty acids
Fibrates	Nafcillin
Furosemide (↓)	Phenylbutazone (↓)
Mycophenolate mofetil	Probenecid
Penicillins	Thiopental (↓)
Phenytoin (↓)	Warfarin (↓)
Sulfonamides (↓)	Thyroxine (↓)
Globulins: Binding Site for Basic Compounds	
Digoxin (↓)	Adenosine
Methadone	Amitriptyline
Propranolol	Chloramphenicol

Table 77-3 Protein binding of drugs in renal disease. ↓ indicates reduced protein binding in renal impairment. For all other drugs listed, protein binding is increased. The therapeutic effect is, however, not easily predicted (see text).

Mathematics of Drug Elimination

Total body clearance = Drug dose / AUC

Renal clearance = Total amount of drug in urine/plasma drug concentration

Total amount of drug in urine = Drug × volume of the sample collected in a fixed time

Drug half-life ($t_{1/2}$) = $V_D \times 0.693$ / Clearance

Box 77-1 Mathematics of drug elimination. *AUC,* Area under the concentration-time curve; V_D, volume of distribution (dose/blood concentration).

concentrations to halve and is related to V_D and clearance. Quantitation of drug elimination by the kidney is expressed as renal clearance, which depends on renal blood flow and the ability of the kidney to remove the drug. Renal drug clearance is the balance of its glomerular filtration rate (GFR), renal tubular secretion, and tubular reabsorption. Glomerular filtration depends on molecular size (<10 kd), charge, and protein binding (increased when binding decreases). Secretion of drugs eliminated by tubular transport may change with renal disease, but measurement of tubular function is difficult. Practically, as GFR decreases, drugs dependent on tubular secretion are also excreted more slowly. Assuming no change in nonrenal clearance, as GFR falls, clearance of drugs (and metabolites) eliminated by the kidney decreases, and their half-life is prolonged.

PRESCRIBING PRINCIPLES FOR CHRONIC KIDNEY DISEASE AND RENAL REPLACEMENT THERAPY

Ideally, dose modification recommendations should be made by comparing the pharmacokinetics of a drug at varying stages of renal impairment relative to normal function. However, lack of reliable data and individual patient factors limit such generalities, and clinical judgment about a patient's ability to handle a drug is vital.[12] Dose nomograms, tables, and computer recommendations are helpful but not necessarily associated with better outcomes. Physicians should use clinical judgment to evaluate every situation individually, choose a dosage regimen based on factors in that patient, and continually reevaluate response to therapy.

Initial Assessment and Laboratory Data

A targeted history is important in assessing dose in patients with renal impairment. Previous drug efficacy or toxicity should be determined and the current drug list reviewed for potential interactions or nephrotoxins. Physical and laboratory parameters indicate volume status, height, weight, and extrarenal disease (e.g., liver).

Estimating Renal Function for Drug Dosage

Estimating renal function is essential in renal drug dosage. The greater the degree of renal impairment, the greater the potential for dose modification. With exceptions, dose modification is usually not clinically necessary until GFR is below 30 ml/min. Assessment of renal function for drug administration is not a precise science, and what is essential for clinical decision making is awareness that renal function is impaired, and approximately to what extent, rather than knowledge of the precise GFR.[13] For drug prescribing, renal impairment is usually graded as mild (30 to 60 ml/min), moderate (10 to 30 ml/min), or severe (dialysis). For drug dosage calculation, methods of estimating GFR are sufficient (see Chapter 3). The Cockcroft-Gault equation has been the most widely used and accepted method for drug dosage calculation. The Modification of Diet in Renal Disease (MDRD) formula, if not corrected for body surface area, can lead to recommendations different from those obtained by the Cockcroft-Gault equation. An important limitation of many renal function estimates is inaccuracy of single-point estimates when renal function is rapidly changing. This may lead to overestimation or underestimation of renal function and underdose or overdose. In patients with severe acute kidney injury (AKI), the decline in GFR is so rapid that patients should receive dosages appropriate for a GFR below 10 ml/min. The opposite is true in rapidly improving renal function after AKI or early post-transplant.

Activity and Toxicity of Metabolites

It is essential to consider the activity (or toxicity) of drug metabolites in addition to that of the parent drug itself. Renally cleared metabolites can accumulate, leading to enhanced drug action or toxicity (Table 77-4).

Fraction of Active Drug (and Active or Toxic Metabolite) Excreted Unchanged in Urine

The greater the fraction of active drug or metabolite excreted unchanged by the kidneys (fe), the greater the need for dose modification. It is usually clinically necessary to modify doses only if the fe is greater than 25% to 50%. The reported fe is often determined from studies that do not distinguish between parent drug and metabolites. The contribution of inactive nontoxic metabolites to overall renal drug elimination may exaggerate the potential for harm. Active or toxic metabolites should be assessed separately for

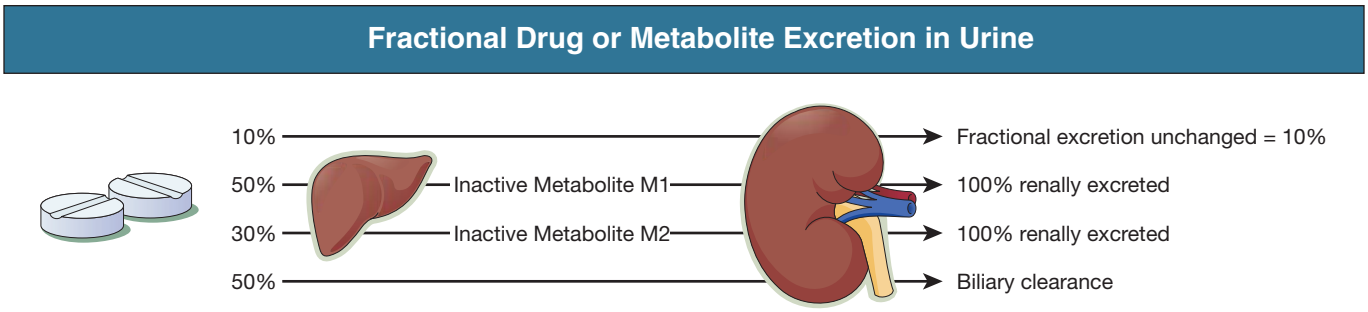

Figure 77-2 Fraction of drug or metabolite excreted in urine. In this hypothetical example, 10% of the dose is excreted unchanged in urine (fe = 10%); 50% of the dose is metabolized to inactive metabolite M1, which is then all renally excreted; 30% of the dose is metabolized to inactive metabolite M2, which is all renally excreted; and the remaining 10% is excreted unchanged in bile. For this drug, the total excretion of drug dose in urine is 90%. However, this 90% comprises 10% as parent drug and 80% as inactive metabolites, and dose modification is probably not essential even in severe renal impairment. Total renal excretion of the dose is 90%; however, the clinically significant fraction of active drug excreted in urine is 10%.

Drugs with Active or Toxic Metabolites That Accumulate in Subjects with Reduced GFR

Drug	Active Metabolite	Consequence
Allopurinol	Oxypurinol	
Cefotaxime	Desacetylcefotaxime	
Glyburide	4-*trans*-Hydroxyglibenclamide 3-*cis*-Hydroxyglibenclamide	Hypoglycemia
Morphine	Morphine-6-glucuronide	CNS side effects
Tramadol	*O*-Desmethyltramadol	CNS side effects
Venlafaxine	*O*-Desmethylvenlafaxine	CNS and cardiovascular side effects
Drug	**Toxic Metabolite**	**Consequence**
Dapsone	Monoacetylated metabolite	
Meperidine (pethidine)	Normeperidine (norpethidine)	CNS (seizures)
Nitroprusside	Thiocyanate	Cyanide toxicity
Procainamide	*N*-Acetylprocainamide (NAPA)	Arrhythmia
Propoxyphene	Norpropoxyphene	Cardiac toxicity

Table 77-4 Drugs with renally cleared active or toxic metabolites. *CNS,* Central nervous system.

their dependence on renal elimination in the same way as the parent drug (Fig. 77-2).

Therapeutic Index of the Drug or Metabolites

The decision to modify dosage for patients with renal impairment is influenced by the therapeutic window or index of the drug. The therapeutic window is the range of plasma drug concentrations spanning the minimum concentration for clinical efficacy and toxicity. The therapeutic index is the ratio of these concentrations (Fig. 77-3). If the therapeutic window is wide (e.g., many penicillins), there may be no clinical need for dose modification despite significant renal elimination. If the therapeutic window is narrow (e.g., digoxin), dose modification is more critical. Clinicians should judge the clinical relevance of increased exposure to drug or metabolites.

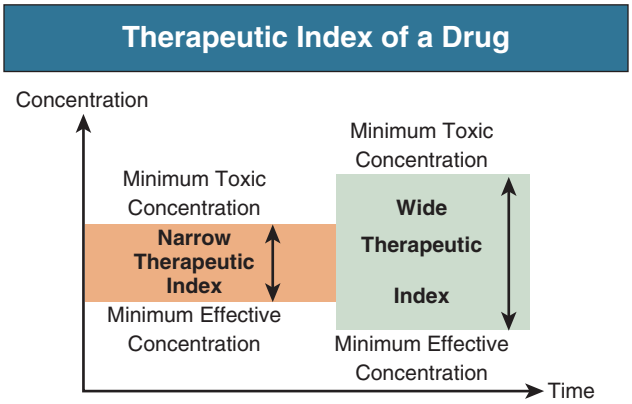

Figure 77-3 Therapeutic index of a drug. Two examples of drugs with, on the left, a narrow therapeutic index, and on the right, a wide therapeutic index.

Avoid Nephrotoxic Drugs

A wide range of drugs can cause nephrotoxicity (Table 77-5). Idiosyncratic nephrotoxicity (e.g., interstitial nephritis) is unpredictable and independent of dose. Predictable hemodynamic-related nephrotoxicity can occur with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), nonsteroidal anti-inflammatory drugs (NSAIDs), diuretics, antihypertensives, and laxatives. Direct tubular nephrotoxins include aminoglycosides, vancomycin, amphotericin, cisplatin, calcineurin inhibitors (CNIs), and radiographic contrast media. Obstructive uropathy can occur with tubular crystallization of acyclovir, statin-induced rhabdomyolysis, or tricyclic antidepressant use. In dialysis patients with no significant residual renal function, use of nephrotoxic drugs may be acceptable. Drug nephrotoxicity is discussed further in Chapter 69.

Drugs That Aggravate the Metabolic Effects of Renal Impairment

Some drugs have no direct adverse effect on renal function but when used in patients with renal impairment can aggravate the metabolic consequences of renal failure. Hyperkalemia is worsened with potassium supplements, potassium-sparing diuretics, aldosterone antagonists, and blockers of the renin-angiotensin system. The catabolic effects of tetracycline can exacerbate uremia. Sodium-containing drugs and those that promote sodium and water retention should be used cautiously because they may provoke fluid overload and hypertension.

Nephrotoxic Drugs		
Examples	**Mechanism**	**Prevention and Management**
ACE inhibitors, ARBs	Impairment of angiotensin II–mediated afferent arteriole dilation during renal hypoperfusion	Withdraw in renal hypoperfusion
Aminoglycosides Amikacin Gentamicin Tobramycin	In proximal tubules, aminoglycosides bind to anionic phospholipid, are delivered to megalin, are taken up into the cell, accumulate, and cause direct toxicity	Alternative if possible Monitor drug concentrations Avoid multiple daily doses Withdraw if creatinine rises
Antifungals Amphotericin	Afferent vasoconstriction and direct action to reduce GFR Distal tubular injury via creation of pores that increase membrane permeability leading to hypokalemia, hypomagnesemia, metabolic acidosis caused by tubular acidosis, polyuria from nephrogenic diabetes insipidus	Avoid use Administer slowly with hydration Use liposomal preparation
Antivirals		
Acyclovir	Deposition of drug crystals → intratubular obstruction and foci of interstitial inflammation	Avoid bolus dose Reduce dose in renal impairment Hydrate during therapy
Cidofovir	Induces apoptosis in proximal tubule → tubular dysfunction, diabetes insipidus, renal failure	Oral probenecid and hydration
Foscarnet	Direct tubular toxicity → acute tubular necrosis, nephrogenic diabetes insipidus Crystals in glomerular capillary lumen and proximal tubular lumen	Hydration
Indinavir	Crystal neuropathy, nephrolithiasis → obstructive AKI	Hydration
Calcineurin inhibitors Cyclosporine Tacrolimus	↓ PG and ↑ 20-HETE acid production → vasoconstriction, generation of H_2O_2 resulting in depleted glutathione → decreased GFR, ischemic collapse or scarring of the glomeruli, vacuolization of the tubules, and focal areas of tubular atrophy and interstitial fibrosis	Measure plasma concentrations Avoid interacting drugs Withdraw drug (switch to mTOR inhibitor)
Chemotherapeutics		
Cisplatin	*Cis* chloride replaced by H_2O → highly reactive OH radical → DNA injury, tubular cell death Nephrogenic diabetes insipidus, hypomagnesemia (may be persistent)	Forced diuresis and hydration
Ifosfamide	Direct tubular injury and mitochondrial damage → renal tubular acidosis, Fanconi-like syndrome, nephrogenic diabetes insipidus hypokalemia	
Intravenous immunoglobulin (sucrose-containing products)	Accumulation of sucrose in proximal convoluted tubules, ↑ osmolarity → cell swelling, vacuolization, and tubular luminal occlusion	Infusion rate <3 mg sucrose/kg/min Avoid radiocontrast Avoid sucrose-containing product Hydration
Lithium	Impairment of collecting duct concentrating ability → diabetes insipidus Chronic tubulointerstitial nephropathy (tubular atrophy and interstitial fibrosis)	Measure plasma concentrations Prevent dehydration Avoid thiazides
NSAIDs	Hemodynamically induced AKI caused by vasoconstriction via reduced prostaglandin production Recruitment and activation of lymphocytes → acute and chronic tubulointerstitial nephritis, with or without nephrotic syndrome	Avoid use Withdraw during hypoperfusion Withdraw (add corticosteroids)
Proton pump inhibitors	Interstitial nephritis	Withdraw (add corticosteroids)
Radiocontrast media	High osmolarity, medullary vasoconstriction, ↑ active transport in thick ascending loop of Henle → ↑ O_2 demand	Hydration preprocedure and postprocedure Acetylcysteine
Sulfonamides	Intrarenal precipitation → Kidney stone formation	Fluid intake >3 l/day; monitor urine for crystals Alkalinize urine to >7.15 if crystal seen

Table 77-5 Some examples of nephrotoxic drugs. *ACE,* Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ARBs,* angiotensin receptor blockers; *GFR,* glomerular filtration rate; *20-HETE acid,* 20-hydroxyeicosatetraenoic acid; *H_2O_2;* hydrogen peroxide; *mTOR,* mammalian target of rapamycin; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PG,* prostaglandin.

Effect of Renal Impairment on Pharmacodynamic or Physiologic Mechanisms

Renal disease may alter a pharmacodynamic response or physiologic process, which in turn affects clinical response. For example, the inability of impaired kidneys to activate vitamin D precursors means that vitamins D_2 and D_3 may be less effective. Patients with renal impairment often have a coagulopathy from the effects of uremia on platelet function and may be more prone to the bleeding complications of anticoagulant and antiplatelet therapy.

Effect of Renal Impairment on the Concentration of Drug at the Site of Action

Renal impairment can alter drug concentration at the site of action. Some diuretics and antibiotics become ineffective in patients with renal impairment because they do not achieve adequate concentrations at their site of action in the renal tubules or bladder. This may preclude the use of drugs such as thiazide diuretics and nitrofurantoin or may require increased doses of others (e.g., loop diuretics).

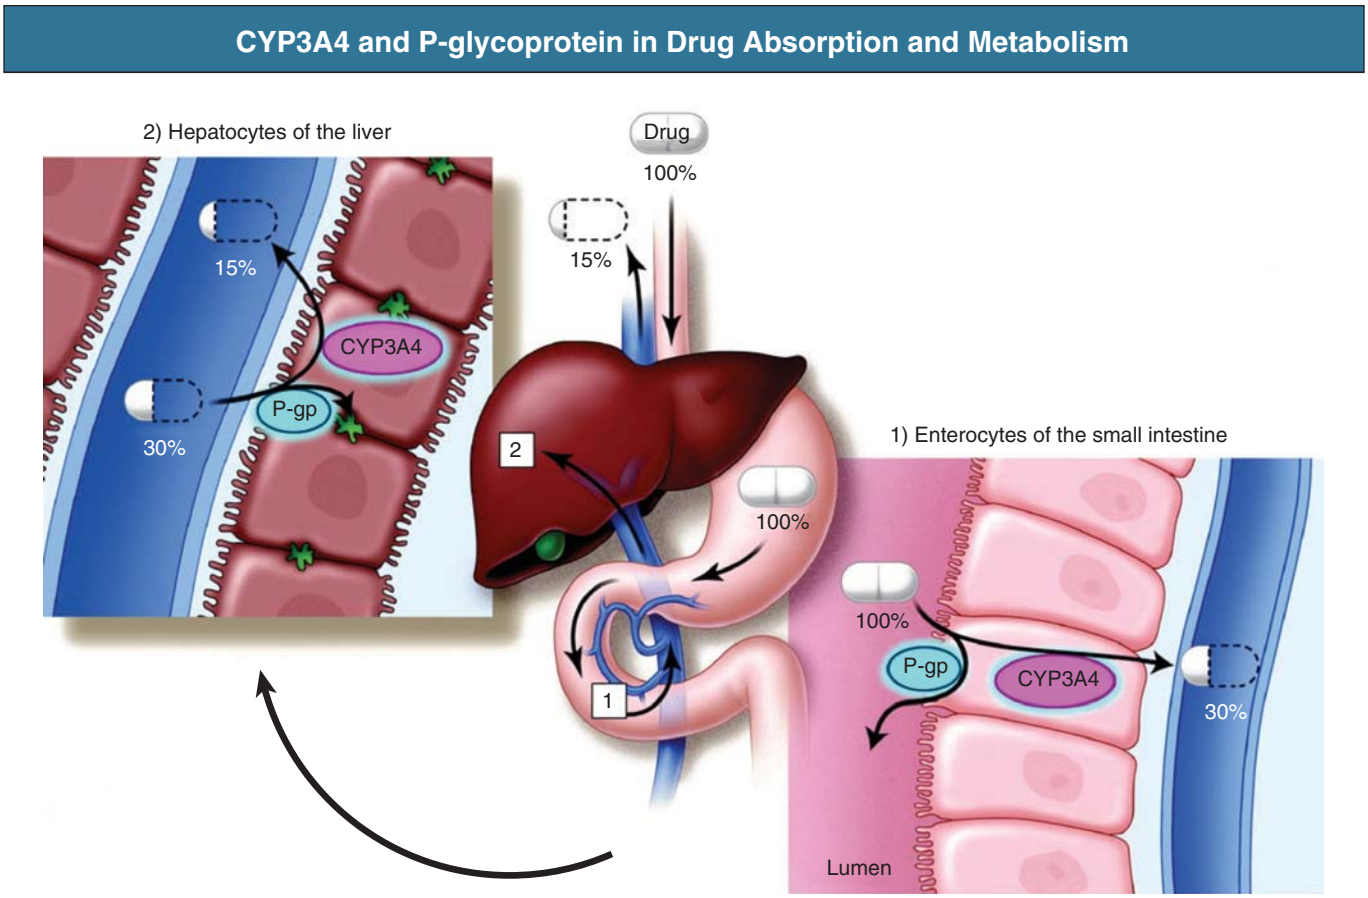

Figure 77-4 CYP3A4 and P-glycoprotein in drug absorption and metabolism. Schema for absorption and metabolism of drugs that are substrates for CYP3A4 and P-glycoprotein. Overall, approximately 15% of ingested drug reaches the systemic circulation. *1),* Enterocyte: P-glycoprotein on the apical surface of enterocytes prevents drug absorption, maintaining drug in the gastrointestinal lumen; CYP3A4 in enterocytes metabolizes drug. The net effect is that approximately 30% of ingested drug reaches the portal circulation. *2),* Hepatocyte: P-glycoprotein on the cell surface prevents drug entry into hepatocytes; CYP3A4 in hepatocytes metabolizes drug. The net effect is that drug entry to the systemic circulation is further reduced.

Location of Drug Action

Drugs that have negligible bioavailability and that are used for a local or topical effect may be given safely at normal dose despite toxicity with systemic doses. These include topical NSAIDs, nebulized gentamicin, and oral vancomycin.

Method of Administration

In fluid-restricted patients, administration of intravenous drug infusions with approved fluid volumes may be undesirable. When administration exceeds daily fluid restrictions, consider alternatives or more concentrated solutions if physiochemical parameters allow. Similarly, oral drug administration with large fluid volumes (e.g., bisphosphonates) may not be advisable. In patients with severe nausea and vomiting, essential immunosuppressants should be administered intravenously.

Drug Interactions

Pharmacokinetic drug interactions are frequently problematic, and awareness of clinically significant interactions is essential, especially with regard to patients receiving transplant immunosuppressants. The most important of these are cyclosporine, tacrolimus, everolimus, and sirolimus, which are substrates of both the CYP3A4 enzyme system and P-glycoprotein expressed in gastrointestinal mucosa and liver.[14] Co-prescription of drugs that inhibit these systems (e.g., some azole antifungals, calcium channel blockers (CCBs), macrolides, and grapefruit juice) can increase absorption and reduce metabolism of the immunosuppressant, causing toxicity. Conversely, drugs that induce these systems (e.g., barbiturates, phenytoin, carbamazepine, rifampin, and St John's wort *[Hypericum]*) can reduce absorption and increase metabolism and therefore increase the risk of rejection (Fig. 77-4 and Table 77-6). All drug changes in patients receiving transplant immunosuppression should be considered for their potential to interact, and appropriate dose modifications or alternatives used.

Clinical Condition of the Patient

The patient's welfare should override theoretical concerns. Higher-than-recommended doses may be appropriate when there is a strong clinical indication. For example, excessive reduction in initial antibiotic doses based on renal function may be inappropriate in patients with life-threatening infection when the consequences of failed therapy are greater than potential toxicity.

Methods of Dose Reduction

Loading Doses

For most drugs, steady-state concentrations are achieved after five drug half-lives. Hence, for some drugs, a loading dose is given to reduce time to steady state. Because renal impairment may prolong the half-life, simply reducing drug doses could be a therapeutic error

Common CYP3A4/P-gp–Mediated Interactions with Transplant Immunosuppressants (Cyclosporine, Tacrolimus, Sirolimus, and Everolimus)

Drug Class	Examples	Relative Potency
Drugs That Inhibit CYP3A4 and P-gp		
Macrolide antibiotics	Azithromycin	–
	Clarithromycin	+++
	Erythromycin	+++
	Roxithromycin	+
Azole antifungals	Fluconazole	+/–
	Itraconazole	++
	Ketoconazole	+++
	Voriconazole	+++
Calcium channel blockers	Amlodipine	+/–
	Nifedipine	+/–
	Felodipine	+/–
	Diltiazem	++
	Verapamil	+++
Herbals, foods	Grapefruit juice	++
Drugs That Induce CYP3A4 and P-gp		
Antiepileptics	Carbamazepine	++
	Phenytoin	+++
	Phenobarbitone	++
Antibiotics	Rifampin	+++
Herbals, foods	St John's wort	+++

Table 77-6 Common CYP3A4/P-gp–mediated drug interactions with transplant immunosuppressants (cyclosporine, tacrolimus, sirolimus, everolimus). *P-gp,* P-glycoprotein.

because this would further delay achievement of steady state. The loading dose (mg/kg) is equal to the product of the desired plasma concentration (mg/ml) and V_D (ml/kg) and is independent of clearance. Provided the desired concentration and V_D are unchanged, loading doses do not require modification in patients with renal impairment. In some instances, V_D is altered, especially with hypoproteinemia or fluid overload, and hence some clinicians alter the loading dose of drugs with a narrow therapeutic index such as digoxin. Aminoglycoside doses may need to be increased in patients with fluid overload or sepsis who have an increased V_D.

Maintenance Doses

When specific pharmacokinetic information is not available, and assuming no change in nonrenal clearance, maintenance doses should be reduced in proportion to the extent of renal impairment and renal drug elimination. For example, if renal function is 50% of normal and the drug is 100% renally excreted, a maintenance dose of 50% is required. If the drug is 50% renally cleared and the patient has 20% renal function, the dose should be 60% of normal. The dose reduction factor is estimated from first principles or the following formula:

$$\text{Dose rate in renal impairment/Dose rate in normal renal function} = (1 - \text{fe}) \times (1 - \text{Fraction of remaining renal function})$$

where fe is the fraction of active drug excreted unchanged in urine.

Once a dose reduction factor has been determined, the clinician must decide on a dose reduction method. Two methods are used, either alone or in combination (Fig. 77-5).

Interval Method Because drug clearance is reduced, a reduction in delivered dose is achieved by administering the same dose less frequently. This method is particularly useful when the size of the dose and peak blood concentrations are important for efficacy (e.g., aminoglycosides). If this method is used, practical dose intervals should be recommended rather than inconvenient or complex intervals.

Dose Method An alternative method is to administer a smaller dose at the usual interval. This method is common, especially when the size of a dose and peak concentrations are less critical for efficacy. If this method is used, clinicians should consider the availability of smaller dose formulations and the ability of the patient to accurately and safely divide available dosage forms.

Combination Method Sometimes, especially for drugs with a narrow therapeutic index, for which tight control of concentrations is required (e.g., digoxin), a combination of the dose and interval methods is used.

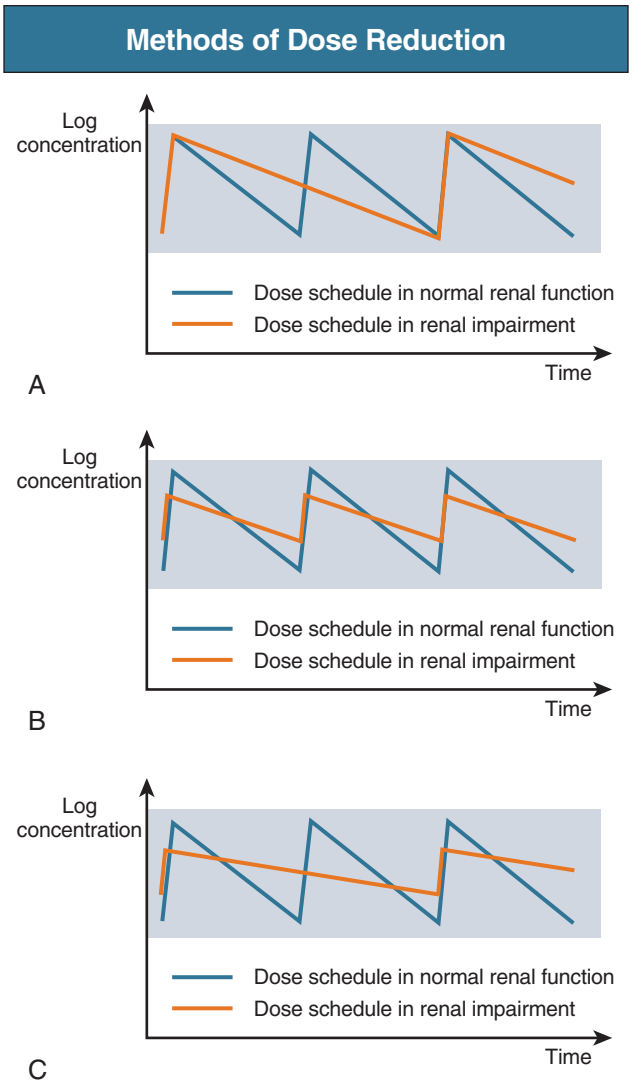

Figure 77-5 Methods of dose reduction. A, Interval method. **B,** Dose method. **C,** Combination method.

Ongoing Assessment

Even with appropriate dose modification in patients with renal impairment, clinicians should always remain vigilant and closely monitor the response to therapy to guide dose titration.

Therapeutic Drug Monitoring in Renal Impairment

Drug	Therapeutic Range and When to Draw Sample
Aminoglycosides	Peak (30 min after a 30-min infusion)
(24-h dosing)	Trough (6-12 h after dose)
Gentamicin	Peak: >10 mg/l
Tobramycin	Trough: depends on time after dose 0.5-2 mg/l
Amikacin	Peak: >30 mg/l Trough: depends on time after dose 1.5-6 mg/l
Immunosuppressants	
Cyclosporine	C_0 (trough): 150-250 µg/ml C_2 (2 h after dose): 1200-1500 µg/ml AUC_{0-4} >4400 µg/ml/h
Tacrolimus	C_0 (trough): 4-12 µg/ml
Sirolimus	C_0 (trough): 5-15 µg/ml
Antiarrhythmics	
Digoxin	0.8-2.0 µg/ml (trough at least 6 h after dose)
Lidocaine	1-5 µg/ml 8 h after IV infusion starts or is changed
Antipsychotics	
Lithium	Acute: 0.8-1.2 mmol/l (trough) Chronic: 0.6-0.8 mmol/l (trough)
Antiepileptics	
Carbamazepine	4-12 µg/ml (trough before administration)
Phenytoin	10-20 µg/ml (trough before administration)
Free phenytoin	1-2 µg/ml (trough before administration)
Phenobarbital	15-40 µg/ml (trough before administration)
Valproic acid	40-100 µg/ml (trough before administration)
Vancomycin	Trough: 10-20 mg/l

Table 77-7 Therapeutic drug monitoring in renal impairment. Target levels are dependent on assay methodology and clinical context. *IV,* Intravenous.

Therapeutic Drug Monitoring

Therapeutic drug monitoring can provide objective information to guide dosage calculation and is valuable for drugs such as aminoglycosides, glycopeptides, digoxin, lithium, antiepileptics, and immunosuppressants (Table 77-7). Assays usually measure total blood concentrations and may significantly underestimate plasma levels of the active or free form of the drug.

Clinical Response

Ultimately, clinical response should influence the need to modify doses. Doses should be carefully titrated according to response and adverse effects. For example, blood pressure for antihypertensives, blood glucose concentration and hemoglobin A1c (HbA1c) for oral hypoglycemics, and renal function for toxicity from CNIs, ACE inhibitors, and ARBs.

Extracorporeal Drug Losses

Failure to consider dialysis drug clearance may significantly reduce drug efficacy.[5,7] Alternatively, dialysis may be used in overdose to assist drug removal (see Chapter 98). Studies of drug clearance with RRT modalities have often used variations in dialysis technique that make it difficult to compare results. Many studies before the 1990s report data from standard hemodialysis (HD) with low-flux membranes, which are less efficient at drug removal than the high-flux membranes now widely used. Many recommendations report the need for supplemental doses. Clinically, supplemental doses are rarely used, especially if less than 30% of the drug is cleared or the drug has a wide therapeutic index. Rather, drugs known to be significantly cleared by dialysis should be administered after dialysis (Table 77-8). When drugs are given in multiple daily doses, at least one of the daily doses should be administered soon after the completion of dialysis.

Hemodialysis

Hemodialysis drug clearance occurs mainly by passive diffusion along a concentration gradient but also by convectional movement of soluble drug with ultrafiltrated plasma water.[7,15] The efficiency of drug removal depends on physiochemical drug properties. As molecular size decreases (<500 d) and water solubility increases, drug removal increases. Conversely, as protein binding and V_D increase, dialysis clearance decreases. HD factors influencing drug removal include membrane type and surface area, blood flow rates, and dialysis frequency and duration. HD can remove drug from plasma faster than it can redistribute from tissue, so drug concentrations determined from samples drawn soon after beginning or completion of HD may be low. Samples should preferably be drawn before dialysis or about 1 to 2 hours after to allow drug redistribution.

Peritoneal Dialysis

Many drug properties that affect removal by HD also apply to peritoneal dialysis (PD), but PD is usually less efficient.[16] For significant removal by peritoneal PD, the drug must have a very low V_D and low protein binding. For most drugs, there is little evidence of significant removal during chronic PD. A few studies have examined drug clearance from automated PD that uses large volumes of short dwells at night, often accompanied by one or more longer daytime dwells. Clearance of some drugs on automated PD is increased because of the increased drug concentration gradient between blood and dialysate. Increased drug dialyzability may occur with increased peritoneal dialysate flow rates or during peritonitis.

Continuous Renal Replacement Therapy

Drug clearance by continuous RRT (CRRT) with hemofiltration, HD, or hemodiafiltration differs from intermittent HD.[17] Relying on continuous ultrafiltration of plasma water, CRRT can remove large quantities of ultrafilterable drug. CRRT generally uses membranes with larger pore sizes and involves convective transport of solute. Hence, CRRT allows the passage of larger molecules (up to 5000 d). A large V_D and protein binding still prevent removal by CRRT. Protein binding and the device filtration rate determine the rate of removal. A series of sieving coefficients is available that allows calculation of the amount of drug actually lost if the ultrafiltration flow rate is known.[5] The sieving coefficient is the ratio of drug concentration in the ultrafiltrate to the prefilter plasma water drug concentration. The closer the sieving coefficient is to 1.0, the more it passes across the filter. There are few detailed studies of drug clearance with use of these methods, and clinicians must rely on estimates from HD, known physiochemical properties, and clinical response.

COMMON PRESCRIBING ISSUES IN CHRONIC KIDNEY DISEASE AND RENAL REPLACEMENT THERAPY

Anemia

Erythropoiesis-Stimulating Proteins

The pharmacokinetics of erythropoiesis-stimulating agents (ESAs) are not affected by renal function *per se.* However, as renal function

Dialysis Clearance of Commonly Prescribed Drugs

Drugs Significantly Cleared by Hemodialysis That Require Administration After Dialysis or a Supplement After Dialysis	Drugs Not Significantly Cleared by hemodialysis and That Do Not Require Administration After Dialysis or a Supplement After Dialysis or That Must Be Administered at Specific Times Independent of Hemodialysis
Analgesics	**Anemia**
Morphine 6-glucuronide (in toxicity)	Erythropoietins
Aspirin, high dose (contraindicated)	Iron
Antibiotics	**Analgesics**
Aminoglycosides	Morphine
Amikacin	Paracetamol
Gentamicin	Fentanyl
Tobramycin	Oxycodone
Cephalosporins	NSAIDs
Cefotaxime	**Antibiotics**
Cefazolin	Penicillins
Ceftazidime	Amoxicillin
Carbapenems	Flucloxacillin
Imipenem	Fluoroquinolones
Meropenem	Moxifloxacin
Metronidazole	Rifamycins
Penicillins	Rifampin
Amoxicillin	Rifabutin
Ticarcillin	Glycopeptides
Piperacillin	Vancomycin (oral or "low flux")
Fluoroquinolones	Tetracyclines
Ciprofloxacin	Tetracycline
Glycopeptides	Doxycycline
Vancomycin (high-flux dialyzers)	Minocycline
Teicoplanin	**Antifungals**
Miscellaneous antibiotics	Amphotericin
Ethambutol	Voriconazole
Cotrimoxazole	Ketoconazole
Antifungal	Itraconazole
Fluconazole	**Antiviral**
Antivirals	Amphotericin
Acyclovir	**Antiepileptic**
Cidofovir	Carbamazepine
Famciclovir	**Cardiovascular Agents**
Foscarnet	Amiodarone
Ganciclovir	Perhexiline
Ribavirin	Nitrates
Valganciclovir	**Anticoagulants**
Zidovudine	Heparin
Antineoplastics	Warfarin
Cyclophosphamide	LMWHs
Methotrexate	**Antiplatelet Drugs**
Anticoagulant	Low-dose aspirin
Lepirudin	Clopidogrel
Antiepileptics	Dipyridamole
Gabapentin	**Immunosuppressants**
Pregabalin	Azathioprine
Levetiracetam	Cyclosporine and tacrolimus
Cardiovascular Agent	Mycophenolate
Sotalol	Prednisolone
Antidiabetic	Sirolimus and everolimus
Metformin (in overdose)	T cell–depleting antibodies
Vitamins	Rituximab
Water-soluble B, C, and folate	Anti-CD25 antibodies
Psychotropic	**Antidiabetics**
Lithium	Sulfonylureas
	Musculoskeletal Agents
	Bisphosphonates
	Antiepileptics
	Sodium valproate
	Carbamazepine
	Antidepressants
	SSRIs (administer in morning)
	Vitamins
	Fat-soluble vitamins A, D, E, K

Table 77-8 Dialysis clearance of drugs. *LMWHs,* Low-molecular-weight heparins; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *SSRIs,* selective serotonin reuptake inhibitors.

decreases, their dose may need to be increased to account for reduced endogenous erythropoietin production. The use of ESAs is discussed further in Chapter 83.

Iron Therapy

Oral supplements may be sufficient in the early stages of CKD or in PD patients who do not have the same degree of regular blood loss as HD patients. Maximum absorption of oral iron occurs with frequent administration of small doses away from food, although gastrointestinal intolerance limits therapy. It is important to avoid interactions with drugs whose absorption is affected by oral iron. Patients with severe iron deficiency and those on HD often require intravenous supplementation (see Chapter 83).

Analgesics

Various analgesics (or their metabolites) undergo renal excretion or are nephrotoxic, and dose modification or avoidance is required.[20,21] Fear of adverse effects often prevents use of sufficient doses to manage pain appropriately. Adequate initial doses should be followed by careful assessment and dose titration.

Acetaminophen (Paracetamol)

Despite suggestions that acetaminophen may be nephrotoxic, lack of platelet inhibition and gastrointestinal irritation makes it a safer base analgesic in the settings of CKD and RRT than NSAIDs and opioids. Acetaminophen is hepatically metabolized and does not require dose adjustment.

Opioid Analgesics

Opioids have metabolites with variable activity and dependence on renal excretion.[22,23] Metabolite accumulation in patients with renal impairment prolongs drug action and predisposes to central nervous system (CNS) toxicity (sedation, respiratory depression, confusion, hallucinations, and seizures), which is often difficult to distinguish from uremic symptoms. Regular opioid use in fluid-restricted renal patients can exacerbate constipation. Opioids should be used cautiously in patients with renal impairment, with adequate doses given to establish control and titrated to the smallest effective dose for the shortest period.[24] Morphine is metabolized to two renally cleared active metabolites (morphine 3-glucuronide and morphine 6-glucuronide). Their accumulation in patients with renal impairment may be responsible for CNS toxicity, respiratory depression, and sedation.[25] Morphine is best avoided, but if it is essential, then significant dose reduction is recommended. Meperidine (pethidine) is metabolized to a renally cleared metabolite (normeperidine) that can cause CNS toxicity (seizures, myoclonus, mental state changes, respiratory depression, and psychosis).[26] It should be avoided in patients with moderate to severe renal impairment. Dextropropoxyphene should be avoided because it is metabolized to the renally cleared metabolite norpropoxyphene, which can cause cardiac toxicity. Hydromorphone is metabolized to hydromorphone 3-glucuronide, which has minor activity and does not accumulate substantially. Buprenorphine is metabolized to relatively inactive metabolites, which are excreted in bile, and is relatively safe. Weaker opioids (codeine, dihydrocodeine, and hydrocodone) can still cause CNS and respiratory depression. They should be avoided or used cautiously in patients with severe renal impairment. With appropriate titration, alfentanil, fentanyl, sufentanil, methadone, and oxycodone are relatively safer choices because they do not have significantly active metabolites. The partial opioid tramadol is metabolized to a renally cleared active metabolite, *O*-desmethyltramadol; its half-life doubles in patients with renal impairment and it predisposes patients

to seizures, respiratory depression, and other CNS adverse effects. In patients with opioid intoxication, naloxone may be used at normal dose for reversal.

Nonsteroidal Anti-inflammatory Drugs

The most frequent nephrotoxic effect of NSAIDs is to cause acute renal impairment by preventing renal prostaglandin-mediated afferent arteriolar vasodilation (see Chapter 69). In healthy individuals, cyclooxygenase (COX) inhibition has little effect on renal function. Nephrotoxicity is more likely in those with a high renin state or renal hypoperfusion, in whom renal prostaglandins are upregulated and play a supportive role in maintaining glomerular filtration. Use of NSAIDs with ACE inhibitors, ARBs, diuretics, or antihypertensives increases the potential for nephrotoxicity, and these combinations should be prescribed cautiously. When essential, NSAIDs should be used at the lowest effective dose for the shortest period with monitoring of renal function. Increases in potassium, sodium, and fluid retention may also occur.

Nonsteroidal anti-inflammatory drugs can cause a rare idiosyncratic nephritis that may present with acute interstitial nephritis or nephrotic syndrome with minimal change disease.[27] NSAIDs have also been associated with renal papillary necrosis and other pathologic changes during long-term administration. Because COX-2 is expressed in the kidney, COX-2–selective agents offer no advantage in renal toxicity over nonselective inhibitors.[28] The potential for cardiovascular complications of COX-2 inhibitors is also undesirable in renal patients at high risk for cardiovascular disease.

Drugs for Neuropathic Pain

Low-dose tricyclic antidepressants are used at normal doses, although renal patients may be more sensitive to anticholinergic side effects. Low-dose valproate and carbamazepine are used at normal doses. Extreme caution is required with gabapentin[29] and pregabalin[30] because they are extensively renally cleared and can cause significant CNS adverse effects (somnolence, lethargy, dizziness, and ataxia).

Antihistamines

Normal doses of sedating antihistamines can be used initially with titration based on response and typical cholinergic side effects to which renal patients may be more susceptible. Sedating antihistamines should be used cautiously in patients with bladder outflow obstruction because they may cause or aggravate urinary frequency or retention. Newer, less sedating antihistamines are better tolerated and have a wider therapeutic index, and accumulation rarely causes significant complications during short-term treatment. Cetirizine relies more on renal clearance, and dose reduction is suggested. Loratadine and desloratadine have active metabolites but are safe. Fexofenadine is safe; however, terfenadine should be avoided because of the risk of arrhythmias.

Anti-infective Agents

The kidneys excrete many anti-infectives, and dose reduction is often required in patients with severe impairment or who are undergoing extended therapy. Many anti-infectives have a wide therapeutic index, and dose adjustment is clinically unnecessary despite their reliance on renal excretion. An important principle of anti-infective dosage in patients with renal impairment is to initiate effective drugs at sufficient doses. Excessive dose reductions may fail to achieve effective drug concentrations. Normal doses or doses larger than expected on the basis of renal function may be appropriate in treating less susceptible organisms and when drug distribution to the site of infection is reduced (e.g., in meningitis). Normal loading doses may be appropriate to achieve therapeutic concentrations. More severe infection, particularly in severely immunocompromised patients, may require extended therapy. In patients with urinary tract infection, if GFR is below 30 ml/min and the drug does not undergo tubular secretion, inadequate renal tract concentrations may result and systemic accumulation could lead to toxicity. Nitrofurantoin becomes ineffective in patients with advanced renal impairment,[31] and accumulation causes peripheral neuropathy. Anti-infective prescribing for urinary tract infection is discussed further in Chapter 53.

Antibacterials

Variations in pharmacokinetics of antibiotics in patients with impaired renal function have significant impacts on clinical care.[32]

Aminoglycosides

Aminoglycosides are extensively excreted unchanged by the kidneys and can cause nephrotoxicity and ototoxicity.[33] When use is essential, the total daily dose should be reduced, treatment courses kept to a minimum, and serum concentrations and renal function monitored closely. Because aminoglycosides undergo tubular secretion, high urine concentrations are achieved even in patients with advanced renal impairment, and lower doses may be appropriate for uncomplicated urinary tract infections.

Aminoglycoside Dosage Schedules Despite short half-lives (2 to 3 hours with normal renal function), aminoglycosides are usually given once daily rather than in divided daily doses for most indications. This is based on data showing that their action is dependent on peak concentration and that once-daily regimens have reduced toxicity. The required dose regimen depends on V_D and renal clearance. Dosage calculation in renal impairment first involves reducing the normal daily dose (5 to 7 mg/kg for gentamicin and tobramycin or 15 mg/kg for amikacin) according to renal function (e.g., with 25% remaining renal function, reduce the total daily dose to 25% of normal). Because of their peak concentration–dependent activity, aminoglycosides should be administered at a minimum effective dose (≥2.5 mg/kg for gentamicin and tobramycin; ≥7.5 mg/kg for amikacin) to achieve target peak serum concentrations (>10 μg/ml for gentamicin and tobramycin; >30 μg/ml for amikacin). The calculated reduced normal daily dose might be lower than the minimum individual dose required to achieve target peak concentrations. If this is true (e.g., with moderate to severe renal impairment), it may be necessary to administer the minimally effective dose at an extended interval (e.g., every 36 or 48 hours) rather than reducing the size of the individual dose. Although use of longer administration intervals (>48 hours) is a common practice, its efficacy relies on a postantibiotic effect, and it is uncertain whether this effect lasts for extended dosage schedules.

Aminoglycoside Concentration Monitoring Because of pharmacokinetic variability in patients with infection and renal impairment as well as toxicity, monitoring is essential to guide calculation of aminoglycoside dosage. It is particularly important at the initiation of therapy or when significant changes occur in renal function or clinical condition. Routine monitoring is not required for short treatment (less than 48 hours). Graphic methods that use a single-point concentration 6 to 14 hours after administration are valid only with relatively normal renal function. They do not provide information on attainment of peak concentrations and are not recommended in patients with renal impairment. Trough concentrations can be measured but must be interpreted in the context of the time after the dose when the sample was drawn. Trough monitoring does not

provide information on the attainment of peak concentrations and may be below the limit of quantification of some assays. Some patients, especially those with severe sepsis and renal impairment, may have altered (usually higher) V_D, which results in lower peak concentrations. Measuring peak concentrations (30 minutes after dosing) is the only certain way to determine if adequate peak concentrations have been achieved and to assist in determining the size of subsequent doses. Combining peak and trough monitoring provides information on both V_D and clearance and can therefore be used to determine both the size of individual doses and the administration interval. Provided the relationship between the time of administration and blood sampling is known, simple dose modifications are made on first principle estimates (see the earlier discussion of methods of dose reduction).

Carbapenems

Ertapenem, doripenem, imipenem,[34] and meropenem[35] are significantly excreted in urine but with appropriate dose modification can be used safely. Imipenem can cause significant neurotoxicity (myoclonic activity, seizures, and confusion), especially in high doses in those with underlying CNS disorders or renal impairment. Meropenem and doripenem may be preferable because they appear less neurotoxic. Imipenem is inactivated by renal dehydropeptidase 1 and is combined with cilastatin to prevent this.

Cephalosporins

Despite the fact that cephalosporins are predominantly renally cleared, the relative safety of many of them means that normal doses are used for short-course therapies even in dialysis patients (e.g., ceftriaxone, cefaclor, and cephalexin). High-dose parenteral therapy and prolonged courses of some agents require dose reduction in patients with severe impairment. Reduction is suggested in patients with severe impairment for cefepime,[36] cefotaxime,[37] ceftazidime,[38] cefoxitin, and cefazolin.[39] Therapeutic concentrations of cefazolin are maintained after doses of 20 mg/kg (approximately 2 g) after dialysis three times weekly.[40] Some cephalosporins cause a creatinine-like reaction in assays based on the picrate method. This can falsely elevate serum creatinine and be mistaken for nephrotoxicity.[41]

Fluoroquinolones

Renal excretion is significant with ciprofloxacin, norfloxacin, and gatifloxacin, and doses should be halved if GFR is below 30 ml/min.[42,43] Moxifloxacin is 20% renally excreted, and dose reduction is not required. Norfloxacin is well secreted by kidneys and useful in urinary tract infections. Quinolones are generally well tolerated but can cause CNS effects (headache, dizziness, insomnia, depression, restlessness, and tremors), interstitial nephritis, and crystalluria. Fluids should be encouraged (if tolerated) and excessively alkaline urine avoided to prevent crystalluria. Quinolone absorption is reduced when the drug is coadministered with compounds containing metals such as magnesium, calcium, aluminum, and iron, and therefore they should be administered away from meals and metallic phosphate binders.[9]

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are extensively renally excreted. Because of potential nephrotoxicity and ototoxicity, dose modification is essential even in mild to moderate impairment. Nephrotoxicity is greater in those with renal impairment, prolonged therapy, high doses, and concomitant nephrotoxins. Nephrotoxicity may be less common with teicoplanin. Ototoxicity may involve sensorineural deafness and tinnitus. Permanent deafness is more likely with previous auditory compromise or impaired renal function. If glycopeptides are essential, duration of therapy should be minimized, with regular monitoring of serum concentrations and renal function. Glycopeptides demonstrate time-dependent antibacterial activity, so dosage calculation should be repeated once serum concentrations have fallen below minimum inhibitory concentrations. In dialysis patients, single doses (e.g., 1 g) of vancomycin maintain therapeutic concentrations (>15 μg/ml) for 3 to 5 days.[44] Vancomycin is removed more extensively with high-flux than with low-flux dialysis membranes.

Lincosamides

Lincosamides (e.g., clindamycin and lincomycin) are relatively safe and are not significantly excreted by the kidneys. A significant adverse effect is pseudomembranous colitis. If this occurs, the drug should be stopped. Fluid management and treatment with oral metronidazole or vancomycin are required to prevent hypovolemia and electrolyte disturbances.

Macrolides

Macrolides are mostly hepatically cleared, and dose modifications are usually not required even in patients with end-stage renal disease (ESRD). Dose reduction is required with high-dose or intravenous erythromycin,[45] which may prolong the QT interval and cause ototoxicity. Various macrolides are potent inhibitors of CYP3A4 and P-glycoprotein, so there may be major interactions with and increased exposure to coadministered drugs that rely on CYP3A4- or P-glycoprotein–mediated absorption and metabolism (cyclosporine, tacrolimus, sirolimus, everolimus, and statins). Erythromycin and clarithromycin are the most potent inhibitors, and dose modification of the concomitant drug is required. Roxithromycin is a much weaker inhibitor and usually causes little or no clinically significant interactions. Azithromycin does not interact.

Penicillins

Most penicillins have a short half-life and are rapidly eliminated by renal filtration and secretion. Most have a relatively wide therapeutic window and are used at normal doses for short courses of oral therapy. High-dose parenteral therapy or prolonged high-dose oral therapy may require dose reduction to prevent electrolyte disturbances and neurotoxicity in patients with advanced renal failure. Because most penicillins exert little or no postantibiotic effect, the amount of time above the minimum inhibitory concentration is more important than the maximum concentration. Severe reductions in frequency of administration are not advised. Dose reduction of ticarcillin-clavulanate[46] and piperacillin is advised.

Rifamycins

Rifamycins are mainly hepatically metabolized and used at normal doses. Orange-red coloration of body fluids (e.g., urine and PD fluid) is common. Infrequently, these agents cause hepatotoxicity and blood dyscrasias. Rifampin is a potent enzyme inducer and significantly increases metabolism of drugs, including immunosuppressants. Although structurally similar, rifabutin does not induce CYP450 enzymes to the same extent.

Tetracyclines

Tetracycline depends more on renal excretion than do doxycycline and minocycline. In patients with renal impairment, tetracycline is antianabolic causing uremia, hyperphosphatemia, and metabolic acidosis; it may also aggravate preexisting renal failure.[47] Tetracycline should be avoided in renal impairment; however, doxycycline, minocycline, and tigecycline are not antianabolic and may be used as usual. Nephrotoxicity has occurred in association with acute fatty

liver with high-dose tetracyclines. Degraded tetracycline (anhydro-4-epitetracycline) may result in renal tubular damage and a Fanconi-like syndrome.

Sulfonamides and Trimethoprim

Most sulfonamide use is accounted for by cotrimoxazole (sulfamethoxazole in a 5:1 combination with trimethoprim). Sulfonamides are eliminated by acetylation followed by renal excretion. Acetylated metabolites may cause crystalluria and tubular damage. Sulfamethoxazole and trimethoprim display similar renal excretion except at extremes of urine pH. Alkaline urine promotes sulfamethoxazole excretion, whereas acidic urine promotes trimethoprim excretion. Accumulation of both occurs in renal impairment,[48] and dose reduction is advisable except perhaps in the initial treatment of *Pneumocystis jiroveci* infection, in which the risk of toxicity is balanced against the seriousness of infection. Trimethoprim inhibits tubular secretion of creatinine, resulting in a reversible increase in serum creatinine[49] that can be misinterpreted as trimethoprim nephrotoxicity.

Other Antibiotics

Linezolid is used at a normal dose. Metronidazole has a partially active, renally cleared metabolite, although only 15% of the parent drug is renally cleared. It is usually given in usual doses or reduced to twice-daily doses with dialysis.[50]

Antimycobacterials

Antimycobacterial treatment (see also Chapter 54) requires dose modification according to renal function and avoidance of drug interactions.[51] Ethambutol is significantly renally cleared (80%) and has a prolonged half-life in patients with renal impairment. Dose reduction is essential to avoid visual toxicity. Isoniazid, pyrazinamide, and rifampin-rifabutin can be given in usual doses. Rifampin causes induction of hepatic enzymes and severe drug interactions with transplant immunosuppressants. Of the second-line agents, amikacin, kanamycin, streptomycin, capreomycin, and gatifloxacin are extensively renally cleared, are nephrotoxic, and require significant dose reduction.

Antifungals

Amphotericin

Amphotericin use is limited by nephrotoxicity (see Chapters 55 and 69). Nephrotoxicity with crystalline amphotericin may be minimized with prehydration and administration by continuous infusion. Newer liposomal formulations have fewer infusion-related problems and are less nephrotoxic[52] but more expensive. In maintenance dialysis patients who do not have potential for further clinically significant loss of renal function, liposomal or lipid preparations offer no major advantage except a lower incidence of infusion reactions. Oral amphotericin is not absorbed and does not contribute to nephrotoxicity.

Azole Antifungals

Most azole antifungals (ketoconazole, itraconazole, and voriconazole) are extensively metabolized and do not require dose reduction. Fluconazole[53] is renally excreted; after an adequate loading dose, maintenance doses should be reduced in patients with moderate to severe renal impairment, and it should be given after dialysis. Fluconazole is significantly excreted in urine and therefore preferred for fungal urinary tract infections. The manufacturer recommends avoiding intravenous voriconazole because of possible accumulation of the intravenous vehicle (sulfobutyl betadex sodium). Ketoconazole and itraconazole require an acidic environment for absorption. Given the widespread use of acid suppressants in renal impairment, this is a clinically important interaction. Voriconazole, ketoconazole, and itraconazole are potent inhibitors of CYP3A4 and P-glycoprotein, which are involved in the metabolism and absorption of a variety of drugs, including cyclosporine, tacrolimus, sirolimus, everolimus, and statins. A twofold to 10-fold reduction of the concomitant drug may be required with drug monitoring; however, the magnitude of interaction may restrict the ability to use the concomitant drug. Interactions between ketoconazole and CNIs or mammalian target of rapamycin (mTOR) inhibitors have been exploited as a cost-reducing, "immunosuppressant-sparing" strategy. Increased exposure to statins (except pravastatin) increases the risk of rhabdomyolysis-induced renal impairment. Fluconazole is a weak enzyme inhibitor, and although caution should be exercised, the need for preemptive dose reduction of concomitant drugs is less certain. Topical azoles including bifonazole, clotrimazole, econazole, ketoconazole (topical), tinidazole, and miconazole are minimally absorbed and do not cause interactions.

Other Antifungals

Absorption of nystatin from topical and oral preparations is minimal and safe in patients with renal impairment. Terbinafine is hepatotoxic, and dose reduction of 50% is suggested in patients with moderate to severe renal impairment. Griseofulvin and caspofungin can be given in usual doses. Flucytosine[54] is extensively renally cleared and requires dose reduction. These agents do not interfere with CYP450 enzymes or P-glycoprotein.

Antivirals

Many antivirals (or their active metabolites) are extensively renally excreted and can cause nephrotoxicity (see Chapter 69).

Guanine Analogues

Acyclovir, its prodrug valacyclovir, and famciclovir[55] are extensively renally cleared and can crystallize in tubules, causing obstructive uropathy. High concentrations cause severe CNS toxicity (cerebral irritation, ataxia, and myoclonus). Ganciclovir and its prodrug valganciclovir are extensively renally cleared,[56] and accumulation leads to severe bone marrow toxicity. Strict dose reduction based on renal function is essential, even in mild renal impairment. All these agents are freely dialyzed and should be given after HD.

Hepatitis B and C

Pegylated interferon alfa-2a has a larger metabolic clearance than pegylated interferon alfa-2b,[57] which has higher renal clearance and requires dose reduction in patients with renal impairment. Interferons can upregulate cell surface expression of class II histocompatibility antigens, which increases the potential for transplant rejection. Ribavirin and its metabolites rely on renal excretion, and accumulation causes severe anemia; therefore ribavirin is contraindicated if GFR is below 50 ml/min. Adefovir,[58] entecavir, lamivudine,[59] and telbivudine[60] are extensively renally excreted, and significant dose reduction is essential.

Neuraminidase Inhibitors

Oseltamivir is converted by hepatic esterases to its active metabolite, oseltamivir carboxylate, which is extensively (99%) renally cleared through filtration and secretion.[61] AUC is increased 10-fold in patients with severe renal impairment (GFR <30 ml/min). Although the drug is well tolerated, doubling the dosage interval is

recommended in patients with GFR <30 ml/min. Despite the fact that intravenous doses show significant reliance of zanamivir on renal clearance, dose modification is not necessary because absolute bioavailability from inhaled doses is approximately 2% and high intravenous doses are well tolerated.[61]

Other Antivirals

Cidofovir[62] and foscarnet[63] are extensively renally cleared and require dose reduction in patients with renal impairment. Both are nephrotoxic, require close monitoring of renal function, and should be administered with hydration. Cidofovir is often administered with probenecid to slow renal secretion and to minimize nephrotoxicity.

Anticoagulants, Antiplatelet Agents, Thrombolytics, and Hemostatics

The risk of bleeding complications with anticoagulants, antiplatelet agents, thrombolytics, and hemostatics is increased in patients with CKD and ESRD.[64,65]

Unfractionated Heparin

Unfractionated heparin (UFH) clearance occurs by a rapid saturable mechanism of the endothelium and reticuloendothelial system and a slower nonsaturable mechanism through the kidneys.[64,66] Half-life is slightly prolonged (1.5-fold) in patients with renal impairment, especially at higher doses, when renal elimination is more significant. However, UFH is initially used at normal dose with titration based on activated partial thromboplastin time monitoring. In some centers, UFH is preferred in patients with severe renal impairment because its effect is shorter and more easily measured and reversed.

Low-Molecular-Weight Heparins

Low-molecular-weight heparins (LMWHs) rely more on renal clearance than UFH, and in patients with moderate to severe renal impairment they accumulate, increasing the risk of serious bleeding.[67] Strong consideration should be given to the use of UFH in this setting. Some studies suggest that enoxaparin does not need dose reduction in the first 48 hours of therapy and that tinzaparin is less likely to accumulate. If prolonged treatment doses of LMWHs are used, the dose should be reduced and, if possible, anti-Xa activity measured to guide therapy.

Other Parenteral Anticoagulants

Other anticoagulants that accumulate in patients with renal impairment and that should be avoided or used with significant dose reduction include bivalirudin,[68] danaparoid,[69] fondaparinux,[70] lepirudin,[71] ximelagatran,[72] and melagatran.[72] Argatroban may be used at normal dose.[73] Prostacyclin, used to prevent platelet aggregation in HD circuits, is rapidly hydrolyzed and not affected by renal impairment.

Oral Anticoagulants

The liver extensively metabolizes warfarin. In patients with renal impairment, it is usually commenced at normal dose and titrated according to the international normalized ratio. Warfarin is highly protein bound, and in renal patients with hypoalbuminemia there may be increased sensitivity to warfarin.[74] Similarly, hepatic metabolism may be altered with renal impairment, increasing sensitivity.[75] Warfarin dosage in patients with advanced CKD becomes difficult given that CKD is often accompanied by vitamin K deficiency. In addition, warfarin promotes vascular calcification and should be avoided in patients with advanced CKD unless absolutely necessary—for example, in the presence of a mechanical heart valve.

Antiplatelet Drugs

Commonly prescribed doses of oral antiplatelet drugs (aspirin, clopidogrel, and dipyridamole) do not require adjustment. Despite their efficacy in patients with reduced renal function, eptifibatide[76] and tirofiban are renally excreted and have been associated with bleeding in this setting. Abciximab is cleared by platelet binding and is not associated with increased bleeding risk in patients with renal impairment.

Thrombolytics

Streptokinase, anistreplase, and alteplase are used as normal, but the high risk of hemorrhage should be considered. Urokinase is also used to unclot dialysis catheters.

Hemostatics

Tranexamic acid requires dose reduction in patients with moderate to severe renal impairment. Protamine and vitamin K are used as normal, as are fresh frozen plasma and whole blood with critical bleeding.

Diuretics

Diuretics must reach the renal tubule lumen unbound to exert an effect.[77] Pharmacokinetic and pharmacodynamic properties of diuretics can change with proteinuria or renal impairment, usually causing a resistance to their effect.[77] Tubular secretion of various organic acid diuretics is reduced because of competition from uremic organic acids. Diuretics, in particular loop diuretics, must be used cautiously in patients with AKI or renal hypoperfusion to avoid nephrotoxicity. Diuretic use in the immediate post-transplantation setting may increase urine flow in native kidneys, giving a false appearance of transplant function.

Thiazide Diuretics

Thiazide diuretics generally become ineffective as diuretics when GFR is below 30 ml/min, although they may augment the effectiveness of a loop diuretic and retain their antihypertensive effects. Metolazone can maintain efficacy at a lower GFR.

Loop Diuretics

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) remain effective at low GFR and are generally the preferred diuretics in patients with renal impairment, although higher doses are usually required.

Potassium-Sparing Diuretics

Potassium-sparing diuretics are the least effective diuretics and should be used only with great caution and at low dosage in patients with moderate to severe renal impairment because of the risk of life-threatening hyperkalemia.

Antihypertensives

Antihypertensives should be used cautiously to avoid renal hypoperfusion.[78] Hypotension from HD may require that doses be withheld or delayed on dialysis days.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Although various ARBs and the active metabolites of ACE inhibitors are renally excreted, they can be used effectively in patients with CKD if initiated at moderate doses and titrated cautiously to response, renal function, and serum potassium level. An increase in

serum creatinine (up to 20% to 30% in the first 2 months) may be associated with blood pressure response. All ACE inhibitors and ARBs can cause acute renal impairment by inhibiting angiotensin II–mediated homeostatic vasoconstriction of the efferent renal arteriole during renal hypoperfusion (e.g., with dehydration, hypotension, blood loss, and infection) or preexisting renal impairment (see also Chapter 69). Nephrotoxicity is more likely with coadministration of drugs that reduce renal perfusion including diuretics, antihypertensives, and NSAIDs.[79] Hyperkalemia is more likely in those with renal impairment and those taking potassium-sparing diuretics or supplements. Rarely, ACE inhibitors or ARBs can worsen anemia.

β-Blockers

Most β-blockers (carvedilol, labetalol, metoprolol, pindolol, and propranolol) are hepatically metabolized and used at normal doses according to response. Sotalol[80] and atenolol[81] rely on renal clearance, and dose reduction and titration are essential, although atenolol can be titrated up to normal doses even in dialysis patients. β-Blockers may slightly elevate serum potassium.

Calcium Channel Blockers

Pharmacokinetic parameters of CCBs are essentially unaltered in patients with renal impairment. These drugs are generally well tolerated and used in normal doses according to response. Dihydropyridine CCBs can cause significant edema, which can aggravate the edema of renal impairment. To varying extents, CCBs inhibit CYP3A4 and P-glycoprotein, causing increased absorption and reduced elimination of various substrate drugs, including cyclosporine, tacrolimus, sirolimus, and everolimus. Verapamil and diltiazem are moderately potent inhibitors, and dose modification and monitoring of the concomitant drug are required. This interaction has been exploited so that the CCB is used as an immunosuppressant-sparing agent.[82] Other CCBs do not usually cause clinically significant changes in concomitant drug concentrations, and dose modification is usually not required.

Other Antihypertensives

Methyldopa, clonidine, prazosin, terazosin, doxazosin, and minoxidil are renally cleared but can be initiated and titrated at conventional dosage. They are often associated with a higher incidence of adverse effects in patients with renal impairment. α-Blockers cause profound orthostatic hypotension. Nitroprusside must be used cautiously because the toxic metabolite thiocyanate may accumulate with renal impairment but is hemodialyzable.[83]

Antianginal Agents

Most antianginals (nitrates, CCBs, nicorandil, and perhexiline) can be used as normal.

Antiarrhythmics

Various antiarrhythmics (digoxin, disopyramide, procainamide,[84] and sotalol[80]) rely on renal excretion and require dose modification. Digoxin is commonly used, and because of its significant reliance on renal excretion and narrow therapeutic window, dose reduction is essential even in patients with mild impairment. Because of reduced tissue protein binding and V_D, some physicians use a smaller loading dose of digoxin than in patients with normal renal function. Cautious monitoring and titration should be exercised to prevent accumulation and further toxicity. When possible, monitoring of antiarrhythmic drug concentrations and the electrocardiogram is recommended. Other agents (amiodarone, flecainide, metoprolol, mexiletine, and verapamil) are used at normal doses.

Lipid-Lowering Agents

Bile Acid–Binding Resins

Bile acid–binding resins are now rarely used. The large fluid volumes required to administer them limit their use. They can interfere with absorption and enterohepatic recirculation of various drugs, including mycophenolate.

Statins

Statins (HMG-CoA reductase inhibitors) can be used effectively in patients with renal impairment and those who have undergone transplantation.[85] Most are extensively metabolized to products with varying activity; however, normal doses may be used in the first instance and titrated to target cholesterol values. Rhabdomyolysis with acute renal impairment can occur, although the risk does not appear to be greatly increased with renal impairment. The risk increases with use of fibrates and drugs that inhibit the CYP3A4 metabolism of statins. Patients commencing therapy should have lipids, renal function, and creatine kinase monitored regularly.

Fibrates

Fenofibrate but not gemfibrozil is extensively renally excreted, and dose reduction is required. Combination of statins and fibrates significantly increases the risk of rhabdomyolysis and should be used only when benefits outweigh risks and with monitoring for muscle symptoms, creatine kinase, and alanine aminotransferase.

Diabetes

The kidney plays an important role in insulin metabolism,[86] and thus renal function influences glycemic control. Diabetes is also common after transplantation because of resumption of insulin metabolism by the functioning transplant and the effect of drugs (tacrolimus and corticosteroids). Various antidiabetic drugs (or their metabolites) depend on renal excretion, and accumulation in patients with renal impairment can cause adverse effects.[87] Patients with renal impairment are at markedly increased risk of hypoglycemia, and drugs should be initiated and titrated cautiously.[88] Management of diabetes in patients with CKD is discussed in Chapter 32.

Diabetes Management in Peritoneal Dialysis

Peritoneal dialysis patients may have higher antihyperglycemic requirements because of the glucose load in PD fluid. If intraperitoneal insulin is used, dosages may vary from intravenous requirements. Icodextrin solutions can significantly interfere with blood glucose monitoring because of metabolites (maltose, maltotriose, or maltotetraose) that falsely elevate blood glucose readings as a result of monitors that use the enzyme glucose dehydrogenase pyrroloquinoline quinone. A glucose-specific test strip is required to avoid interference.

Biguanides

Metformin is excreted almost entirely unchanged in urine, and accumulation can contribute to severe or fatal lactic acidosis (see Chapter 32).[89] Metformin should be temporarily discontinued in situations known to increase the risk of lactic acidosis or to reduce renal function (e.g., acute tissue hypoxia, dehydration, serious infection or trauma) and 24 to 48 hours before anticipated surgery or use of iodinated radiocontrast media. Although metformin is not

usually recommended if GFR is below 60 ml/min and certainly below 30 ml/min, low-dose protocols may be considered in a specialized setting. Nevertheless, stability of a patient with renal impairment receiving low-dose metformin does not abolish the risk of lactic acidosis. Lactic acidosis has occurred with doses of 500 mg/day, and any acute deterioration in renal function can result in reduced drug clearance at any time. Patients on this regimen should be advised to seek early medical advice in any cases of acute deterioration in health.

Insulin

As renal function decreases, insulin clearance decreases. Uremia, however, can cause peripheral resistance to insulin, requiring increased doses. Most insulin regimens can be used in patients with CKD or transplantation with cautious titration and monitoring. Theoretically, insulin glargine is preferable to insulin detemir because the latter is highly bound to serum albumin, and in patients with decreased or unstable serum albumin, a higher free fraction may occur.

Meglitinides

The nonsulfonylurea insulin secretagogues repaglinide and nateglinide can be used in patients with renal failure without dose adjustment.

Sulfonylureas

Sulfonylureas are metabolized and some (glibenclamide and glimepiride) have active, renally excreted metabolites. In patients with moderate to severe renal impairment, hypoglycemic risk is increased.[90] These agents should be initiated at low dose and titrated to response. Gliclazide and glipizide are preferable because they do not have active metabolites. Regardless of which agent is used, the effect of sulfonylureas may still be increased because the insulin released by the drug will itself have a prolonged duration of action in patients with renal impairment.

Thiazolidinediones

Thiazolidinediones are extensively metabolized and excreted in bile. Their pharmacokinetics are not significantly altered by renal impairment and in fact show reduced exposure, possibly because of reduced protein binding.[91,92] However, they can cause fluid retention and edema, exacerbating the difficulties of fluid management and heart failure.[87] Thiazolidinediones have been associated with dilutional anemia because of an increase in plasma volume, which may complicate management of renal anemia.

Drugs for Thyroid Disorders

Thyroid hormones generally do not require dose alteration in patients with CKD.[93] Doses should be initiated and titrated to thyroid-stimulating hormone levels and clinical effect. In circulation, thyroxine (T_4) is 99.98% protein bound (0.02% free) and triiodothyronine (T_3) is 99.8% bound (0.2% free). T_3 and T_4 bind partially, in slightly different proportions, to three different plasma proteins: thyroid-binding globulin, thyroid-binding prealbumin, and albumin. In protein-deficient states (e.g., nephrotic syndrome), there is the possibility of transient or permanent changes in thyroid hormone protein binding that may alter the free fraction of T_3 and T_4, leading to transient toxicity. Uremic toxins can also inhibit enzymes associated with conversion of T_4 to T_3. Oral absorption of thyroid hormones is affected by coadministration with metallic phosphate binders and iron. Euthyroid patients with CKD may have abnormal thyroid function test results, possibly because of decreased peripheral conversion of T_4 to T_3, decreased clearance of reverse T_3 generated from T_4, or decreased binding of thyroid hormones to proteins. Antithyroid drugs can be used at usual doses.

Mineral and Bone Disorders

Phosphate Binders

Phosphate binders should be taken with meals for maximal efficacy. Patients can be instructed to tailor phosphate binder intake to the phosphorus content and frequency of meals. Administration is not affected by renal function except that reducing function increases the need for phosphate binders. Dosage is based on phosphate levels and the need to avoid biochemical abnormalities (see Chapter 85). Acid suppression may reduce the effectiveness of phosphate binders by inhibiting hydrolysis of metallic ions in the gut. Phosphate binders may reduce gastrointestinal absorption of drugs, including thyroid hormones, fluoroquinolones, tetracyclines, digoxin, and immunosuppressants.

Vitamin D

In patients with renal impairment, inability of the kidneys to activate 25-hydroxycholecalciferol to calcitriol may produce relative vitamin D deficiency and hypocalcemia. The use of vitamin D preparations in patients with CKD mineral and bone disorders is discussed in Chapter 85.

Calcimimetics

Cinacalcet (see Chapter 85) dosage is independent of renal function except that progressive renal impairment exacerbates secondary hyperparathyroidism. When possible, cinacalcet should be administered with the evening meal to with the evening meal to minimize nausea. Morning blood samples for parathyroid hormone levels should be drawn at least 12 hours after administration.

Dyspepsia, Gastroesophageal Reflux Disease, and Peptic Ulcers

Proton pump inhibitors and H_2 receptor blockers are commonly used in patients with CKD (see Chapter 87). Acid suppression may reduce the effectiveness of phosphate binders by inhibiting the release of free metallic ions in the gastrointestinal tract.

Antacids

Alginates, magnesium trisilicate, and sodium bicarbonate are useful for symptom control but have high sodium content, which exacerbates hypertension and fluid status. Magnesium and aluminum salts can reduce the absorption of mycophenolate. Aluminum salts should be avoided in patients with advanced CKD.

H_2 Antagonists

Most H_2 antagonists are renally cleared but relatively safe, so dose reduction is not required.[94] Protein binding and V_D are unaltered; however, the bioavailability of nizatidine is reduced in patients with renal impairment. Cimetidine accumulation[95] produces CNS effects and also causes significant interactions through the CYP450 system and falsely elevates serum creatinine levels.[96]

Proton Pump Inhibitors

Proton pump inhibitors are generally safe and well tolerated and have a wide therapeutic index, although they have rarely been associated with interstitial nephritis.[97]

Antiemetics

Dopamine Antagonists

Domperidone, metoclopramide, and prochlorperazine are not significantly renally cleared; however, extrapyramidal and CNS effects may occur in patients with CKD, especially at high doses. Dosage should be cautiously titrated to effect. Domperidone does not cross the blood-brain barrier and may be preferable for long-term management. Metoclopramide and domperidone increase gastric emptying, which may alter drug pharmacokinetics.

5-HT_3 Antagonists

Most 5-HT_3 antagonists are minimally excreted in urine with a wide therapeutic window. Dolasetron, granisetron, ondansetron, and tropisetron are safe, and dose modification is not required.

Aperients and Laxatives

Common low-potency agents including docusate, bisacodyl, glycerin, lactulose, liquid paraffin, senna, and sorbitol may be used for acute or chronic constipation. Normal doses should be titrated to effect while avoiding significant dehydration, fluid shifts, or electrolyte disturbances. High-potency laxatives and bowel preparations should be used cautiously. They can cause significant fluid and electrolyte disturbances, especially in susceptible renal patients. Preparations containing high amounts of phosphate should be avoided. Despite the large fluid volumes required for administration, isoosmotic laxatives may be used for bowel preparation in patients with renal impairment and dialysis.

Antidiarrheals

Opioids or their derivatives should be used with the same caution as when they are used as analgesics. Loperamide and diphenoxylate-atropine can be given in usual doses.

Drugs for Erectile Dysfunction

Phosphodiesterase-5 Inhibitors

The AUCs of sildenafil, tadalafil, and vardenafil are increased in patients with severe renal impairment (sildenafil, twofold; tadalafil, fourfold; vardenafil, 20% to 30%) despite minimal dependence on renal excretion.[98] However, provided relevant cardiovascular and drug contraindications are excluded, they can be used safely. They should be initiated at low doses and titrated to response. Shorter-acting agents (sildenafil and vardenafil) may be preferable. Vardenafil can prolong the QT interval.

Intracavernosal Therapy

Drugs given directly by intracavernosal injection do not achieve significant concentrations in the systemic circulation and can be used in patients with renal impairment.

Immunosuppressants

Immunosuppression in renal transplantation as well as its adverse effects are discussed in Chapter 101. Initial and maintenance doses in any individual are highly variable and depend on local protocol, concomitant therapy, rejection risk, drug concentrations, and response. Immunosuppression is required for the life of the transplant and should never be withheld except in exceptional circumstance (life-threatening infection or malignancy). Regimens should preferably be limited to twice daily, spread at convenient times about 12 hours apart. In practice, the precise timing of doses or intake relative to time and food is not as important as consistency in relation to time and food. Patients should take their medications consistently, and doses can be titrated to levels and response. Most immunosuppressants are hepatically metabolized and do not require dose modification based on altered excretion in patients with renal impairment.

Immunosuppressants are prone to a range of significant drug interactions, and this should be considered whenever a patient receiving these agents has a change in drug regimen. Significant interactions can also occur with "natural" or "herbal" medicines (e.g., St John's wort; see also Chapter 78). If these products are deemed essential, it is advisable to monitor response, renal function, blood counts, and serum drug concentrations regularly. Therapeutic monitoring is recommended for several immunosuppressants[99] (tacrolimus, cyclosporine, everolimus, sirolimus, and mycophenolate). Target levels should be interpreted in the context of the patient's response, immunosuppressive regimen, time after transplantation, and assay methodology.[100] Pharmacokinetics may vary in relation to food (e.g., tacrolimus) or concomitant drugs (e.g., sirolimus with or without cyclosporine), so blood sampling should aim to reflect the patient's usual routine.

Calcineurin Inhibitors

Calcineurin inhibitors are extensively metabolized to inactive metabolites. The major adverse effect of CNIs is nephrotoxicity (acute and chronic),[101] and regular assessment of renal function is essential. Nephrotoxicity may increase with concurrent use of mTOR inhibitors. Early detection of CNI nephrotoxicity on biopsy assists in planning maintenance therapy (see Chapters 101 and 104). Lower doses or temporary withdrawal may be used when CNIs have caused or are likely to cause nephrotoxicity (e.g., delayed graft function).

Calcineurin inhibitors are substrates of P-glycoprotein and CYP3A4. Drugs that inhibit or compete as substrates for these enzymes can increase absorption and reduce metabolism of CNIs, causing increased serum concentrations and adverse effects. Drugs that induce these enzymes can reduce absorption and increase metabolism of CNIs, causing reduced serum concentrations, and increase the risk of rejection (see Table 77-6). Cyclosporine but not tacrolimus interferes with the enterohepatic recirculation of mycophenolate, and so the mycophenolate dose may need to be higher if this agent is coadministered with cyclosporine than if it were administered alone or with other immunosuppressants. Tacrolimus trough concentrations (C_0) show good correlation with drug exposure (AUC) and are used to monitor therapy. Debate continues about the optimal method of monitoring cyclosporine. Clinically, a combination of C_0 (trough), C_2 (concentration 2 hours post dose), and $AUC_{0\text{-}4}$ (multipoint AUC, 0 to 4 hours) is used. Different assay methodologies (high-performance liquid chromatography [HPLC] and immunoassays) have differing abilities to detect parent compound from metabolites. Specific HPLC methods are recommended, and results from different laboratories may not be interchangeable.[100]

Corticosteroids

Corticosteroids are predominantly cleared by hepatic metabolism to inactive metabolites. Dose modification based on impaired renal function is not required.

Antiproliferative and Cytotoxic Agents

Various antiproliferatives and cytotoxics are used to prevent rejection (azathioprine and mycophenolate) and in patients with

autoimmune and inflammatory renal disorders (azathioprine, cyclophosphamide, chlorambucil, methotrexate, and mycophenolate). Their primary dose-limiting toxicity is bone marrow suppression, which is exacerbated by combined use with other bone marrow suppressants (e.g., ganciclovir, cotrimoxazole, and mTOR inhibitors). Regular blood monitoring is needed to guide dosage.

Methotrexate relies on renal clearance and should be avoided or used cautiously at a reduced dose in patients with CKD. It can also cause obstructive uropathy. Renal clearance is significant with cyclophosphamide[102] (which also causes hemorrhagic cystitis) and chlorambucil, and dose modification is required. Accumulation of mycophenolate metabolites in patients with severe renal impairment predisposes to toxicity. Allopurinol significantly interferes with the metabolism of the active metabolite of azathioprine (6-mercaptopurine), and co-prescription can lead to life-threatening bone marrow suppression. The combination should be avoided by exchanging azathioprine with mycophenolate or by significant (75%) dose reduction of azathioprine or mercaptopurine.

mTOR Inhibitors

Although not nephrotoxic when used alone, mTOR inhibitors (sirolimus, everolimus) can potentiate the nephrotoxicity of CNIs. mTOR inhibitors are almost entirely hepatically metabolized to essentially inactive metabolites. Dosage is independent of renal function and based on response, serum drug levels, and specific toxicities (especially hematologic and lipids). mTOR inhibitors are substrates of CYP3A4 and P-glycoprotein. Drugs that inhibit or compete as substrates for these enzymes can increase absorption and reduce metabolism of mTOR inhibitors, causing increased blood concentrations and adverse effects. Drugs that induce these enzymes can reduce absorption and increase metabolism of mTORs and consequently reduce serum concentrations and increase the risk of rejection (see Table 77-6). Bone marrow toxicity (neutropenia, anemia, and thrombocytopenia) is increased when they are used in combination with other myelosuppressants (azathioprine, mycophenolate, ganciclovir, and cotrimoxazole). Trough levels show good correlation with drug exposure (AUC) and are used to monitor therapy. Different assay methodologies (HPLC vs. immunoassays) vary in their ability to detect parent drug from metabolites. Specific HPLC methods are recommended, and results from different laboratories or methods may not be interchangeable.

Immunosuppressant Antibodies

Antibodies used for immunosuppression include T cell–depleting antibodies (antithymocyte globulin [ATG], anti-CD3 antibodies [OKT3]), anti–interleukin-2 receptor (CD25) antibodies (basiliximab and daclizumab), and B cell–depleting antibodies (rituximab) (see Chapter 101). Dosage is independent of renal function, and these agents should be administered after plasma exchange[103] to avoid drug removal. They are not removed by HD.

Musculoskeletal Drugs

Nonsteroidal Anti-inflammatory Drugs

NSAIDs can cause significant nephrotoxicity (see Chapter 69) and should be avoided or used with extreme caution in patients with CKD.

Miscellaneous Arthritis Drugs

Gold salts and penicillamine[104] are now rarely used for rheumatoid arthritis. Both were associated with nephrotic syndrome caused by membranous nephropathy. Glucosamine and fish oil can been used safely.

Gout and Hyperuricemia

Gout is highly prevalent in patients with renal impairment. In acute therapy, short courses of oral corticosteroids are safe and preferable to NSAIDs. Colchicine[105] accumulation in patients with renal impairment may cause diarrhea and hypoperfusion-induced renal impairment as well as myelosuppression. In maintenance therapy, allopurinol is effective but the dose should initially be reduced in patients with moderate to severe renal impairment because of its renally cleared active metabolite (oxypurinol).[106] Despite this, some ESRD patients tolerate normal doses. Allopurinol significantly interacts with azathioprine, with a risk of severe myelosuppression. If the combination is unavoidable, the dose of azathioprine should be reduced to 75% and blood counts monitored carefully. Uricosuric agents (e.g., probenecid) inhibit secretion of acids in the proximal tubule and prevent reabsorption of uric acid from the tubular lumen. They often become ineffective with diminishing renal function and are best avoided if the GFR is below 40 ml/min.[107] Probenecid also interferes with the tubular secretion of many drugs, causing interactions.

Bisphosphonates

Bisphosphonates are extensively excreted in urine. The fraction not excreted is incorporated into bone, from which it slowly dissociates. In patients with renal impairment, impaired clearance of absorbed drug may increase the fraction available for incorporation into bone. The long terminal elimination half-life of these agents reflects rate-limiting dissociation from bone and may not be significantly altered in patients with renal impairment. Oral bisphosphonates appear to be safe in patients with CKD stages 2 and 3.[108] Their safety in patients with CKD stages 4 and 5 is less well established; they are contraindicated in adynamic bone disease. Rapid administration of intravenous bisphosphonates (pamidronate and zoledronic acid[109]) without hydration has been associated with acute nephrotoxicity. Intravenous preparations should be administered slowly with hydration, and renal function assessed regularly. Oral bisphosphonate administration may be complicated by the volumes of fluid recommended. In addition, many patients with renal impairment are taking calcium-based phosphate binders or supplements that impair the absorption of oral bisphosphonates. Once-weekly administration given at least 30 minutes before food and any calcium-based medications or supplements is preferable to daily doses to reduce the total weekly fluid load required to administer the tablets and helps ensure absorption.

Antiepileptics

Chronic kidney disease patients may be more prone to seizures (e.g., uremic encephalopathy and dialysis disequilibrium syndrome) and to the CNS effects of antiepileptics. Some antiepileptics rely on renal excretion, and dose modification is essential. Some antiepileptics (barbiturates, phenytoin, and carbamazepine) are strong inducers of drug-metabolizing enzymes. Coadministration with drugs reliant on hepatic metabolism (e.g., immunosuppressants) can reduce exposure and efficacy of the concomitant drug. Therapeutic drug monitoring is available for many antiepileptics and should be used to guide dosage.

Benzodiazepines

See the later discussion of psychotropic drugs.

Carbamazepine

Carbamazepine is initially administered as normal and titrated to response and blood concentrations. It is a potent enzyme inducer, and care must be taken to account for important drug interactions.

Phenytoin

Caution should be exercised with phenytoin in patients with renal impairment because of its erratic absorption, saturable metabolism, nonlinear pharmacokinetics, reduced protein binding, and increased V_D. The concentration of free drug may be higher than in patients with normal renal function; because most laboratories measure total drug concentration, a low serum total phenytoin level in patients with renal impairment should not be mistaken as subtherapeutic. Nystagmus, cerebellar ataxia, and seizures can occur in overdose, and small dose increases may result in disproportionate increases in serum concentrations. Physical findings such as nystagmus are helpful in deciding not to increase the dose. Cautious titration based on effect and monitoring of free plasma concentration is advised. Phenytoin is a potent enzyme-inducing agent, and care must be taken to account for drug interactions.

Other Antiepileptics

Levetiracetam, topiramate, and vigabatrin undergo significant renal excretion, and dose modification is required. Valproate and lamotrigine are not significantly renally excreted and do not cause enzyme induction or inhibition. Protein binding changes can increase the free fraction of valproic acid, predisposing to increased responsiveness.

Antiparkinsonian Drugs

In addition to their use for Parkinson disease and hyperprolactinemia disorders, dopaminergic drugs are used to treat restless legs and other limb movement disorders in patients with renal impairment. Most are hepatically cleared and safe, although dopaminergic agents may exacerbate postural hypotension. Amantadine[110] is highly dependent on renal excretion, and dose modification is essential.

Antimigraine Drugs

Simple analgesics (acetaminophen) are used as normal, although aspirin should be avoided at therapeutic doses and opioids used cautiously (see discussion of analgesics). NSAIDs are best avoided because of potential nephrotoxicity. 5-HT_1 agonists are effective in patients with renal impairment and transplantation. Naratriptan relies the most on renal excretion (50%), and a lower maximum dose is recommended. Sumatriptan and zolmitriptan are preferred because they are less dependent on renal excretion.

Psychotropic Drugs

Most psychotropics are fat soluble and nondialyzable, undergo significant hepatic metabolism, and are excreted as inactive compounds. Even so, patients with renal impairment are often more susceptible to common adverse effects (especially CNS effects).[111,112] Consequently, slow titration and dose modifications are required. Adverse effects are not easily distinguished from symptoms of uremia. Despite being metabolized extensively by CYP450 enzymes, very few psychotropics cause clinically significant inhibition or induction of CYP3A4.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors are extensively metabolized by the liver. Although they are less commonly used in current practice, normal doses of reversible monoamine oxidase inhibitors (moclobemide) are preferred, and these can be titrated cautiously up to full doses. Monoamine oxidase inhibitors can cause peripheral edema, which is not usually associated with fluid retention and is unresponsive to diuretics. Prostatic hypertrophy and urinary retention may also occur.

Selective Serotonin Reuptake Inhibitors

Most selective serotonin reuptake inhibitors (SSRIs) are extensively metabolized to compounds without significant SSRI activity.[113] Normal doses of most SSRIs (citalopram, fluvoxamine, paroxetine, and sertraline) can be used with cautious dose titration. Fluoxetine is metabolized to an active metabolite (norfluoxetine), but single- and multiple-dose studies have shown little change in pharmacokinetics even in dialysis patients.[114] Patients with renal impairment may be more prone to the CNS toxicity of SSRIs and serotonin syndrome. SSRIs can cause the syndrome of inappropriate antidiuretic hormone secretion and platelet aggregation or hemorrhagic complications, which theoretically increases the risk of bleeding in uremic patients who are already prone to bleeding complications. Although most SSRIs have some inhibitory effect on CYP3A4, this is usually not significant. Fluoxetine and fluvoxamine are more likely to interact than citalopram and sertraline, but all can be used in patients taking immunosuppressants. Cinacalcet can cause significant inhibition of CYP2D6-mediated metabolism of SSRIs and perhexiline. This may increase the possibility of serotonin syndrome or perhexiline toxicity.

Tricyclic Antidepressants

Tricyclic antidepressants are now infrequently used for depression but more for neuropathic pain and their anticholinergic properties in urinary tract disorders. They are predominantly metabolized to metabolites with varying activity. Patients with renal impairment may be more prone to the common anticholinergic adverse effects, particularly urinary retention, orthostatic hypotension, confusion, and sedation.[115] Obstructive uropathy can occur from the anticholinergic properties. Cautious initial doses and titration of tricyclic antidepressants are recommended. Depending on response, many agents can be used at up to normal or maximal doses in patients with renal impairment.

Other Antidepressants

Venlafaxine dose should be initially reduced in patients with severe renal impairment because of reduced clearance of the active metabolite *O*-desmethylvenlafaxine.[116] Nefazodone is used at a normal dose.

Antipsychotics

Conventional antipsychotics cause a variety of side effects to which patients with renal impairment may be susceptible (sedation, confusion, and postural hypotension). Caution is advised for atypical antipsychotics that prolong the QT interval (e.g., pimozide, thioridazine, mesoridazine, droperidol, and ziprasidone). Newer atypical agents are more commonly used and better tolerated. Clozapine, olanzapine, quetiapine, and aripiprazole are commenced at normal doses and titrated to response. Risperidone[117] and its active metabolite 9-hydroxyrisperidone are renally excreted, and clearance is reduced by 60% in patients with severe renal impairment. Lithium is filtered and reabsorbed mainly in the proximal tubules. It is extensively renally excreted and accumulates even in patients with mild renal impairment, causing toxicity, and should be avoided if possible. If use is essential, the dose must be reduced with monitoring of plasma concentrations. In hyponatremic patients, tubular reabsorption of lithium is increased, leading to increased plasma concentrations and toxicity. NSAID co-prescription may also increase toxicity. HD is efficient in removal of lithium and can be used in overdose; however, multiple dialysis treatments are usually required because plasma

concentrations rebound soon after HD. Chronic lithium nephrotoxicity is discussed further in Chapter 64.

Benzodiazepines

Benzodiazepines are extensively metabolized by the liver to a range of active and inactive metabolites. Enhanced CNS toxicity, especially sedation, is the main concern in renal patients.[118,119] Because of the potential for accumulation, chronic use should be discouraged. Short-acting benzodiazepines are preferred, and the dose should be titrated cautiously according to response. The dose of midazolam should be reduced because of changes in plasma protein binding. Hemoperfusion and dialysis are not useful in patients with benzodiazepine intoxication. Flumazenil may be used as normal in patients with overdose.

Vaccines

Live vaccines (bacillus Calmette-Guérin, oral poliovirus, rubella, typhoid, yellow fever, and varicella) in immunosuppressed patients are contraindicated because of the potential for causing disease. Attenuated vaccines (diphtheria-tetanus, hepatitis B, influenza, meningococcal, and pneumococcal) may be used; but impaired response in immunocompromised individuals may lead to inadequate protection (see Chapter 84). Hepatitis B may need more doses for seroconversion to be achieved in HD patients. Immunization should preferably occur at least 1 month before initiation of immunosuppression. After transplantation, the immune response may be inadequate for at least 6 to 8 months, meaning that vaccination should be withheld until then.[120]

Vitamin Supplementation

Patients with renal impairment may become vitamin deficient as a result of poor dietary intake and the effect of dialysis on removal of water-soluble vitamins. Administration of vitamin supplements (B, C, and folic acid) is recommended after dialysis.

CHAPTER 78

Herbal and Over-the-Counter Medicines and the Kidney

Mark S. Segal and Xueqing Yu

In recent years, the use of herbal medicines and dietary supplements to promote the health and to treat various chronic diseases has increased globally. An estimated one third of adults in developed countries and more than 80% of the population in many developing countries are using herbal and folk medicines to promote health and to manage common maladies, such as colds, hay fever, inflammation, heart disease, indigestion, constipation, liver cirrhosis, cancer, acquired immunodeficiency syndrome, diabetes, and central nervous system diseases.[1] In Africa, up to 80% of the population depends on traditional medicine for primary health care; in China, herbal preparations account for up to 50% of the total consumption of pharmaceutical agents. There has been a surge in the popularity of herbal medicine in the West. For instance, the size of the U.S. herbal medicine market increased from $1.6 billion in 1994 to $5.3 billion in 2011.[1,2] In addition, European countries spent almost $5 billion (at manufacturers' prices to wholesalers) on over-the-counter (OTC) herbal medicines in 2003. Germany and France are the leaders in OTC sales and also have large markets for prescription herbal preparations (Fig. 78-1).[3] The European Union has taken steps with the Traditional Herbal Medicinal Products Directive (THMPD, also known as Directive 2004/24/EC) implemented in May 2011 to regulate herbal remedies. THMPD mandates that all herbal medicinal products be required to obtain an authorization to market within the European Union and that herbal medicines be manufactured under Good Manufacturing Practice. Complementary and alternative medicines, including Chinese herbal medicines and herbal plants, have been used by about 50% of Australians.[1]

Herbal medicine was widely recorded in ancient literature. To date, there are at least 11,000 species of plants for medicinal use, and about 500 of them are commonly used by various ethnic groups.[1,4] These herbal plants may be used either in their primary forms or in mixtures. However, the source and composition of botanical medicines vary depending on the prevalent local practices. Notably, these herbal remedies have not been tested for efficacy and safety, their ingredients are mostly unknown, and the dosage and route of administration are not standardized. Although the prevalence of toxicity of organs caused by traditional medicines is directly related to a combination of ignorance, poverty, lack of medical facilities, lack of legislation, and widespread belief in indigenous systems of medicine in rural areas, it has been realized recently that the problems and concerns regarding herbal medicines arise as a result of intrinsic toxicity, adulteration, contamination, substitution, misidentification, mistaken labeling, unfavorable herb-drug interactions, lack of standardization, or poor quality control.[1,4] Increasing evidence for both adverse drug reactions and poisoning events associated with the use of herbal medicines has been reported worldwide. Herbal medicines have been found to be adulterated with synthetic drugs and other potentially toxic compounds. On the other hand, coadministration of herbal medicines with conventional drugs raises the potential for herb-drug interactions, which may cause altered drug elimination, undertreatment, and/or toxicity.[1,4,5]

HERBAL MEDICATIONS AND THE KIDNEY

Kidneys are particularly vulnerable to toxic injury because of their high blood flow rate, large endothelial surface area, high metabolic activity, active uptake by tubular cells, medullary interstitial concentration, and low urine pH. Renal tubules are involved in active transport and urinary concentration, and therefore the local concentration of these toxins is potentially high, leading to direct injury to tubular cells. Herbal medicines may be toxic via one or more common pathogenic mechanisms. These include alterations in intraglomerular hemodynamics, tubular cell toxicity, inflammation, crystal nephropathy, rhabdomyolysis, and thrombotic microangiopathy. Drug-related nephrotoxicity is becoming more common; people are more commonly requiring multiple medications for multiple comorbidities, and are being exposed to more diagnostic and therapeutic procedures with the potential to harm kidney function. Patient-related risk factors for drug-induced nephrotoxicity include age older than 60 years, underlying renal impairment and glomerular filtration rate (GFR) less than 60 ml/min/1.73 m^2, volume depletion, diabetes, heart failure, and sepsis.[6] These risk factors may also make individuals susceptible to renal toxicity from herbal medicines. An overview of the potential renal side effects of herbal medicines is shown in Table 78-1.

ARISTOLOCHIC ACID NEPHROPATHY OR BALKAN NEPHROPATHY

Aristolochic Acids

Aristolochic acids (AAs) are a family of structurally related nitrophenanthrene carboxylic acids that are primarily from herbal medicines such as *Aristolochia* species, including *Aristolochia fangchi, Aristolochia clematitis,* and *Aristolochia manshuriensis* (Table 78-2). The predominant AAs are AAI (8-methoxy-6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid) and AAII (6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid). AAs activated by human NAD(P)H:quinone oxidoreductase[7] and react with DNA to form covalent dA-aristolactam and dG-aristolactam adducts.[8] These aristolactam adducts are mutagenic.[8] After even a single dose, AAI is detectable in the kidneys for a long period of time. Human aristolochic acid nephropathy (AAN) is reproducible in rodents in which AA intoxication results in tubular atrophy and interstitial fibrosis, leading to renal failure.[9] The progressive tubular atrophy is related to impaired regeneration and apoptosis of proximal tubular epithelial cells, which is considered a possible mechanism of tubular epithelial cell deletion. The resident fibroblast

Kidney Syndromes Induced by Herbal Medicines	
Hypertension	*Glycyrrhiza* species (Chinese herbal teas, gancao, boui-ougi-tou) *Ephedra* species (ma huang)
Acute tubular necrosis	Traditional African medicine: toxic plants (*Securidaca longepedunculata, Euphoria matabelensis, Callilepis laureola,* Cape aloes), or adulteration by dichromate Chinese medicine: *Taxus celebica* Morocco: Takaout roumia (paraphenylenediamine)
Acute interstitial nephritis	Peruvian medicine *(Uno degatta)* Tung Shueh pills (adulterated by mefenamic acid)
Fanconi syndrome	Chinese herbs containing AAs (*Akebia* species, boui-ougi-tou, Mokutsu) Chinese herbs adulterated by cadmium
Papillary necrosis	Chinese herbs adulterated by phenylbutazone
Chronic interstitial renal fibrosis	Chinese herbs or Kampo containing AAs (*Aristolochia* species, *Akebia* species, Mu Tong, Boui, Mokutsu)
Urinary retention	*Datura* species, *Rhododendron molle* (atropine, scopolamine)
Kidney stones	Ma huang (ephedrine) Cranberry juice (oxalate)
Urinary tract carcinoma	Chinese herbs containing AAs

Table 78-1 Kidney syndromes induced by herbal medicines. *AA,* Aristolochic acids. *(From reference 6.)*

activation plays a critical role in the process of renal fibrosis during AA toxicity.[10] The nephrotoxic and carcinogenic effects of AAs in animals have been reported, and similar toxicities have been observed in humans. It is now known that exposure to AA causes a progressive renal interstitial fibrosis associated with urothelial malignancy.

Aristolochic Acid Nephropathy

The association of kidney disease with long-term consumption of *Aristolochia fangchi* for slimming purposes was first reported in Belgium. More than 100 young women developed chronic kidney disease (CKD) and several developed renal and urinary tract cancer

Botanicals Known to Contain or Suspected of Containing Aristolochic Acid	
Botanical Name	**Common or Other Names**
Aristolochia species	Aristolochia, Guan Mu tong, Guang Mu tong
Aristolochia acuminata (syn. *Aristolochia tagala*)	Oval leaf Dutchman's pipe
Aristolochia bracteata	Ukulwe
Aristolochia clematitis	Birthwort
Aristolochia contorta	Ma Dou Ling (fruit), Bei Ma Dou Ling (root), Tian Xian Teng (herb)
Aristolochia cymbifera	Mil homens
Aristolochia debilis (syn. *Aristolochia longa, Aristolochia recurvilabra, Aristolochia sinarum*)	Ma Dou Ling (fruit), Tian Xian Teng (herb), Qing Mu Xiang (root), Sei-Mokkou (Japanese), Birthwort, Long birthwort, Slender Dutchman's pipe
Aristolochia fangchi	Guang Fang ji (root), Fang ji, Fang chi, Makuboi (Japanese), Kou-boui (Japanese), Kwangbanggi (Korean)
Aristolochia heterophylla	Han Fang Ji
Aristolochia indica	Indian birthwort (root), Yin Du Ma Dou Ling
Aristolochia kaempferi (syn. *Aristolochia chrysops, Aristolochia feddei, Aristolochia heterophylla, Aristolochia mollis, Aristolochia setchuenensis, Aristolochia shimadai, Aristolochia thibetica, Isotrema chrysops, Isotrema heterophylla, Isotrema lasiops*)	Yellowmouth Dutchman's pipe, Zhu Sha Lian
Aristolochia macrophylla (syn. *Aristolochia sipho*)	Dutchman's pipe
Aristolochia manshuriensis (syn. *Hocquartia manshuriensis, Isotrema manshuriensis*)	Manchurian birthwort, Manchurian Dutchman's pipe (stem), Guan Mutong (stem), Kan-Mokutsu (Japanese), Mokubai (Japanese), Kwangbanggi (Korean)
Aristolochia maxima (syn. *Howardia hoffmannii*)	Maxima Dutchman's pipe, Da Ma Dou Ling
Aristolochia mollissima	Wooly Dutchman's pipe, Mian Mao Ma Dou Ling
Aristolochia moupinensis	Moupin Dutchman's pipe, Huai Tong
Aristolochia sarpentaria (syn. *Aristolochia serpentaria*)	Virginia snakeroot, Serpentaria, Virginia serpentary
Aristolochia triangularis	Triangular Dutchman's pipe, San Jiao Ma Dou Ling
Aristolochia tuberosa	Tuberous Dutchman's pipe, Kuai Jing Ma Dou Ling
Aristolochia tubiflora	Tubeflower, Dutchman's pipe, Guan Hua Ma Dou Ling
Aristolochia versicolar	Versicoloraus Dutchman's pipe, Bian Se Ma Dou Ling
Asarum canodense (syn. *Asarum acuminatum, Asarum ambiguum, Asarum canadense, Asarum furcatum, Asarum medium, Asarum parvifolium, Asarum reflexum, Asarum rubrocinctum*)	Wild ginger, Indian ginger, Canada snakeroot, false coltsfoot, colic root, heart snakeroot, Vermont snakeroot, Southern snakeroot, Jia Na Da Xi Xin
Asarum himalai(y)cum	Tanyou-saishin (Japanese)
Asarum splendens	Do-saishin (Japanese)

Table 78-2 Botanicals known or suspected to contain aristolochic acid and their vernacular names. *(From reference 16.)*

(Fig. 78-2).[11] Increasing evidence demonstrates that AAs present in the herb are the compounds responsible for this renal toxicity (Figs. 78-3 and 78-4).[12,13] The renal syndrome was initially referred to as *Chinese herb nephropathy* and later by the more specific, mechanistic name *AA nephropathy.* AAN is characterized by tubulointerstitial nephritis that rapidly progresses to fibrosis with deterioration of renal function, ultimately leading to end-stage renal disease (ESRD), sometimes within months after first exposure. The renal toxicity of AA is dependent on the dosage and the duration of administration.[14]

Epidemiology

Soon after its initial description, AAN was recognized as a global health problem.[11,12,15] Since the publication of the index cases, new cases of AAN have been reported, not only in Belgium but also worldwide[10,11,13] (see Fig. 78-2). The true incidence of AAN remains unknown and probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in China, Japan, and India (see Fig. 78-3).[16]

Clinical Manifestations

The initial presentation of AAN is usually silent, and the renal disease is discovered by routine blood testing. Occasional patients present with Fanconi syndrome or with acute kidney injury (AKI) caused by acute tubular necrosis.[17] Anemia is often disproportionately severe for the degree of renal impairment. The urinary sediment is unremarkable, and the urinalysis is negative for albuminuria. However, urinary excretion of low-molecular-weight proteins (e.g., β_2-microglobulin, cystatin C) is markedly increased, and the ratio of urinary low-molecular-weight protein to albumin is higher than in glomerular diseases.[18]

Pathology

Aristolochic acid nephropathy is characterized by extensive renal interstitial fibrosis and tubular atrophy, which generally decreases in severity from the outer to the inner cortex (see Fig. 78-4). The glomeruli are relatively spared, although in the later stage of the disease there is some collapse of the capillaries and wrinkling of the

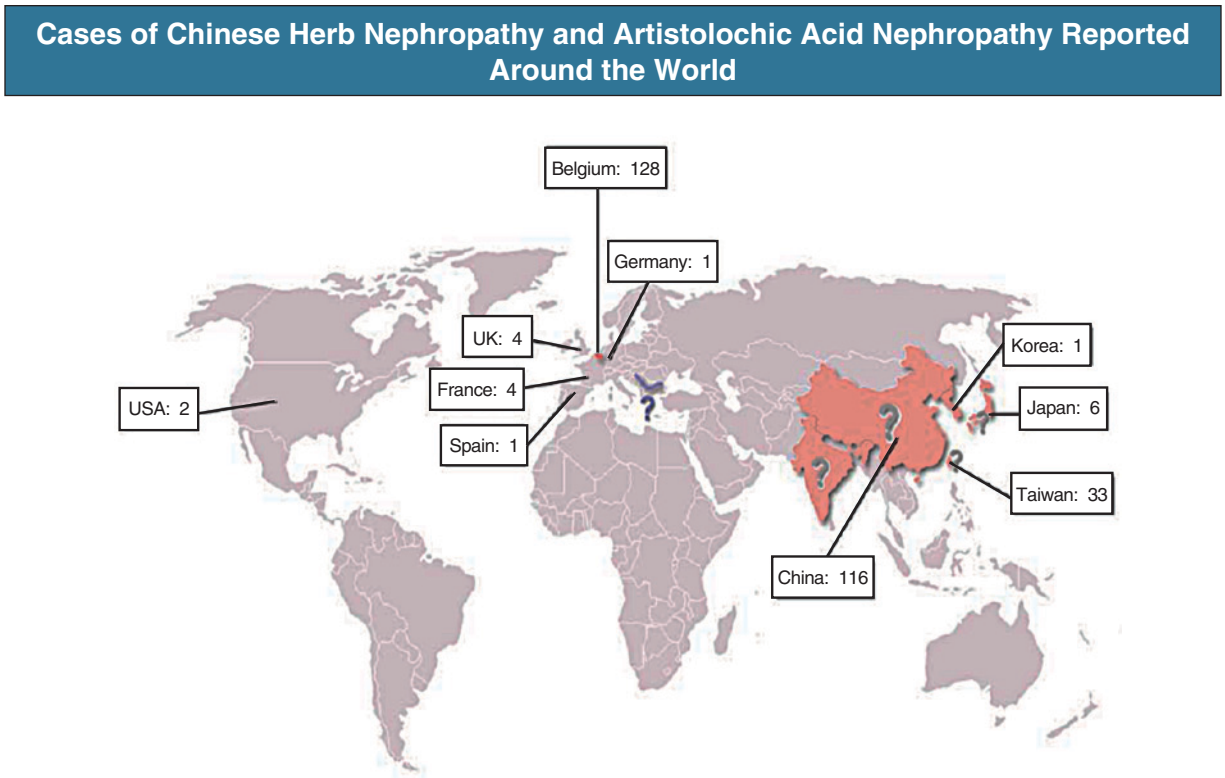

Figure 78-2 Cases of Chinese herb or aristolochic acid nephropathy reported around the world. *(From reference 16.)*

Figure 78-3 A pharmacy selling traditional herbal remedies including Fang Chi and Mu Tong. The true incidence of aristolochic acid nephropathy is largely unknown and probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in India and Eastern Asia. *(From reference 16.)*

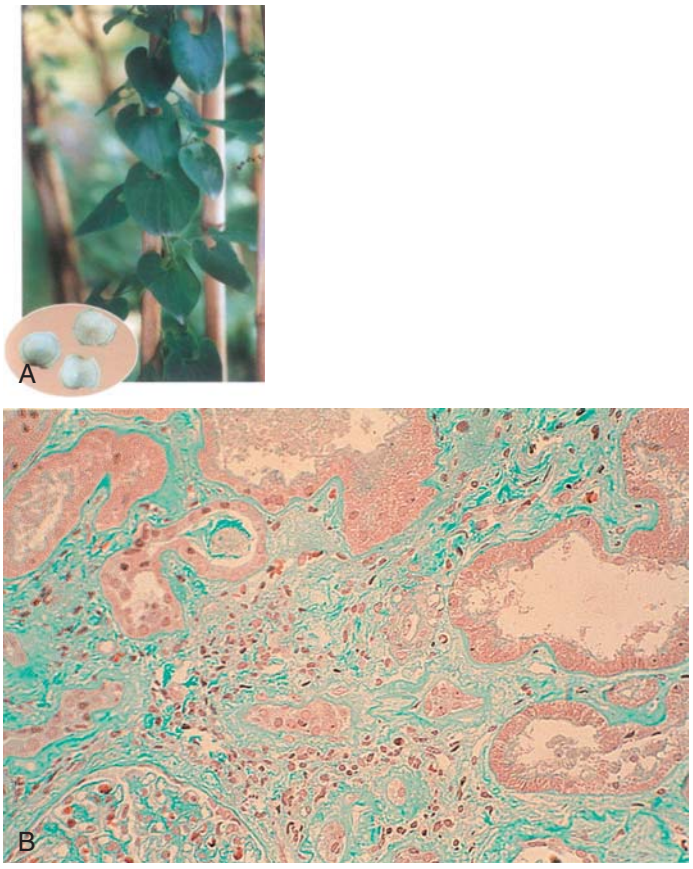

Figure 78-4 Chinese herb or aristolochic acid nephropathy. A, Guang Mu Tong, a Chinese herb that contains AAs. **B,** Extensive paucicellular interstitial fibrosis and tubular atrophy typically found in Chinese herb or aristolochic acid nephropathy. *(From reference 16.)*

basement membrane. There is endothelial cell swelling with consequent thickening of interlobular and afferent arterioles.[16,19] There are no immune deposits.

Pathogenesis

The striking association between AA exposure and urothelial abnormalities was first noted in studies showing moderate atypia and atypical hyperplasia in nephroureterectomy specimens removed at the time of transplantation from individuals with AAN (see Fig. 78-4).[21] The persistence of AA-DNA adducts in renal tissues of the Belgian women cohort is consistent with the postulated role of AA in urothelial cancer. Of AAN patients, 40% to 45% develop multifocal high-grade transitional cell carcinomas, mainly in the upper urinary tract.[13] A case series with 15-year follow-up identified upper-tract urothelial carcinoma as a potent risk factor for the subsequent development of bladder urothelial carcinoma after kidney transplantation for AAN.[22] There is a strong association between DNA adduct formation, mutation pattern, and tumor development. In animal

models, oral ingestion of AA is followed by extensive formation of AA-DNA adducts in the forestomach, accompanied by development of tumors.[22] An early and massive interstitial inflammation characterized by activated monocytes and macrophages and cytotoxic $CD8^+/CD103^+$ T lymphocytes seen in experimental AAN[23] suggests that the pathophysiology includes an immunologic element. In 2002 the International Agency for Research on Cancer Working Group concluded that there is sufficient evidence in humans to identify the carcinogenicity of herbal remedies containing plant species of the genus *Aristolochia.*[24]

Treatment

No treatment for AAN has proven to be effective in randomized trials. However, a pilot study with corticosteroids in 35 AAN patients with CKD demonstrated a significant reduction in the number of patients reaching ESRD after 1 year of corticosteroid therapy.[25] Corticosteroid therapy was later confirmed, in a larger cohort with historical controls, to slow down the progression of renal failure[26]; however, there has been no randomized controlled trial. Corticosteroids, when used for AAN, are initiated in those with an estimated GFR (eGFR) of greater than 20 ml/min at 1 mg of prednisone per kilogram.

Because patients with AAN are at increased risk for uroepithelial malignancies, they should at least be regularly screened with cystoscopy. In addition, prophylactic removal of the native kidneys and ureters should be performed in all patients with ESRD caused by AAN who are going to receive a kidney transplant and thus will be immunosuppressed.[27]

Balkan Endemic Nephropathy

Another manifestation of AAN is Balkan endemic nephropathy (BEN).

Definition

Balkan endemic nephropathy[28] is a slowly progressive condition that causes chronic interstitial fibrosis leading to ESRD and also to urothelial malignancy. BEN affects thousands of people living in Bulgaria, Bosnia, Croatia, Romania, and Serbia along the Danube River basin (Fig. 78-5).[29]

Figure 78-5 Areas where Balkan nephropathy is present. The endemic areas are in *red*.

Clinical Manifestations

Balkan endemic nephropathy typically presents in the fourth or fifth decade of life and is only rarely seen in individuals younger than 20 years. When there is prospective monitoring, tubular proteinuria is usually the first sign. Proteinuria is usually mild or intermittent but may increase in the advanced stages. The urinary sediment is usually unremarkable. Other manifestations of tubular dysfunction include impaired acidification, decreased ammonia and increased uric acid excretion, and urine-concentrating defects with renal salt wasting, which may precede the decrease in GFR. The disease slowly progresses to ESRD. There is anemia disproportionate to the degree of renal impairment. Blood pressure is usually normal until ESRD is reached. There is an increased incidence of uroepithelial carcinomas.

Pathogenesis

The clinical features closely parallel those of AAN, and there is now strong evidence for the role of AA in the pathogenesis of BEN.

In endemic regions, bread is a dietary staple and is traditionally prepared from flour made from locally grown wheat. The seeds of *A. clematitis,* a plant native to the region, have been found interspersed with the harvested wheat grain. dA-aristolactam and dG-aristolactam DNA adducts are found in the renal cortex of patients with BEN but not in those with other chronic renal diseases.[30] Transitional cell cancers from patients with BEN contain aristolactam adducts and also contain a characteristic pattern of tumor protein 53 *(TP53)* mutations: 89% occur at A:T pairs, and 78% of these are A:T to T:A transversions. A:T to T:A transversions are rare events, found in 0% of transitional cell carcinomas of the renal pelvis in an international *TP53* mutational database. Molecular, epidemiologic evidence relates urothelial carcinoma in patients with BEN to dietary exposure to AA.[31] Aristolactam-DNA adducts have been found in 70% of people in the endemic areas with dietary exposure to AA, and in 94% of patients with specific A:T to T:A mutations in *TP53*. Neither aristolactam-DNA adducts nor specific mutations were detected in tissues of those from nonendemic regions. Because BEN occurs only in a fraction of those individuals exposed to AA, there is assumed to be a genetic susceptibility that puts individuals with a dietary exposure to AA at risk for BEN and its resultant urothelial carcinomas.

Diagnosis

Diagnostic criteria for BEN in endemic areas are shown in Box 78-1. Recent analysis of 182 patients in Serbia showed that proteinuria, urine α_1-microglobulin, and kidney size are significant predictors of BEN, whereas renal failure as well as several tubular disorders (urine specific gravity, fractional sodium excretion, and tubular phosphate reabsorption) had an insignificant predictive value.

Treatment

As in AAN, there have been no randomized trials performed for treatment of BEN. Based on the nonrandomized studies of corticosteroids in AAN, a trial of corticosteroids is reasonable in those with BEN in addition to blood pressure control and management of electrolyte abnormalities.

ACUTE KIDNEY INJURY CAUSED BY HERBS

The most frequently reported nephrotoxicity caused by medicinal herbs is from southern Africa and Asia. The use of traditional herbal remedies has been implicated in 37% of all cases of acute renal failure in Nigeria.[32] Herbal plants reported as the cause for renal damage include *Securidaca longepedunculata* (or violet tree), which contains

Diagnostic Procedures for Balkan Endemic Nephropathy

Diagnosis of Balkan nephropathy is made in inhabitants from endemic settlements using the following:

1. Epidemiologic criteria
2. Demonstration of
   - GFR decrease
   - Proteinuria generally below 1 g/24 h
   - Microalbuminuria
   - Little urinary sediment
   - Tubular markers (renal glucosuria, increased urinary excretion of β_2-microglobulin or α_1-microglobulin, and *N*-acetyl-β-D-glucosaminidase)
   - Typical renal histology showing hypocellular cortical interstitial fibrosis decreasing from the outer to the inner cortex (if renal biopsy feasible)
3. Exclusion of other known kidney disease (e.g., chronic pyelonephritis [obstructive and atrophic], adult dominant polycystic kidney disease, glomerulonephritis)

Box 78-1 Diagnostic procedures for Balkan endemic nephropathy. *(Modified from reference 30.)*

methyl salicylate and saponin; *Euphorbia matabelensis,* which contains latex; *Crotalaria laburnifolia,* which contains hepatonephrotoxic alkaloids; *Uncaria tomentosa* (cat's claw); *Lepidium meyenii* (common name: maca); *Tripterygium wilfordii* (Lei Gong Teng); licorice *(Glycyrrhiza glabra)* root; and *Callilepis laureola* (Impila). The following section describes some of the important examples of nephrotoxicity caused by herbal remedies.

T. wilfordii Hook F (TWHF) is a Chinese herbal medicine used for over 2000 years. As a cream, it was used externally for treatment of arthritis and inflammatory tissue swelling for many years. Extracts of TWHF are also given orally for rheumatoid arthritis, lupus, minimal change disease, and other inflammatory conditions. The adverse effects of TWHF include gastrointestinal upset, infertility, and *in vitro* suppression of lymphocyte proliferation. In rats, daily intragastric ingestion of an effective compound extracted from TWHF for 16 days led to proximal tubular dysfunction.[33]

Cat's claw, or *Uno degatta,* is a Peruvian herbal preparation made from *Uncaria,* a woody vine found in the Amazon basin. It has been used for treatment of cirrhosis, gastritis, gonorrhea, cancers of the female genital tract, and rheumatism. The oxindole alkaloids from the root bark of cat's claw are thought to invoke its most widely sought-after medicinal effects as an herbal remedy against inflammation, but it appears that other unknown substances contribute to the overall effect of cat's claw extracts. A case of reversible acute interstitial nephritis after the use of this preparation has been reported, likely an idiosyncratic allergic reaction to the remedy.[34]

The majority of renal problems associated with mushrooms are a consequence of renal failure resulting from mushroom-induced hepatic failure. However, throughout Europe and North America there are a variety of nephrotoxic mushrooms that can be confused with edible mushrooms and can directly cause AKI. The *Cortinarius* species (*Cortinarius callisteus, Cortinarius cinnamomeus* group, *Cortinarius gentilis, Cortinarius orellanus, Cortinarius rainierensis, Cortinarius speciosissimus, Cortinarius splendens,* and *Cortinarius semisanguineus* group) are the most notorious. The most common nephrotoxic mushroom is probably *C. gentilis.* In 2011, there were 6818 mushroom exposures reported in the United States, American Samoa, Federated States of Micronesia, Guam, Puerto Rico, and the U.S. Virgin Islands with two fatalities, but only eight exposures were attributed to the *Cortinarius* group. However, the type of mushroom is unknown in over 80% of the cases, so *Cortinarius* exposures are almost certainly higher.[35] The history of mushroom ingestion may be remote, particularly with *Cortinarius.* Although gastrointestinal symptoms are usually noted at the time of ingestion, they may not be severe enough for patients to seek medical attention, and symptoms of renal failure may not present until 1 to 3 weeks after exposure. Presentation with a shorter latent period suggests a more severe toxicity and greater risk of severe renal failure. Improvement in renal function may occur within several weeks to months, but patients may require chronic dialysis or renal transplantation.

A more recently described mushroom syndrome involves *Amanita smithiana* or *Amanita proxima.* It is thought that the toxin is 2-amino-4,5-hexadienoic acid.[36] Although it causes acute tubular necrosis within hours of the time of ingestion, the clinical outcome is usually good.

OTHER RENAL COMPLICATIONS OF HERBAL REMEDIES

Hypertension

Ma huang is an ephedra-containing herbal preparation used in the treatment of bronchial asthma, cold and flu symptoms, fever and chills, headaches and other aches, edema, and lack of perspiration. In Western countries, ephedrine and herbal ephedra preparations have been used to promote weight loss and to enhance athletic performance. Dietary supplements that contain ephedra alkaloids have been reported to induce hypertension, palpitations, tachycardia, and stroke. Prescribed ephedrine was not associated with a substantially increased risk of adverse cardiovascular outcomes in a registry-based case-crossover study.[37,38] However, ephedra may pose a serious health risk to some users, such as renal patients who are particularly prone to hypertension.

The dried roots of the licorice plant *(G. glabra)* have been consumed for over 6000 years and are used as flavoring and sweating agents, as demulcents and expectorants in the Western world, and as antiallergic and anti-inflammatory agents in Asian countries, including China, Japan, and Korea. Licorice contains glycyrrhizin. After oral administration of licorice preparations, glycyrrhizinic acid is hydrolyzed by intestinal bacteria into glycyrrhetic acid. Glycyrrhetic acid can inhibit 11-β-hydroxysteroid dehydrogenase-2 (11-BOHD-2), which is found in the distal tubule and converts the corticosteroid hormone cortisol to cortisone. Decreased activity of 11-BOHD-2 leads to an excess of cortisol and an overstimulation of this mineralocorticoid receptor, leading to sodium and water retention and increased excretion of potassium. Large doses of glycyrrhizinic acid over a prolonged period can cause hypokalemia, hypernatremia, edema, pseudoaldosteronism, hypertension, arrhythmia, and other cardiac disorders.[1] To minimize the adverse effects, it is recommended that licorice not be ingested for longer than 4 to 6 weeks.[39]

Crystalluria and Nephrocalcinosis

Many health drinks that are well tolerated by individuals with normal renal function can cause serious problems in patients with limited renal function. One example of this is oxalate crystalluria. Star fruit (carambola) juice can contain as much as 800 mg of oxalate in 100 ml. Sour carambola juice is a popular beverage in Taiwan, and although preparation of commercial carambola juice by pickling and dilution markedly reduces oxalate content, fresh juice or only mildly diluted postpickled juice may contain high quantities of oxalate.

Cranberry concentrate tablets also can lead to an increase in urinary excretion of oxalate. Ma huang ingestion also has been reported to lead to kidney stones, and the use of ephedrine and guaifenesin individually or in combination has been shown to cause greater than 35% of urinary stones that are related to pharmaceutical metabolites and 0.1% of all urinary stones.[37]

Hyperkalemia

Dietary potassium restriction is commonly recommended for people with renal impairment, especially because hyperkalemia is a side effect of medications used to slow down the progression of renal disease. Common foods high in potassium include oranges, bananas, tomatoes, and potatoes. However, some health drinks are also very high in potassium. Noni juice, often taken to increase energy, contains more potassium than any other fruit juice. The legume alfalfa *(Medicago sativa)* and the plants dandelion *(Taraxacum officinale),* stinging nettle *(Urtica dioica),* and horsetail *(Equisetum arvense)* all contain significant amounts of potassium[40] and may induce hyperkalemia in people with CKD.

Urinary Obstruction

Djenkol beans or Jering *(Pithecellobium jiringa)* are broad, round, reddish beans that grow during monsoon season in Myanmar, Indonesia, and Malaysia and are considered a delicacy. The Jering seeds are extolled for their supposed ability to prevent diabetes and high blood pressure. In addition, the seeds have bladder spasmodic properties and are used as a remedy to eliminate stones from the bladder. Jering poisoning or djenkolism is characterized by spasmodic pain, urinary obstruction, and AKI.[41] The underlying pathology is an obstructive uropathy. On a more chronic basis, djenkol bean consumption is associated with a fourfold higher risk of nonglomerular hematuria.[42]

Renal Toxicity from Contaminants Within Herbal Medicines

Herbal medicines may be contaminated with excessive or banned pesticides, microbial contaminants, heavy metals, or chemical toxins or adulterated with orthodox drugs. These contaminants are related to the source of these herbal materials, whether grown in a contaminated environment or contaminated during collection of these plant materials. The herbal materials may be contaminated with chemical toxins unintentionally or intentionally during storage. The presence of orthodox drugs is often a result of the intentional adulteration of the herbal remedy by the manufacturers.[43] A report found undeclared pharmaceuticals or heavy metals in 32% of Asian medicines sold in the state of California. These included ephedrine, chlorpheniramine, methyltestosterone, phenacetin, sildenafil, corticosteroids, and fenfluramine; 10% to 15% contained lead, mercury, or arsenic. Out of more than 500 Chinese drugs, approximately 10% contained undeclared drugs or heavy metals.[4]

There have been case reports concerning these adulterations leading to renal injury. The first was a report of a 73-year-old Malaysian woman who presented with renal failure and bilateral papillary necrosis after having consumed two tablets daily of a traditional herbal preparation, freely available from Chinese medical halls, for 10 years for osteoarthritis. She denied the consumption of any other analgesics, but the analysis of the herbal preparation showed 120 mg of phenylbutazone in each tablet. The second report was of a 34-year-old housewife taking a mixture of Chinese herbs who presented with Fanconi syndrome and nephrogenic diabetes insipidus. She was found to have urinary excretion of cadmium 50 times greater than normal. In another report, a patient presented with AKI, with marked albuminuria, microscopic pyuria, and hematuria after a 4-week treatment with Tung Shueh pills for arthralgias. The cause was acute interstitial nephritis, and the Tung Shueh pills were found to contain both diazepam and mefenamic acid. In Morocco, the traditional *el badia,* a powder made of the seeds of *Tamarix orientalis*, is used by women for hair dye; however, in times when the *T. orientalis* seeds are scarce, they are replaced with Takaout roumia, which contains paraphenylenediamine. This substitution is responsible in Morocco for about 10% of all cases of AKI, 50% of all cases of rhabdomyolysis, 25% of intensive care unit (ICU) admissions for poisonings, and two thirds of poisoning-related deaths.[4,6]

In Thailand and other parts of Southeast Asia and India, herbal remedies have been shown to be contaminated with lead, cadmium, and/or mercury. In South Africa, about 15% of herbal remedies are contaminated with uranium. In the United States, ginseng dietary supplements have been shown to contain the pesticides quintozene and hexachlorobenzene, or to have exceeded the standard for lead content.

Herb-Drug Interactions Resulting in Adverse Renal Effects

Herbs are often administered in combination with therapeutic drugs, with potential for pharmacokinetic and/or pharmacodynamic herb-drug interactions. Pharmacokinetic herb-drug interactions are caused by altered absorption, metabolism, distribution, and excretion of drugs. A frequent underlying mechanism of altered drug concentrations by concomitant herbal medicines is the induction or inhibition of hepatic and intestinal cytochrome P-450 enzymes (CYPs). There are reports of 32 drugs interacting with herbal medicines in humans. These drugs include anticoagulants (warfarin, aspirin, and phenprocoumon), sedatives and antidepressants (midazolam, alprazolam, and amitriptyline), oral contraceptives, anti–human immunodeficiency virus (HIV) agents (indinavir, ritonavir, and saquinavir), cardiovascular drug (digoxin), immunosuppressants (cyclosporine and tacrolimus), and anticancer drugs (imatinib and irinotecan). Most of them are substrates for CYPs and/or P-glycoprotein (P-gp), and many have narrow therapeutic indices. Toxicity arising from drug-herb interactions may be minor, moderate, or even fatal, depending on a number of factors associated with the patients, herbs, and drugs.[1]

St John's wort, derived from the plant *Hypericum perforatum,* has been used since ancient times for depression and anxiety. It is the most common antidepressant used in Germany. St John's wort induces a hepatic enzyme through activation of the CYP system, leading to decreased plasma levels of a wide range of prescribed drugs, with possible clinically serious consequences. For example, St John's wort ingested for 10 days by a group of healthy volunteers reduced the bioavailability of digoxin by an average of 25%. St John's wort ingested for 2 weeks reduced total absorption of indinavir by 50%, which is large enough to cause treatment failure. Other reports indicated significant increases in the metabolism of warfarin, theophylline, oral contraceptives, or cyclosporine. In transplant recipients, toxicity and underdosage of calcineurin inhibitor–based immunosuppression have been linked to phytochemically triggered activity changes of cytochrome P-450 isoenzyme CYP3A4 metabolism and drug transport proteins. Concomitant use of St John's wort in renal transplant recipients treated with cyclosporine or tacrolimus could favor graft rejection.[44,45]

Gingko biloba is one of the most popular plant extracts in Europe and recently received approval in Germany for treatment of

dementia. *G. biloba* is composed of several flavonoids, terpenoids (e.g., ginkgolides), and organic acids believed to act synergistically as free radical scavengers. It has been suggested that *G. biloba* should not be administered with concomitant anticoagulation or in patients with bleeding disorders. Concomitant use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs), as well as anticoagulants such as warfarin and heparin, is ill advised. Spontaneous hyphema and spontaneous bilateral subdural hematomas have been observed in patients taking *G. biloba* and attributed to ginkgolide B, a potent inhibitor of platelet-activating factor needed to induce arachidonate-independent platelet aggregation. Hemorrhagic complications were observed often in patients administered concomitant antiaggregant or anticoagulant therapy. The exact mechanism of the interaction of *G. biloba* with aspirin, warfarin, and NSAIDs remains unclear. Experimental data from rats suggest that a *G. biloba* diet markedly increased the content of CYP and activity of glutathione-*S*-transferase and markedly induced the level of CYP2B1/2, CYP3A1, and CYP3A2 messenger RNA in the liver.[46]

In summary, herbal medicines may exert renal toxicity through their inherent properties, occasionally dose-related or idiosyncratic toxicity, herb-drug interactions, and misidentification and adulteration of the preparation. Herbal medicines also may be hazardous for renal patients because of interactions with drugs such as cyclosporine or because of their potassium content. However, most information about the toxicity of herbal medicines is found only in case reports. Precise identities of the culprit substances and the toxicologic characteristics and pathogenic mechanisms of herbal medicines remain largely unknown. Whereas many herbs have been used for centuries without incidence of acute renal damage, insidious damage caused by long-term use is a concern because many herbs have not been rigorously tested for toxicity. There are websites that provide data on herbal therapy hazards (Table 78-3).

OVER-THE-COUNTER MEDICINES AND THE KIDNEY

In addition to the increasing popularity of OTC health foods, nutritional supplements, and medicinal products from plants or other natural sources, there is increasing consumption in many countries of pharmaceutical products bought OTC. These particularly include analgesics and agents for treatment of dyspepsia.

Analgesics

Over-the-counter analgesics constitute one of the most widely used classes of drugs in the developed world. The primary indications for use of OTC analgesics include fever and minor musculoskeletal symptoms; population studies and World Health Organization (WHO) statistics indicate that 10% to 50% of individuals have a history of musculoskeletal disorders. NSAIDs, such as aspirin, ibuprofen, and naproxen, are also used to treat inflammatory conditions; and aspirin is used prophylactically as an anticoagulant in thrombosis-related disorders. Acetaminophen (paracetamol), aspirin, ibuprofen, and naproxen are available OTC in many countries, sometimes in combinations. Easy access to OTC analgesics runs the risk of unwarranted and unsupervised chronic intake. Although studies on the association between the long-term use of aspirin, NSAIDs, and other analgesics and ESRD have given conflicting results, many studies have suggested an association between chronic ingestion of analgesics and kidney disease.

Because analgesic use is very widespread, even a small percentage of increased risk of kidney disease may have major public health implications. NSAIDs inhibit cyclooxygenase and may inhibit lipoxygenase, decreasing the production of prostaglandins and leukotrienes, which accounts for many NSAID-induced renal effects. In patients with volume depletion, renal perfusion depends on circulating prostaglandins to vasodilate the afferent arterioles, allowing more blood flow through the glomerulus. So the contribution of prostaglandins to renal homeostasis is most critical in elderly patients and those with circulatory disturbances, such as renal or liver dysfunction, congestive heart failure, or volume depletion.[47]

Patients who warrant chronic therapy with analgesics and NSAIDs should be closely monitored by regular screening with dipstick urinalysis and serum creatinine for early evidence of kidney injury. Early detection and removal of the offending agent could halt or even reverse analgesic-induced kidney injury. There is a pressing need for multicenter prospective trials to assess the true incidence of this

problem and to study the effects of various analgesic agents (alone and in combination) in at-risk populations.

Analgesic Nephropathy

Analgesic nephropathy is defined as a disease resulting from the habitual consumption over several years of compound analgesics, which is characterized by renal papillary necrosis and chronic interstitial nephritis. It is an increasingly rare condition because phenacetin (the analgesic most implicated as a causative agent) has been banned in many countries. A retrospective cohort study using data from the Australia and New Zealand Dialysis and Transplant registry showed that among 31,654 patients receiving renal replacement therapy over the previous 35 years, 10.2% had analgesic nephropathy, but there was a marked decrease in the incidence more recently to less than 3.5% in 2005.[48] Analgesic nephropathy is discussed further in Chapter 64.

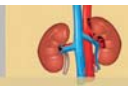
SECTION XVI

Chronic Kidney Disease and the Uremic Syndrome

CHAPTER 79



Epidemiology, Natural History, and Pathophysiology of Chronic Kidney Disease

Meguid El Nahas and Arif Khwaja

DEFINITION AND CLASSIFICATION OF CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is defined as kidney damage or an estimated glomerular filtration rate (eGFR) below 60 ml/min/1.73 m^2 persisting for 3 months or more irrespective of the cause. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines have classified CKD into five stages.[1] The Kidney Disease: Improving Global Outcomes (KDIGO) group suggested clarifications including the addition of the suffix *T* for patients with renal allografts and *D* to identify CKD stage 5 patients on dialysis.

The latest 2012 KDIGO CKD classification recommends detailing the cause of CKD and classifying into six categories related to glomerular filtration rate (G1 to G5, with G3 split into 3a and 3b) but also based on three levels of albuminuria (A1, A2, and A3), each assessed according to the urinary albumin-creatinine ratio (in mg/g or mg/mmol in an early morning "spot" urine sample). The term *microalbuminuria* is no longer incorporated into this classification; the term *moderate level of albuminuria* is used (30 to 300 mg/g or 2.5 to 30 mg/mmol) (Fig. 79-1).[2]

The improved classification of CKD has been of benefit to identify prognostic indications related to decreased kidney function as well as increased albuminuria. This has led to increased awareness of CKD as well as appreciation of the significant impact of CKD on health care worldwide. However, a downside of the use of the classification systems is the possible overdiagnosis of CKD, at least among certain categories of eGFR and albuminuria, especially among the elderly.

Limitations of Chronic Kidney Disease Classification

Estimating Glomerular Filtration Rate

The current CKD classification is based on eGFR (see Chapter 3). The Modification of Diet in Renal Disease (MDRD) study equation and the more recently developed Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation are both commonly used equations to calculate eGFR; however, both are relatively inaccurate in reflecting measured glomerular filtration rate (mGFR) above 60 ml/min/1.73 m^2. This underestimation by eGFR of true mGFR can lead to misclassification of a large number of individuals as having CKD stage 3a, whereas in reality their true GFR is above 60 ml/min. Also, the inaccuracy of eGFR to reflect mGFR above 60 ml/min/1.73 m^2 makes the distinction between CKD stages 1 and 2 difficult and artificial. The limitations of using creatinine-based estimations have spurred the search for alternative filtration biomarkers, such as β-trace protein (βTP), cystatin C, and β_2-microglobulin (β_2M). (See Chapter 3 for alternative estimations of GFR.)

Microalbuminuria (Moderately Increased Albuminuria) as a Definition for Chronic Kidney Disease

Isolated microalbuminuria (i.e., moderate level albuminuria; A2 category) is a common feature of aging and can be associated with a large number of acute and chronic inflammatory as well as vascular pathologies.[3] It is also associated with obesity, cigarette smoking, and unhealthy diets. Furthermore, microalbuminuria is often transient and reversible, thus not justifying its specific defining role in CKD (stages 1 and 2). Whereas microalbuminuria may highlight those at increased relative risk of CKD progression or cardiovascular risk, the absolute risk to the individual remains low. Therefore the retention of microalbuminuria as a sole definition of CKD in spite of its obvious lack of specificity to kidney disease remains controversial and potentially misleading.

Age-Related Decline in Kidney Function

The great majority of individuals classified as having CKD in the community are over the age of 60 years—in part a reflection of physiologic age-related decrease in kidney function.[3] The current CKD definition and classification are age neutral; therefore the difference in outcomes among different age groups is not recognized. Thus, under the current classification, an 80-year-old man with G4A1 is deemed to be at higher risk of progression to end-stage renal disease (ESRD) than a 20-year-old with G3A2, yet the outcomes in CKD are markedly age sensitive. This was elegantly demonstrated by the calculation of a threshold eGFR. ESRD exceeded the risk of death in a cohort of more than 200,000 U.S. veterans with CKD stages 3 to 5; the level of eGFR below which the risk of ESRD exceeded the risk of death varied by age, being 45 ml/min/1.73 m^2 for 18- to 44-year-olds to 15 ml/min/1.73 m^2 for those 65 to 85 years old.[4] Thus in the absence of associated albuminuria, CKD is seldom progressive to ESRD in the elderly, as it may to a large extent reflect age-related decline in kidney function.

Further Considerations

The current classification takes no notice of the single most important risk factor associated with CKD, namely, systemic hypertension. The current classification also does not determine whether CKD is progressive or not—that is, it does not incorporate values for the trajectory of renal function (eGFR) over time. KDIGO suggests defining progressive kidney disease as a sustained decline in eGFR of more than 5 ml/min/1.73 m^2/yr or a decline in GFR category accompanied by a greater than 25% drop in eGFR from baseline. Defining progression is problematic because the eGFR equations perform relatively poorly when the GFR is greater than 60 ml/min/1.73 m^2 and because serum creatinine often fluctuates in patients with nonprogressive CKD. Also, declining true or measured GFR concomitant with loss of muscle mass (sarcopenia) may not be

appropriately detected by creatinine-based eGFR assessment. Thus the current classification system has no mechanism to alert the clinician to the patients in whom the disease is actually progressing and who therefore may require intervention.

Altogether, although classification of CKD based on eGFR and albuminuria has undoubted advantages and has achieved greater awareness of CKD and its impact on global health, there remain a number of limitations that may give rise to misinterpretation and miscategorization of individuals, particularly in the growing elderly population.

EPIDEMIOLOGY OF CHRONIC KIDNEY DISEASE

The true incidence and prevalence of CKD within a community are difficult to ascertain because early to moderate CKD is usually asymptomatic. However, various epidemiologic studies suggest a prevalence of CKD of approximately 10% to 14% in the general population, albuminuria (mostly microalbuminuria or A2) of approximately 7%, and GFR below 60 ml/min/1.73 m^2 of approximately 3% to 5% (Fig. 79-2 and Table 79-1).[5]

Most of these studies are limited by the fact that individuals were tested only once; thus the studies merely reflect a snapshot with no clear evidence of chronicity.[6] KDOQI stipulates that tests should be undertaken on three occasions over a 3-month period, with two of three results being consistently positive to justify the labeling of chronicity and CKD.[1]

Of note, the high reported prevalence of CKD is confounded by a number of facts:

- Low-level albuminuria (previously designated *microalbuminuria*) is included, despite its obvious lack of specificity to kidney disease (discussed earlier)
- The majority of those screened in the community and found to have reduced eGFR are elderly individuals, most probably with age-related decline in kidney function.
- Formulas such as those of MDRD and CKD-EPI are used to estimate GFR in spite of their known limitations (see Chapter 3). It is interesting to note that the prevalence of CKD in communities varies up to threefold based on the type of equation applied.[7]

All these limitations of current CKD screening strategies are at risk of overinflating the true prevalence of significant CKD.

CHRONIC KIDNEY DISEASE DETECTION RECOMMENDATIONS

The rationale for screening at-risk individuals for CKD is to permit earlier detection of CKD, allowing interventions aimed at slowing its progression. In addition, detection of CKD may identify individuals within communities at risk for complications, including cardiovascular disease (CVD) and associated morbidity and mortality.

Several guidelines for screening, mostly targeted at high-risk individuals, have been issued and implemented worldwide. Those include the KDOQI guidelines in the United States, the CKD National Institute for Health and Care Excellence (NICE) guidelines, and the Australian Caring for Australasians with Renal Impairment (CARI) guidelines. There are few differences regarding the recommended targeted high-risk populations, but they invariably include individuals with hypertension and diabetes mellitus (Table 79-2). The KDOQI guidelines additionally recommend screening those older than 65 years. Screening should consist of urinalysis, a urine albumin or protein estimation (such as urine albumin-creatinine ratio [uACR]), and measurement of serum creatinine and estimation of GFR (see Chapter 3), preferably by the CKD-EPI equation (KDIGO 2012). Targeted screening is the most cost-effective

approach, and there is no evidence to justify screening asymptomatic individuals in the general population for CKD (see Table 79-2).[8]

Chronic kidney disease screening would best be associated with broader national strategies and programs to minimize obesity, diabetes, hypertension, and primarily CVD. This is the essence of the U.K. National Vascular Campaign strategy launched in 2009 and of the campaigns implemented by the Centers for Disease Control and Prevention (CDC) in the United States and in Australia.

EPIDEMIOLOGY OF END-STAGE RENAL DISEASE

Incidence rates of ESRD refer to the number of patients per million population per year (pmp/yr) beginning renal replacement therapy (RRT). Incidence rates of ESRD in most national registries do not take into account patients not treated with RRT and therefore underestimate the true incidence of ESRD (CKD stage G5). This is true not only in countries where provision of RRT is limited or absent, but also in countries where there is an active conservative management program for patients who opt not to have RRT (Table 79-3).

The prevalence rate of ESRD is the number of patients per million population (pmp) who have undergone treatment for ESRD. Prevalence rate is a function of the incidence rate (newly treated cases) and outcomes (i.e., mortality and return of ESRD after a failed renal transplant) in a given population. It is important to note that the eGFR at initiation of dialysis will have a marked impact on the prevalence of ESRD—indeed, most of the growth in the ESRD population in the United States in the last 15 years may be accounted for by earlier initiation of dialysis rather than by a true increased incidence of ESRD.[9,10]

Disparities in the incidence and prevalence of ESRD relate to cultural, socioeconomic, and demographic factors. Racial and ethnic diversity within societies affects not only the prevalence of diabetes and hypertension but also progression rates and ESRD prevalence.

Incidence and Prevalence of End-Stage Renal Disease (ESRD) in Different Countries (2010)

Country and Ethnicity	**Incidence**	**Prevalence**

United Kingdom	107	832
France	149	1060
Russia	40	186

Table 79-3 Incidence and prevalence of ESRD in different countries.

Differing referral patterns and quality of pre-ESRD care have all been linked to the heterogeneity of ESRD rates in different parts of the world. Developed countries with liberal access policies toward ESRD treatment will logically have the highest prevalence rates of treated ESRD,[11] although economically emerging countries with historically low ESRD treatment rates can experience rapid growth rates when access to treatment improves. Presently, 90% of the global RRT population is from high-income economies, and more than 100 countries have no provision for RRT.

During the forthcoming decades, even industrialized nations will struggle to meet the demands of expanding ESRD programs; in the United States, the annual expenditure on ESRD will likely reach more than $52 billion by 2030.[12] The improving survival rate while patients are undergoing treatment (dialysis or transplantation) aggravates the spiraling cost of care. In the United Kingdom, expenditure on ESRD currently consumes about 2% of the National Health Service budget, even though the number of patients undergoing ESRD treatment is about 0.05% of the population. Globally, the number of individuals receiving RRT has risen from 426,000 in 1990 to 2.5 million in 2010, and the cumulative global cost for RRT is estimated to exceed $1 trillion during the current decade.[12]

The limited provision of RRT in some low and middle economies may also reflect the fact that CKD and ESRD are not health care priorities in these countries. This is a direct consequence of the fact that CKD and its associated mortality ranked as low as the 18th cause of death in 2010, well after coronary heart disease, chronic respiratory diseases, diabetes, hypertension, cancer, and major communicable diseases.[13] Increased awareness of the detrimental and multiplicative effect of CKD on other major causes of global morbidity and mortality may in the future increase the awareness of the global health care impact of CKD.

Impact of Chronic Kidney Disease on Morbidity and Mortality

A decrease in eGFR below 60 ml/min/1.73 m^2 and increased albuminuria are associated with increased cardiovascular as well as overall morbidity and mortality, and the effects of combined

decreased GFR and increased albuminuria on mortality are synergistic (see Chapter 82).[14] However, decreased GFR and increased albuminuria are markers of ill health, thus generally reflecting poor outcomes. Also, albuminuria is increasingly defined by a raised uACR. Interpretation of the predictive value of albuminuria as albumin-creatinine ratio (ACR) is confounded by the inclusion of urine creatinine because a fall in urinary creatinine excretion that causes a rise in ACR, may also reflect ill health and the associated sarcopenia. Sarcopenia may also be associated with a low serum creatinine and an elevation of eGFR (>120 ml/min) that has been associated with poor outcomes.[14]

The fall in GFR with age has been linked to underlying comorbidities such as lifelong hypertension and diabetes. The term *cardio-kidney-damage* has been coined to highlight the close links between cardiovascular and kidney damage.[15] It is therefore not surprising that CKD in the elderly predicts cardiovascular morbidity and mortality.

Nevertheless, when the predictive values of albuminuria and/or eGFR on morbidity and mortality have been compared with or when these values have been added to well-established cardiovascular prognostic markers and scores, such as the Framingham Risk Score (FRS), they were found to add very little to the accuracy of risk prediction.[16]

NATURAL HISTORY OF CHRONIC KIDNEY DISEASE

Describing the natural history of CKD calls for a distinction between CKD detected in the general population (community CKD) and in those who are referred to nephrology centers (referred CKD).

Community CKD is to a large extent a disease of elderly individuals with comorbidities, associated with a reduced and very slow age-related decline in GFR, with the majority dying before reaching ESRD. In contrast, referred CKD patients often have significant acquired or inherited nephropathies causing early renal functional impairment and progression with time to ESRD. The cause and natural history of these two populations is likely to be considerably different.

Causes and Natural History of Community Chronic Kidney Disease

In the developed world, the majority of community CKD is identified in older people. The average rate of decline of GFR in this population is approximately 0.75 to 1 ml/min/yr after the age of 40 to 50 years.[3] CKD affects those who have had a lifelong exposure to cardiovascular risk factors—hypertension and diabetes—that can also affect the kidneys. U.S. Medicare data demonstrate that 48% of patients with CKD have diabetes, 91% are hypertensive, and 46% have atherosclerotic heart disease. Given that more than one third of aging adults have systolic hypertension and about 20% have type 2 diabetes mellitus (T2DM), it is not surprising that up to 40% of such individuals have evidence of CKD. They also have a higher incidence of cardiovascular and atherosclerotic diseases. This has led to the formulation of prediction scores of incident community-based CKD, based on the presence of vascular risk factors such as hypertension and diabetes as well as peripheral vascular disease and heart failure—the SCORED model (Screening for Occult Renal Disease).[17]

In a large analysis of community-based CKD over 5 years, only 1% and 20% of patients with CKD G3 and G4 required RRT, whereas 24% and 45%, respectively, died, predominantly from CVD.[18] Thus death rather than progression to ESRD is the predominant outcome in elderly community-based CKD.[18]

Community CKD in emerging countries is often multifactorial because of communicable and noncommunicable disease affecting the kidneys. In these countries, in addition to the poverty that has an impact on CKD, individuals often develop infections that can cause CKD (see Chapters 53 to 58). They are also subject to increased globalization and westernization of lifestyle that predispose them to obesity, diabetes, hypertension, and CVD, which can lead to CKD. The renal risk is increased further by unfavorable environmental factors, including maternal deprivation and malnutrition, which relate to CKD in later life[19]; air and water pollution; exposure to heavy metals and agricultural pollution; and aristolochic acid (see Chapter 64) and other herbal toxins, in particular in China and Taiwan (see Chapter 78). Reports of epidemics of CKD have emanated from a number of regions of the world, including Central American countries such as Salvador, among agricultural workers in sugar cane and cotton plantations who are exposed to excessive heat resulting in chronic dehydration, hypokalemia, and premature death.[20] These effects may be compounded by exposure to pesticides and consumption of nonsteroidal anti-inflammatory drugs (NSAIDs).

Causes and Natural History of Referred Chronic Kidney Disease

In contrast to community CKD, the causes and natural history of referred CKD vary considerably. Patients with referred CKD often present at an earlier age because of an underlying hereditary nephropathy (such as autosomal dominant polycystic kidney disease [ADPKD]) or acquired nephropathy (such as glomerulonephritis [GN], diabetic nephropathy, or tubulointerstitial disease) causing progressive damage and loss of function. Some present early with signs of kidney damage such as moderate albuminuria or hematuria in the absence of impaired kidney function (CKD stages G1 and G2, A1 and A2). The prognosis of such patients in the absence of hypertension, overt proteinuria, and/or impaired renal function is generally good because they can remain within these stages for years without progressing to CKD stage G3 or higher. However, some go on to progress with time, thus justifying vigilance and regular follow-up.

The rate of progression of referred CKD varies according to the underlying nephropathy and between individual patients. Historically, the rate of decline in GFR of patients with diabetic nephropathy has been among the fastest, averaging around 10 ml/min/yr. Control of systemic hypertension, hyperglycemia, and other factors slows the rate of GFR decline (see Chapter 80). In nondiabetic nephropathies, the rate of progression of CKD is usually faster in patients with chronic proteinuric GN than in those with chronic interstitial nephritis and low-level proteinuria. It is slowest in those with hypertensive nephrosclerosis with good blood pressure (BP) control and minimal proteinuria. Patients with ADPKD and impaired renal function, CKD stage G3b and beyond, may also have a fast rate of progression compared with patients with other nephropathies.

It is generally assumed that the majority of patients with underlying nephropathies reaching CKD stages G3 to G5 progress relentlessly to ESRD, yet even in the referred population progression is variable, with a sizable percentage of patients either having stable kidney function or dying prematurely of CVD. A Canadian study showed the natural history of referred CKD stages G3 and G4 to be variable, reflecting the patient's risk factor profile.[21,22] Even some patients with CKD stage G5 remain stable for a number of years.

A straight-line relationship is often found between the reciprocal of serum creatinine (1/SCr) values or the eGFR and time (for methodologic aspects, refer to Chapter 80). However, this is not the rule because many patients have a nonlinear decline in renal function. Many patients have breakpoints in their progression slopes, suggesting acceleration or slowing down of the rate of progression of CKD, in particular because of intercurrent or superimposed acute kidney injury (AKI). However, the true significance of the association between AKI and CKD remains to be elucidated because there is co-localization of risk factors for both AKI and CKD.[23]

PREDICTORS OF PROGRESSIVE CHRONIC KIDNEY DISEASE

Prediction of CKD progression is essential in targeting therapeutic intervention and planning care. In older community-based CKD patients, a history or manifestations of CVD or even subclinical signs such as an increased carotid-intima thickness or cerebral microinfarcts have all been associated with incident as well as progressive CKD.[24]

In younger patients with referred CKD, progression is predictable by the degree of impaired kidney function at presentation, hypertension and its control, and the severity of proteinuria and albuminuria. One such model includes age, gender, eGFR, albuminuria, serum calcium, serum phosphate, serum bicarbonate, and serum albumin.[21] Models of CKD progression and its cardiovascular complications as well as those predicting all-cause mortality linked to CKD have been systematically reviewed and found to lack strong validation and usefulness justifying additional research.[25]

Whether novel biomarkers of CKD (circulatory or genetic) can improve prediction remains unclear, and impact studies of CKD prediction models have not been conducted.[25] Given the diverse complexity of the pathophysiologic processes underpinning progression, it is unlikely that a single biomarker will identify those at risk of progression with robust sensitivity and specificity.

CHRONIC KIDNEY DISEASE RISK FACTORS

Progression of age-related mostly community CKD tends to be slow and most likely affected by the severity of the underlying atherosclerotic vascular pathology (Box 79-1). In fact, some research has shown that the baseline severity of atherosclerosis, as estimated by the carotid intima-media thickness, correlates well with the severity of age-related decline in kidney function.

In referred CKD, once kidney function reaches stages G3 and above (eGFR <60 ml/min), progression is common and is influenced by a number of modifiable and nonmodifiable risk factors.

Nonmodifiable Chronic Kidney Disease Progression Risk Factors

Age (older age), gender (generally worse in males), and ethnicity (generally worse in non-Caucasian and ethnic minorities in the West: African Americans, Afro-Caribbean individuals, Hispanics, and Asians [South Asians and Pacific Asians]) all affect CKD progression.

Genetics

Genetic factors play an important role in CKD and its progression (discussed in Chapter 19). Genome-wide association studies (GWASs) have identified certain major histocompatibility complex (MHC) loci that affect the rate of CKD progression. Patients with monogenic conditions, such as ADPKD carrying the genotype PKD1, are thought to have a worse prognosis than others. Progression of CKD may also be influenced by polymorphisms of genes coding for putative mediators of renal scarring, including those coding for the renin-angiotensin-aldosterone system (RAAS).[26] Increasing interest has focused on the role of the myosin heavy chain MYH9 locus and the adjacent *APOL1* gene coding for apolipoprotein L1, on chromosome 22, in the development and progression of kidney disease in individuals of African descent (discussed in Chapter 19). Also, mutations affecting the structure and composition of podocytes (podocytopathies) have been identified in individuals affected by a range of conditions causing nephrotic syndrome in children and adults, with some linked to resistance to available therapies and progressive focal segmental glomerulosclerosis (FSGS). GWAS analysis also showed that single-nucleotide polymorphisms (SNPs) in the genes *TCF7L2* and *MTHFS* are associated with diabetic kidney disease and CKD progression in population-based cohorts.[26] Also, increasing attention is being paid to mutations of the uromodulin (Tamm-Horsfall protein) gene *(UMOD)* and its link to hypertension, hyperuricemia, tubulointerstitial fibrosis, and the progression of CKD.[27,28] Finally, epigenetic modifications may also be involved in the expression and progression of CKD.

Risk Factors Associated with Chronic Kidney Disease

- Age (older)
- Race or ethnicity (non-Caucasian)
- Genetics
- Birth weight (low)
- Systemic hypertension
- Diabetes mellitus
- Cardiovascular disease
- Albuminuria
- Obesity or metabolic syndrome
- Dyslipidemia
- Hyperuricemia
- Smoking
- Low socioeconomic status
- Nephrotoxin exposure: nonsteroidal anti-inflammatory drugs (NSAIDs), analgesics, traditional herbal use, heavy metals (such as lead)

Box 79-1 Risk factors associated with chronic kidney disease (CKD).

Modifiable Chronic Kidney Disease Progression Risk Factors

Modifiable risk factors for CKD progression include systemic hypertension, proteinuria, and metabolic factors.[29] In addition, interest has focused on the contribution of cigarette smoking, alcohol consumption, herbal agents, and recreational drug use to the risk for development of ESRD (see also Chapters 78 and 80).

Hypertension

Systemic hypertension is an important cause, consequence, and presenting feature of CKD (see Chapter 80) (Fig. 79-3). It is one of the leading causes of ESRD worldwide, the second leading cause in the United States after diabetes. Some experimental and epidemiologic studies have shown that sustained hypertension is indeed a significant contributor to the progression of CKD. Strong evidence

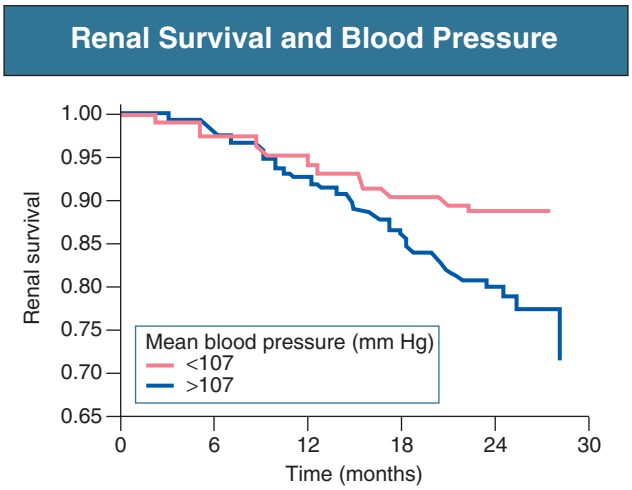

Figure 79-3 Actuarial renal survival in relation to blood pressure. *(Modified from reference 65.)*

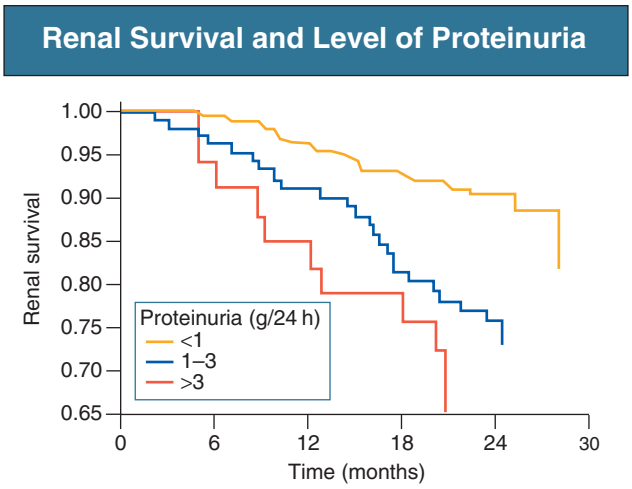

Figure 79-4 Actuarial renal survival in relation to proteinuria. *(Modified from reference 65.)*

links the progression of CKD to systemic hypertension in diabetic and nondiabetic kidney disease.[1] It is believed that the transmission of systemic hypertension into the glomerular capillary beds and the resulting glomerular hypertension contribute to the progression of glomerulosclerosis.[30]

Blood pressure parameters that correlate with the rate of progression of CKD include casual or office BP measurements, daytime versus nighttime BP, and 24-hour ambulatory BP measurement (ABPM). Nighttime and 24-hour ABPM seem to correlate best with CKD progression. Systolic BP (SBP) is also more predictive of CKD progression than diastolic BP and has also been linked to CKD complications. However, a U-shaped curve of SBP has also been reported with SBP values below 110 mm Hg, associated with faster rates of decline in eGFR.[31,32]

Target BPs in CKD patients are discussed in Chapter 80. It is most likely that target BP levels have to be individualized, with age, level of proteinuria, and comorbidities taken into consideration when patients with CKD are being treated, as suggested by the KDIGO CKD and management of blood pressure guidelines of 2012.[32]

Proteinuria

Numerous studies in patients with diabetic and nondiabetic renal diseases confirm that marked proteinuria (or albuminuria A3) is associated with a faster rate of CKD progression (Fig. 79-4).[33] Furthermore, reduction of marked proteinuria by diet or RAS blockade is often associated with a better renal outcome (see also Chapter 80); the extent of reduction in proteinuria is often, but not always, proportional to the benefit accrued by such intervention on CKD progression. A threshold of 1 g/day predicts progression in most kidney diseases but may be higher in certain glomerular diseases (such as membranous nephropathy).

Albuminuria or proteinuria is more likely to be a marker than a cause of progressive CKD because it reflects the severity of the underlying kidney damage. Interventions aimed at modifying the level of proteinuria, although mostly beneficial with regard to CKD progression, have been dissociated from the rate of decline in kidney function in some large interventional studies (e.g., Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension [ACCOMPLISH],[34] Ongoing Telmisartan Alone and in Combination with Ramipril Global End Point Trial [ONTARGET],[35] Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints [ALTITUDE][36]), in which significant declines in GFR were noted in spite of marked reduction in albuminuria. Consequently, moderate-level albuminuria (A2) is not a reliable surrogate marker for CKD progression in intervention clinical trials because reduction of albuminuria can be linked to both improving and worsening of CKD progression.

Renin-Angiotensin-Aldosterone System

The links between systemic hypertension, proteinuria and albuminuria, and CVD may be mediated by changes in the RAS in CKD. Experimental and clinical studies have implicated the RAS in the pathogenesis of hypertension, proteinuria, and renal fibrosis throughout the course of CKD. Consequently, interventions aimed at inhibition of the RAAS have proved effective in slowing the progression of CKD (see also Chapter 80). This has led to the almost universal treatment of patients with proteinuric and/or diabetic CKD with inhibitors of the RAAS.

Some uncertainty remains regarding whether the nephroprotective effect of renin-angiotensin system (RAS) inhibitors is completely dissociated from their antihypertensive effect.[37] Blood pressure has seldom been accurately measured, beyond casual office readings, in trials of RAS inhibition and CKD progression to dispel this assumption. In addition, GFR has once been measured accurately in randomized controlled trials (RCTs) of RAS inhibition and CKD progression; the sole exception is a small subgroup analysis of the Ramipril Efficacy in Nephropathy (REIN) study.[38]

Of interest, an analysis of progression of diabetic kidney disease in T1DM over the last 20 years, since the introduction of RAS inhibition, failed to show a significant impact of interventions on the rising trend of ESRD caused by diabetic nephropathy in the United States.[39] In older patients with T2DM, some studies have shown a detrimental impact of RAS blockade on the progression of CKD.[40,41] Finally, some preliminary observations suggest that the discontinuation of RAS inhibitors in advanced CKD may reverse functional decline to ESRD and lead to some functional recovery and delay in the initiation of RRT in selected patients.[42]

Regarding dual RAS blockade, the ONTARGET study proved such combination to be detrimental to renal function despite a reduction in proteinuria.[35] Dual blockade with renin antagonists failed in the ALTITUDE study, combining an ACE inhibitor and aliskiren (a renin antagonist) to slow progression of diabetic nephropathy, had to be stopped due to increased mortality; this in spite of a reduction in proteinuria.[36] There is consensus that RAS

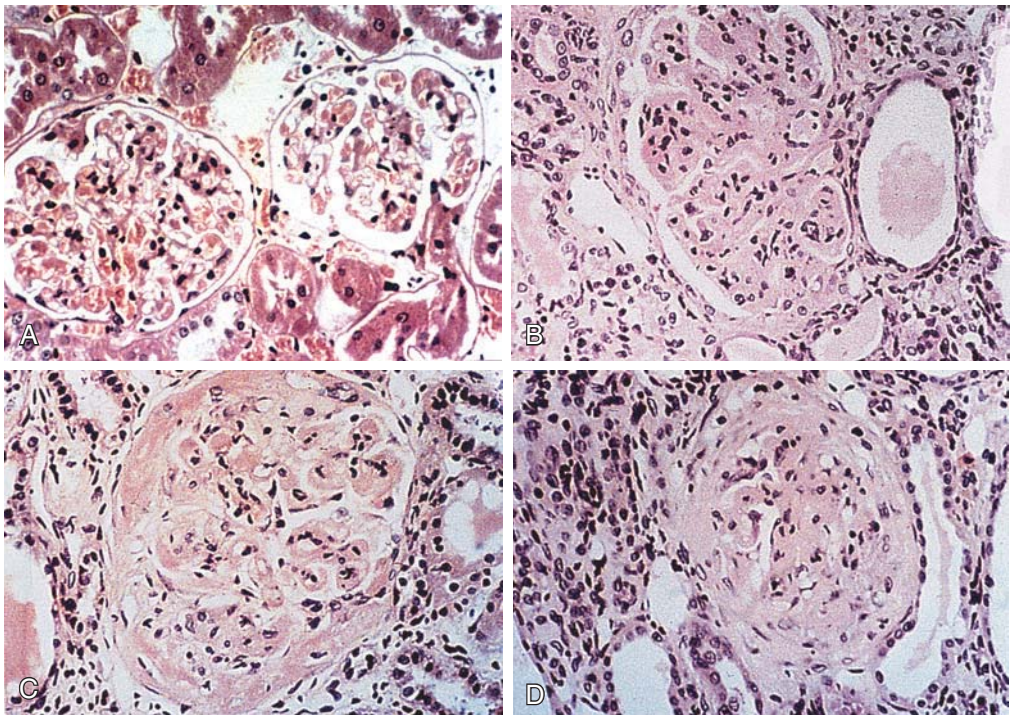

Figure 79-5 Histologic development of glomerulosclerosis. A, Normal glomerulus. **B,** Mesangial hypercellularity. **C** and **D,** Glomerulosclerosis of increasing severity. Note the tubular atrophy and dilation in **B** to **D,** indicating the parallel development of tubulointerstitial scarring.

inhibition is beneficial in hypertensive and proteinuric nephropathies,[32] but its use should be carefully monitored and caution exerted when prescribed in the elderly and those with underlying atherosclerotic disease. Combination therapy should be avoided in diabetic and high-risk individuals.

Additional Factors Implicated in Chronic Kidney Disease Progression

Obesity and smoking have been linked to the development and progression of CKD. Metabolic factors, including the metabolic syndrome and some of its components, such as insulin resistance, dyslipidemia,[43] and hyperuricemia,[44] have been implicated in the development and progression of CKD. In addition, high alcohol intake; use of recreational drugs, herbal agents and remedies, analgesics (paracetamol, phenacetin, and combinations of phenacetin, aspirin, and caffeine), and NSAIDs; and chronic exposure to lead and other heavy metals have all been linked to the development of CKD. The impact of glycemia control on the progression of diabetic nephropathy is discussed in Chapter 31.

MECHANISMS OF PROGRESSION OF CHRONIC KIDNEY DISEASE

Management of CKD is aimed at slowing progression, minimizing complications, and controlling modifiable progression factors such as hypertension, proteinuria, and RAS stimulation. In addition, a better understanding of the pathophysiology of CKD may open the way to treatments based on correction of key mediators of renal scarring and fibrosis.[45,46]

Unlike transient AKI, which often heals and after which the kidney functionally recovers, chronic and sustained insults to the kidney, such as those characterizing chronic and progressive nephropathies, evolve to progressive kidney fibrosis with destruction of the normal microarchitecture of the kidney and its replacement by fibrous tissue made of collagenous extracellular matrix, leading to loss of function and CKD and ESRD. This affects all three functional compartments of the kidney, namely the glomeruli, the tubules, and the interstitium, as well as the vessels and manifests histologically as glomerulosclerosis, tubulointerstitial fibrosis, and vascular sclerosis (Figs. 79-5 through 79-8).

Kidney scarring or fibrosis is a complex, overlapping, multistage phenomenon that could be characterized by a number of processes:

- An inflammatory response with infiltration of damaged kidneys by extrinsic inflammatory cells (blood borne and bone marrow derived)
- Activation, proliferation, and loss of intrinsic renal cells (through apoptosis or necrosis and including mesangiolysis and podocytopenia)
- Activation and proliferation of extracellular matrix (ECM)–producing cells, including myofibroblasts and fibroblasts
- Deposition of ECM replacing the normal renal architecture

Inflammatory Response to Tissue Injury

Inflammatory cells play an important role in both the renal healing and the scarring processes.[47,48] The outcome of initial renal damage depends on the balance between healing and scarring, thus determining whether kidney function recovers or declines.

The severity of the renal inflammatory cellular infiltrate correlates closely with the severity of renal dysfunction and predicts progressive CKD. Nonresolving tissue injury invariably initiates an inflammatory response with further recruitment of neutrophils, lymphocytes, monocytes and macrophages, dendritic cells, and masts cells to injured tissue, perpetuating a cycle of ongoing inflammation, tissue damage, and fibrosis.[47,48]

Neutrophils, platelets, eosinophils, and mast cells have, through their release of products, also been implicated in the pathogenesis of acute and chronic renal inflammation and fibrosis. But for the most part, a marked lymphomonocytic renal interstitial infiltrate is often the hallmark of progressive CKD.

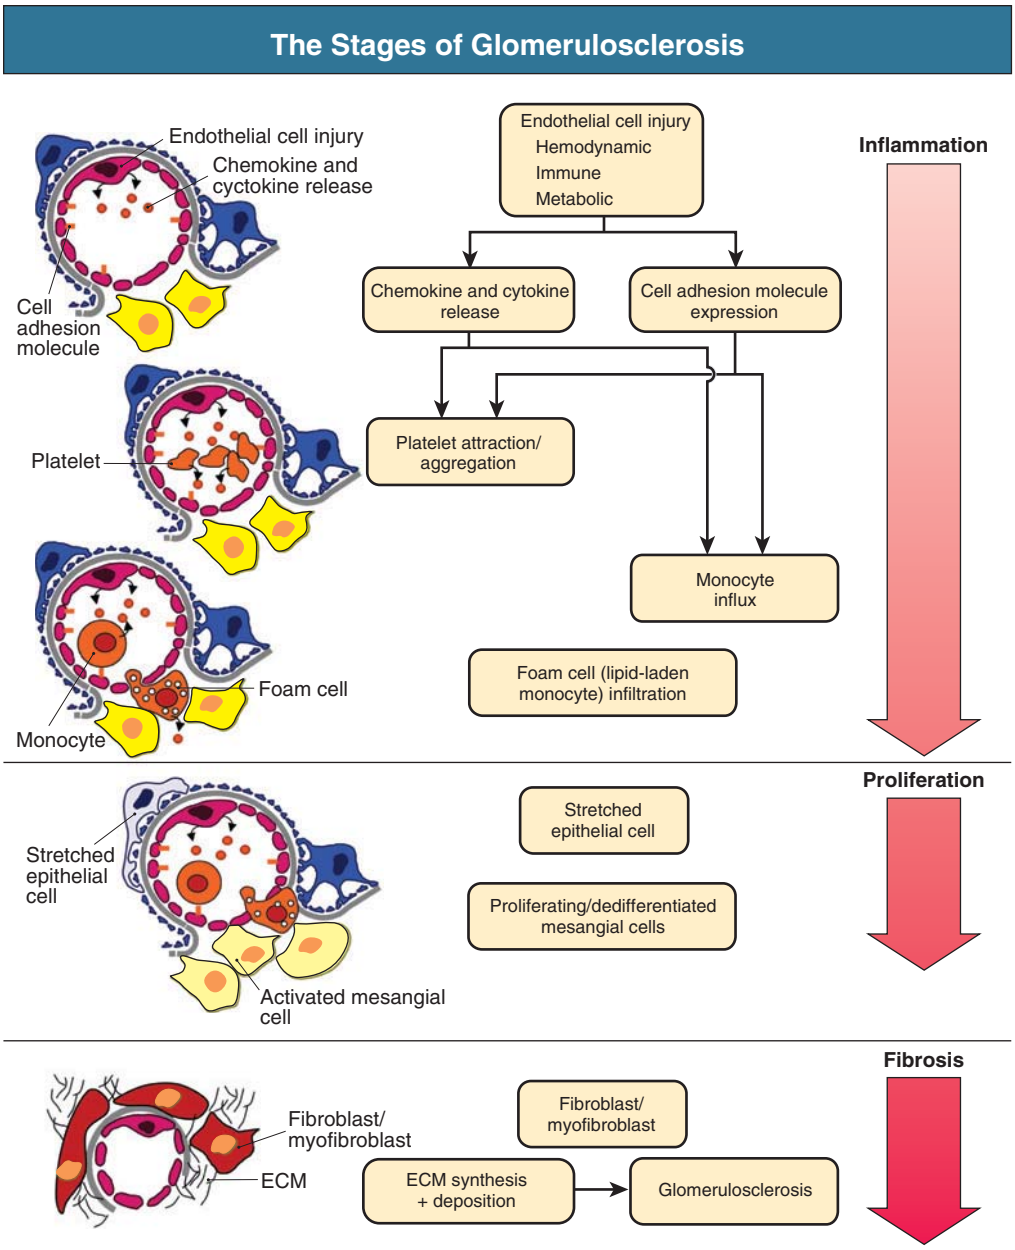

Figure 79-6 The stages of glomerulosclerosis. *ECM,* Extracellular matrix.

Lymphocytes

Lymphocytes, including helper and cytotoxic T cells, are often identified within damaged kidneys. It has been postulated that the balance between the proinflammatory T helper 1 (Th1) and the anti-inflammatory T helper 2 (Th2) lymphocytes may be a key factor in the progression or resolution of renal scarring.[49] This may also depend on the profile of the cytokines released by the T cells, with some—such as interleukin (IL)-1 and IL-2 and tumor necrosis factor α (TNF-α)—having proinflammatory and proliferative properties, and others—IL-4, IL-10, IL-13, and IL-25—having anti-inflammatory and antifibrotic properties. T lymphocytes may be directly cytotoxic but may also activate or attenuate the effector response of other inflammatory cells including monocytes.[49] Evidence also implicates $CD4^+$ T cells in fibrogenesis, either directly through stimulation of myofibroblast and fibroblast proliferation and ECM production or indirectly through activation of macrophages. Another subset of T cells (T regulatory cells [Tregs]) may exert beneficial effects on renal inflammation and fibrosis by switching off the proinflammatory effect of activated macrophages.

Monocytes

Monocytes play an important role in renal healing as well as scarring processes because they evolve into tissue macrophages on infiltration of the damaged kidney.[49,50] It is now clear that when circulating monocytes are recruited to damaged kidneys, they differentiate into two broad macrophage phenotypes. Classically activated (M1) macrophages have a proinflammatory, cytotoxic phenotype, whereas alternatively activated (M2; a to c) macrophages display a wound-healing phenotype that is likely to be the dominant form in response to chronic injury.[50] Macrophages appear to switch phenotype in response to their microenvironment. The release by these cells of cytokines, growth factors, reactive oxygen species (ROSs), and procoagulant factors is likely to contribute to the pathogenesis of glomerulosclerosis and tubulointerstitial fibrosis.

A protective role for macrophages in renal healing is now recognized; these cells also contribute to the termination and resolution of the renal inflammatory response, thus preventing fibrosis. Research based on the depletion of M1 macrophages in a range of experimental models of renal inflammation and fibrosis showed a

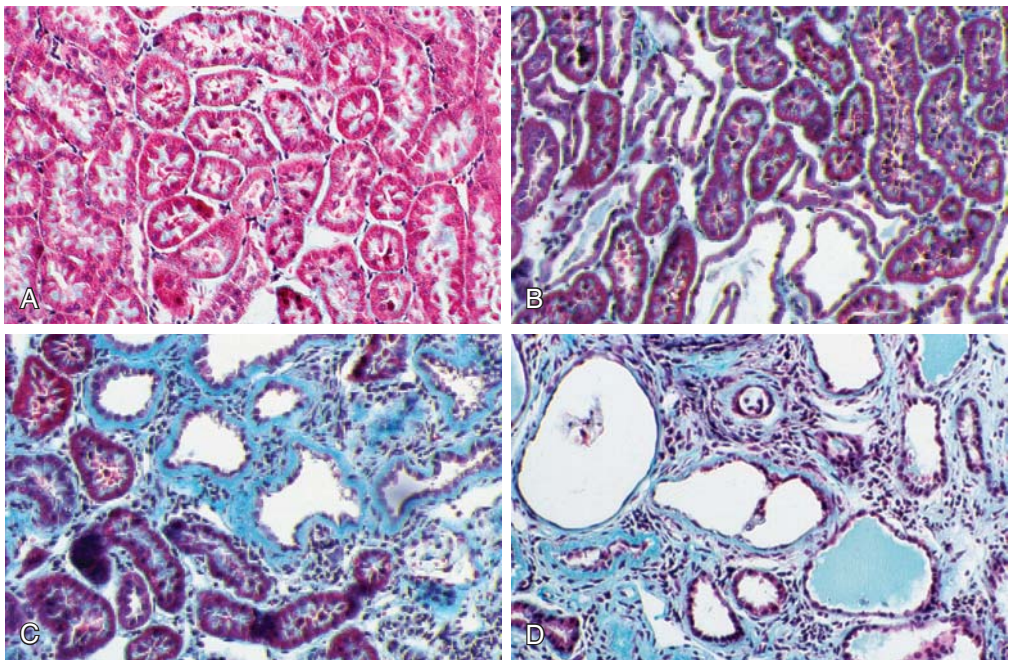

Figure 79-7 Histologic development of tubulointerstitial fibrosis. A, Normal tubulointerstitium. **B,** Mild tubulointerstitial scarring with tubular atrophy and interstitial edema. **C,** Segmental interstitial fibrosis. **D,** Diffuse interstitial fibrosis with tubular atrophy and dilation.

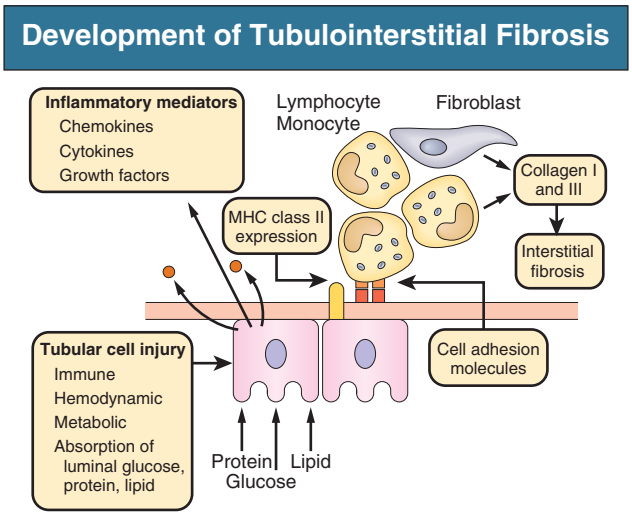

Figure 79-8 Development of tubulointerstitial fibrosis. *MHC,* Major histocompatibility complex.

protective effect. Similarly, the stimulation of M2 macrophages and/or their administration attenuates renal inflammation and subsequent fibrosis.[49,50] Thus, organ-specific and disease phase–specific microenvironments as well as the balance of phenotypic and functional macrophage changes may determine whether there is resolution of inflammation or progression to fibrosis. Macrophages are also capable of stimulating fibrogenesis either directly through their conversion to fibrocytes or the activation of myofibroblasts or indirectly through the stimulation of the transformation of pericytes to myofibroblasts.[51]

Dendritic Cells

Dendritic cells (DCs), a subset of cells that play an essential role in immunopathology of the kidney and the crosstalk with other proinflammatory cells, including T lymphocytes, also have a central role in the pathogenesis of kidney inflammation in different disease processes.[52,53] Immature DCs (iDCs) receive activation signals from injured kidney cells and acquire a mature phenotype that allows their migration into lymph nodes. These mature DCs (mDCs) are highly stimulatory (sDCs) and induce a range of effector responses through interactions with other tissue inflammatory cells.

As with lymphocytes and macrophages, dendritic cells play a role in the resolution of injury through assumption of protective phenotypes, such as tolerogenic dendritic cells (tDCs) and exhausted dendritic cells (exDCs). In fact, injection of activated plasmacytoid dendritic cells in an experimental model of renal fibrosis led to a switching off of the inflammatory response and reduction of fibrosis.

Bone Marrow–Derived Cells

Glomerular remodeling (repair-healing or scarring) may depend on the influx of hematopoietic and mesenchymal stem cells (MSCs) with the potential for repair or scarring.[54] The detection of cells displaying embryonic mesenchymal characteristics in glomeruli has led to the hypothesis that hematopoietic stem cells may be involved in normal glomerular cell turnover as well as in the response of glomeruli to injury. Experiments based on bone marrow transplantation have demonstrated the potential involvement of bone marrow–derived cells in normal mesangium turnover and in glomerular repair-repopulation after experimental mesangial injury. Also, interstitial and medullary renal progenitor cells may be called on after an acute injury to accelerate renal homeostasis and repair.

It has also been postulated that bone marrow–derived MSCs may be involved in fibrogenesis by migrating into scarred kidneys and contributing to the pool of fibroblasts. However, caution must be exerted before assumption of the therapeutic potential of these cells because some experiments have demonstrated their maldifferentiation, for example, into adipocytes within glomeruli. In humans, so far the safety of MSC therapy seems promising, but its efficacy remains to be established.

INTRINSIC RENAL CELL ACTIVATION, PROLIFERATION, AND LOSS

The secretion of profibrotic cytokines in an inflamed kidney leads to the activation of matrix-producing cells in the glomeruli and the tubulointerstitial space. These mediators are released by both infiltrating as well as resident cells. They include autacoids such as angiotensin II, endothelin, nitric oxide, and prostanoids, as well as growth factors such as transforming growth factor β1 (TGF-β1),[55] connective tissue growth factor (CTGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and epidermal growth factor (EGF).[47,48] These factors promote fibrosis by activating a variety of intracellular signaling cascades with consequent multiple effects on cellular activation, transformation, proliferation, migration, and ECM synthesis. Many of these mediators are potential targets for antifibrotic therapy. Of note, the progression of renal scaring and the associated fibrosis depend on the balance between these potentially harmful mediators and some protective ones such as lipoxins, resolvin, and relaxin,[56] as well as growth factors such as hepatocyte growth factor (HGF), and bone morphogenic protein 7 (BMP-7).

Glomerular Cells

Endothelial Cells

Glomerular endothelial damage can be triggered by an acute inflammatory process but also by a metabolic insult, as in diabetes, or hemodynamic shear stress, as in hypertension. The endothelial capillary lining normally displays protective anticoagulant, anti-inflammatory, and antiproliferative functions. Damage to the glomerular endothelium transforms this protective cellular layer to a proaggregatory, proinflammatory, and mitogenic surface, leading to the accumulation of the inflammatory cells discussed earlier as well as platelets within the glomerular capillaries.[57] This leads to the stimulation and proliferation of the mesangial cells. This process bears strong similarities to atherosclerosis with microthrombus formation, infiltration of the glomerular tufts by macrophages and foam cells, and proliferation of the smooth muscle cell equivalent, the mesangial cell.

Mesangial Cells

The mesangial cell is the glomerular capillary equivalent of the smooth muscle cell and provides structural support for the glomerulus, tightly regulates ECM turnover, and interacts closely with endothelial cells and podocytes. Glomerular myofibroblasts arise from mesangial cells and promote ECM accumulation in glomerulosclerosis. Dedifferentiation of mesangial cells into an embryonic mesenchymal (i.e., myofibroblastic) phenotype with the acquisition of stress fibers and α-smooth muscle actin (αSMA) allows these cells to proliferate, to migrate, and to restore the glomerular structural integrity with the laying down of collagenous ECM to seal the wound and to repair structural damage. Chronic injury will, however, lead to aberrant mesangial cell hypertrophy, proliferation, and subsequent ECM accumulation, with the development of glomerulosclerotic lesions.[58]

Podocytes

Visceral glomerular epithelial cells or podocyte are terminally differentiated, specialized epithelial cells of mesenchymal origin that have little capacity to proliferate in response to injury. The interdigitating foot processes of podocytes, maintained by microfilaments in the cytoplasm, are an integral part of the filtration barrier. Mutations in proteins within the foot process are commonly associated with nephrotic syndrome or the risk of developing FSGS (see Chapter 19). Experimental data indicate that podocyte loss of more than 40% leads to segmental sclerosis and progressive CKD. Thus there is now clear evidence that the podocyte is a target in a variety of progressive glomerular diseases, including diabetic nephropathy, most glomerulonephritides, and systemic diseases such as lupus nephritis.

In addition to disease-forming mutations, podocytes can be targeted by other insults such as circulating factors, which leads to reorganization of the actin cytoskeleton and foot process effacement. If the injury is severe or chronic, the podocyte detaches from the GBM because it has little capacity to replicate and as a result exposes areas of denuded GBM. This leads to sclerosis of glomerular capillaries and further interactions between the exposed GBM and parietal epithelial cells, leading to the formation of capsular adhesions and subsequent FSGS.[59] Capsular adhesions formed by contact between the GBM and the parietal epithelial lining of the Bowman capsule may lead to misdirected filtration with the accumulation of amorphous material in the paraglomerular space and the subsequent disruption of the glomerulotubular junction, resulting in atubular glomeruli. Misdirected filtration may also contribute to tubular atrophy and interstitial fibrosis. Tuft-capsule adhesions may allow the influx of periglomerular fibroblasts into the glomerular tuft, thus contributing to glomerulosclerosis.

Tubular Cells and the Renal Interstitium

As with glomerular cells, injury to tubular cells is followed by an attempt at regeneration and repair. After an acute insult, some tubular cells die through necrosis or apoptosis. Apoptosis has been well documented during the course of experimental and clinical models of CKD. Surviving cells attempt to restore tubular integrity by dedifferentiation into an embryonic phenotype that allows them, through the acquisition of cytoplasmic αSMA and stress fibers, to proliferate, to migrate, and to repopulate acellular tubules. Healing and recovery of renal function ensue. On the other hand, repeated or sustained insult will lead to peritubular infiltration of inflammatory cells, activation of ECM-producing myofibroblasts, and possibly epithelial mesenchymal transformation (EMT) of tubular epithelial cells into myofibroblasts (see later). Loss of tubular epithelial cells as a result of both apoptosis and EMT leads to tubular atrophy and further decline in kidney function.

Myofibroblasts are the major driver of interstitial fibrosis and, in addition to expressing αSMA, also express other fibroblastic markers including vimentin and fibroblast-specific protein 1 (FSP1). They derive from a number of cellular sources (Fig. 79-9).[51] Most of the myofibroblast pool probably arises as a result of activation and proliferation of interstitial fibroblasts by growth factors and cytokines such as PDGF, TGF-β1, CTGF, basic FGF, and tissue-type plasminogen activator. However, there are several other important sources of interstitial myofibroblasts.

It was originally thought that EMT of tubular epithelial cells with subsequent migration across the tubular basement membrane makes a significant contribution to myofibroblast number. More recent evidence suggests that some myofibroblasts may arise as a result of endothelial-to-mesenchymal transition (EndMT) which has been elegantly demonstrated by coexpression of endothelial and fibroblast markers in murine models of kidney fibrosis. Another source of myofibroblasts may be bone marrow–derived, blood-borne cells known as *fibrocytes* (bone marrow–derived MSCs) that can migrate from the circulation into the scarred tubulointerstitium. The detection these cells in glomeruli has led to the hypothesis that hematopoietic stem cells may be involved in normal glomerular cell

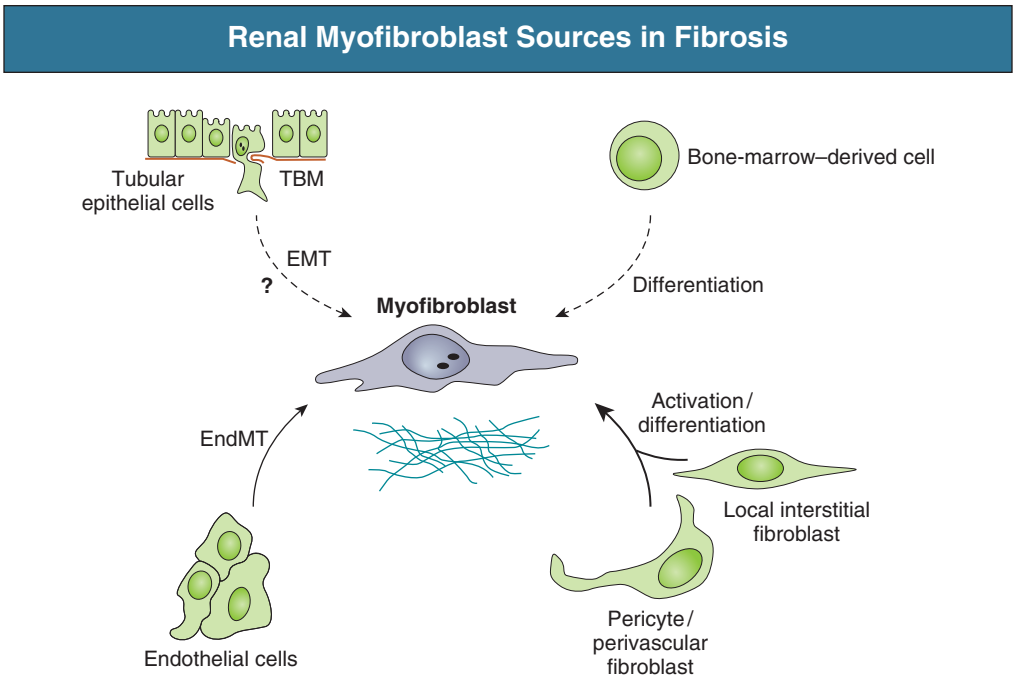

Figure 79-9 Renal myofibroblast sources in fibrosis. *EMT,* Epithelial mesenchymal transformation; *EndMT,* endothelial mesenchymal transformation; *TBM,* tubular basement membrane. *(Modified from reference 50.)*

turnover as well as in glomerular remodeling in response to injury. Finally, there is growing interest in the perivascular pericyte, which is an αSMA-negative, PDGF receptor–positive stromal cell that interacts closely with peritubular capillaries and thereby helps maintain endothelial integrity. Genetic fate mapping studies have suggested that pericytes are a source of the interstitial myofibroblast pool and not EMT,[51] but even the role of pericytes has become controversial very recently.

Vascular Cells

Vascular sclerosis is an integral feature of the renal scarring process. Renal arteriolar hyalinosis is present in CKD at an early stage, even in the absence of severe hypertension. Furthermore, these vascular changes are often out of proportion to the severity of systemic hypertension. Vascular sclerosis is associated with progressive CKD in GN. Hyalinosis of afferent arterioles has been implicated in the pathogenesis of diabetic glomerulosclerosis. Changes in postglomerular arterioles and damage to peritubular capillaries may further exacerbate interstitial ischemia and fibrosis.[50] Ischemia and the ensuing hypoxia are fibrogenic influences that stimulate tubular cells and kidney fibroblasts to produce ECM components and to reduce their collagenolytic activity.[61]

Loss of peritubular capillaries with the associated impaired angiogenesis has been linked in experimental models of renal scarring to a fall in the renal expression of the proangiogenic vascular endothelial growth factor (VEGF). Together with an overexpression by scarred kidneys of thrombospondin, an antiangiogenic factor, this would perpetuate microvascular deletion and ischemia.

Recent evidence also points to lymphatic neoangiogenesis in association with interstitial inflammation and progressive renal fibrosis.[62] Such a process appears to be driven by macrophages that express the lymphangiotropic growth factor VEGF-C. It may play a role in interstitial remodeling because it provides an exit route for inflammatory cells involved in interstitial inflammation.

EXTRACELLULAR MATRIX ACCUMULATION

Accumulation of abnormal ECM laid down by activated myofibroblasts is the final step in renal fibrogenesis. The ECM is composed of a number of proteins, including various collagens, elastin, laminin, fibronectin, and glycoproteins. The ECM is not inert but in a constant state of flux, modulating cell migration, proliferation, and survival. Therefore ECM accumulation not only results in replacement of normal kidney tissue with matrix but also promotes loss of resident renal cells as a result of downregulation of integrin-mediated survival signals from normal matrix.

Fibrogenic cytokines, discussed earlier, stimulate a host of intracellular signaling cascades that ultimately upregulate the transcription of matrix proteins such as collagen and fibronectin. Thus there is both a qualitative and a quantitative change in the nature of deposited ECM, with tubulointerstitial fibrosis being associated with excessive deposition of collagens I, III, and IV, whereas type III collagen predominates in glomerulosclerosis.

Ultimately, ECM accumulation reflects the balance between synthesis from myofibroblasts and degradation by collagenolytic enzymes such as matrix metalloproteinases (MMPs) and plasmin. MMPs are further regulated by tissue inhibitors of matrix metalloproteinases (TIMPs), and plasmin can both directly degrade matrix proteins and indirectly activate MMPs. Plasmin itself is generated as a result of the cleavage of plasminogen by urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA), both of which are inhibited by protease plasminogen activator inhibitor 1 (PAI-1). Cytokines such as TGF-β1 can further drive ECM accumulation by (1) decreasing matrix degradation by inhibiting proteases as well as activating protease inhibitors (e.g., PAI-1), and (2) promoting cell matrix interactions by upregulating integrin expression.[63]

Recent evidence points to another putative pathway to excessive deposition of ECM, namely, resistance to breakdown through structural modification and cross-linking of deposited ECM by an enzyme

called tissue transglutaminase.[64] This enzyme is upregulated during the course of experimental and clinical nephropathies. Mice lacking this enzyme have a reduced propensity for renal scarring. Synthetic inhibitors of this enzyme have been shown to considerably attenuate experimental renal fibrosis.

The process by which renal scarring and fibrosis cause progressive CKD is intricate, involving interactions between invading and resident renal cells with transformation, proliferation, and ECM production culminating in renal fibrosis, loss of function, and ESRD. A better understanding of CKD natural history and the underlying mechanisms of renal scarring has suggested a number of current therapies and will undoubtedly open the way to new strategies and therapies aimed at prevention and slowing of the progression of CKD (Table 79-4).

Mediators of Chronic Kidney Disease and Interventions

Target	Intervention	Mechanism of Action	Evidence Level
Transforming growth factor β1 (TGF-β1)	Administration of bone morphogenetic protein 7 (BMP-7)	Inhibitor of the TGF-β1–Smad signaling pathway	Experimental models of kidney disease Clinical development limited by bone formation at injection site Orally active mimetics in development
	Administration of hepatocyte growth factor (HGF)	Inhibits nuclear translocation of receptor-regulated Smads and upregulates the expression of Smad co-repressors	Experimental models of kidney disease and trials in promoting angiogenesis
	Inhibition of connective tissue growth factor (CTGF)	Mediator of TGF-β1–induced fibrosis	Experimental kidney disease and early clinical studies in diabetic nephropathy
	TGF-β antibodies	Inhibits TGF-β1 signaling pathway	Fresolimumab in Phase I study in FSGS Other TGF-β antibodies have resulted in adverse events in systemic sclerosis
	Serine-threonine kinase receptor and small molecule inhibitors	Inhibits TGF-β1 Smad signaling pathway by targeting activin receptor–like kinase 5	Experimental models of fibrosis
	Tranilast	Inhibits TGF-β1–induced ECM synthesis	Experimental models of kidney disease Early clinical data in diabetic nephropathy and used in the treatment of hypertrophic scars and scleroderma
	Decorin	Sequesters TGF-β1 in the extracellular matrix	Experimental models of kidney disease
Proliferative mitogens	Anti–platelet derived growth factor (PDGF)—for example, PDGF aptamers, imatinib mesylate, CR002, trapidil	Imatinib mesylate, kinase inhibitor of PDGF transduction CR002, monoclonal antibody targeting PDGF-D	Experimental data indicates potential of CR002 in mesangioproliferative disease—Phase I trial completed Cardiotoxicity limits use of imatinib mesylate in clinical use in oncology and beneficial effects in experimental models of kidney disease
	Anti-epidermal growth factor (EGF)	Inhibition of renal fibroblast proliferation and collagen expression	Experimental models of kidney disease
Intracellular transduction cascade	Ras-Raf-Mek-Erk pathway inhibition by Ras: prenyltransferase inhibitors, farnesylthiosalicylic acid (FTS), Raf and Mek kinase inhibitors	Inhibition of cellular proliferation, differentiation, and apoptosis	Experimental model and Phase II clinical trial in cancer treatment
	Rho kinase inhibition: fasudil	Interference with cell proliferation, tubulointerstitial fibrosis, and glomerular hemodynamics	Experimental models of kidney disease and in coronary heart disease Fasudil in clinical use in Japan for cerebral vasospasm
	p38 Mitogen-activated protein kinase inhibitors	Inhibition of proinflammatory and profibrotic mediators	Experimental models and clinical trials in rheumatoid arthritis and type 1 diabetes mellitus
	Protein kinase C inhibitors such as ruboxistaurin	Inhibition of cell growth most evident in diabetic nephropathy	Experimental models Early clinical data with ruboxistaurin in patients with early diabetic nephropathy In development in diabetic retinopathy
	Vasopressin 2 receptor antagonist	Inhibition of cAMP-mediated tubulogenesis and cell proliferation	TEMPO study revealed promising effects of tolvaptan on kidney function and cyst size in polycystic kidney disease (PKD)
Cell cycle inhibitors	Cyclin-dependent kinase inhibitors such as roscovitine	Inhibition of cell cycle progression	Experimental models including polycystic kidney disease and Phase II trials in cancer

Table 79-4 Mediators of CKD and interventions. *cAMP,* cyclic adenosine monophosphate; *ECM,* extracellular matrix, as in chapter body; *EMT,* epithelial mesenchymal transformation; *EPO,* erythropoietin; *Erk,* extracellular–signal-regulated kinase; *FSGS,* focal segmental glomerulosclerosis; *HIF,* hypoxia-inducible factor; *mTOR,* mammalian target of rapamycin; *Nrf2,* nuclear 1 factor (erythroid-derived 2)-related factor 2; *Raf,* rapidly accelerated fibrosarcoma; *Ras;* renin-angiotensin system; *TEMPO,* Tolvaptan Efficacy and Safety in Management of Autosomal Dominant Polycystic Kidney Disease and Its Outcomes; *VEGF,* vascular endothelial growth factor.

Mediators of Chronic Kidney Disease and Interventions			
Target	**Intervention**	**Mechanism of Action**	**Evidence Level**
Immunosuppressants	mTOR inhibitors	Interference with cell proliferation by regulation of ribosomal biogenesis and protein translation	Experimental models variable but can induce proteinuria Everolimus shown to reduce cyst size in PKD but no effect on kidney function Licensed for treatment of angiomyolipomas
Other agents	Pentoxifylline	Phosphodiesterase inhibitor interfering with cell proliferation and EMT	Experimental models of CKD Ongoing clinical trials assessing role in proteinuric CKD with some reduction of proteinuria in Phase II studies
	Endothelin antagonists	Reduce cellular proliferation and intraglomerular hypertension, inflammation, and podocyte dysfunction	Experimental models Ongoing clinical trials in diabetic nephropathy Reduction in blood pressure and proteinuria but risk of fluid retention
	Pirfenidone	Inhibits ECM accumulation	Experimental models of CKD Phase II data in diabetic nephropathy and FSGS Licensed in pulmonary fibrosis
	Peroxisome proliferator-activated receptor gamma agonists	Reduce cell growth, inflammation Antiproteinuric effect	Experimental and clinical data Reduce proteinuria in diabetic nephropathy Ongoing clinical trials in diabetic and nondiabetic CKD
	Prolyl hydroxylase domain (PHD) inhibitors	Upregulation of HIF-regulated genes such as VEGF and EPO	Experimental models Phase II and III clinical trials under way for the treatment of anemia
	Bardoxolone	Antioxidant and anti-inflammatory effects through induction of Nrf2 antioxidant response pathway	Phase III trial terminated because of drug toxicity—improvements in creatinine and estimated glomerular filtration rate (eGFR) caused by weight loss rather than intrinsic effect on kidney function Highlights the importance of measuring GFR when evaluating new therapies
	N-acetylcysteine	Anti-inflammatory	Phase II studies under way in diabetic nephropathy
	Vitamin D	Multifunctional	Phase II studies showing reduction of albuminuria
	Allopurinol	Lowers uric acid	Pilot studies show slowing of eGFR in CKD with asymptomatic hyperuricemia

CHAPTER 80

Retarding Progression of Kidney Disease

Samir V. Parikh, Nabil J. Haddad, and Lee A. Hebert

Progression to end-stage renal disease (ESRD) usually occurs because of activity of the primary kidney disease and the mechanisms of natural progression (see Chapter 79). In those older than 40 years of age, the nephropathy of aging can also contribute to progression. Its pathogenesis is unclear; however, the nephropathy of aging appears to be categorically different from that of natural progression because, unlike natural progression, the nephropathy of aging proceeds without important increases in proteinuria (see Chapter 67). Whether therapy can slow the nephropathy of aging is unclear. However, natural progression is treatable. This chapter focuses on its treatments.

Natural progression creates a vicious cycle that is approached when nephron loss leads to hyperperfusion of the surviving glomeruli and to the metabolic dysfunctions of decreased glomerular filtration rate (GFR). The vicious cycle is entered when the hyperperfusion and metabolic dysfunctions are sufficient to inflict kidney injury. At this point, nephron loss begets more nephron loss. Described herein are evidence-based therapies to prevent entry into the vicious cycle or to slow the cycle once it has been entered.

LEVEL OF GLOMERULAR FILTRATION RATE AND THE RISK OF NATURAL PROGRESSION

Typically, natural progression does not proceed until nephron loss exceeds 50%.[1,2] For example, unilateral nephrectomy as occurs in living kidney donors does not usually lead to natural progression.[1,2] However, a normal solitary kidney is vulnerable to natural progression if the condition is congenital or acquired early in life[3] or if it is associated with obesity, hypertension, hyperlipidemia, or hyperglycemia. Low birth weight, particularly in males, may lead to ESRD in adulthood, by natural progression, presumably because of defective nephron development.[2]

PROTEINURIA MAGNITUDE AND THE RISK OF NATURAL PROGRESSION

Proteinuria-induced glomerular and renal tubular injury is a key mechanism of natural progression (see Chapter 79). The threshold for natural progression attributable to proteinuria appears to be crossed when proteinuria exceeds 500 mg/day.[2] Proteinuria magnitude is the strongest single risk factor in chronic kidney disease (CKD) progression (Fig. 80-1).[1] An exception is highly selective proteinuria (the urine protein is almost entirely albumin), which can persist in the nephrotic range for more than 10 years without causing renal structural damage.[2]

DIAGNOSIS OF NATURAL PROGRESSION

Natural progression is a diagnosis of exclusion. Therefore, in the CKD patient showing signs of progression, it must first be determined whether the primary renal disease is active. If that can be reasonably excluded, it must then be determined whether another kidney disorder has been superimposed (see Chapter 71). The nephropathy of aging must also be excluded. This is relatively easy because it starts after 40 years of age, the decline in GFR is slow (about 1 ml/yr), and it generally does not involve important increases in proteinuria (see Chapter 67).[1] Findings that help confirm the diagnosis of natural progression are as follows:

- The serum creatinine (S_{Cr}) generally is above the expected level for the patient's age, sex, and race (Box 80-1). Natural progression is unlikely if the S_{Cr} is normal.
- Natural progression is usually indolent—for example, the increased S_{Cr} has been stable for at least several years before signs of progression occur.[4] An exception can occur when there are extraordinarily strong forces promoting natural progression, such as a very high salt intake, poorly controlled hypertension, or both.[4]
- Increase in proteinuria is usually the first sign of natural progression. Only after a year or more of rising proteinuria does the S_{Cr} begin to increase.[4]
- The urine sediment is unremarkable, although broad hyaline and granular casts may be present.

In summary, natural progression is seen mainly in those with increased S_{Cr}. Increasing proteinuria is the first sign of natural progression. Only after a prolonged period of increasing proteinuria does the S_{Cr} begin to increase. This pattern is also commonly seen in CKD patients whose condition is progressing because of activity of the glomerular disease. In contrast, certain forms of CKD can show substantial progression even though proteinuria is minimal (Box 80-2).

MONITORING KIDNEY DISEASE PROGRESSION

Progression can be monitored by structural changes—for example, with renal biopsy or renal ultrasound—or by functional changes—for example, change in GFR or proteinuria. Here we discuss the latter, which are the most practical and commonly used methods to monitor progression.

Monitoring Proteinuria Trends

Proteinuria is the strongest single predictor of GFR decline. Therapies that decrease proteinuria generally slow GFR decline (see Chapter 79).[1,5] The most widely used methods to assess proteinuria are measurement of urine albumin and urine total protein (see Chapter 4). The latter is the sum of urine albumin plus nonalbumin proteins. In the typical CKD patient the nonalbumin urine proteins consist mainly of low-molecular-weight proteins such as β_2-microglobulin. They escape reabsorption because of tubular damage (see Chapter 15). In this chapter, total proteinuria is referred to simply as *proteinuria*.

Relationship Between Baseline Proteinuria and Subsequent Glomerular Filtration Rate Decline

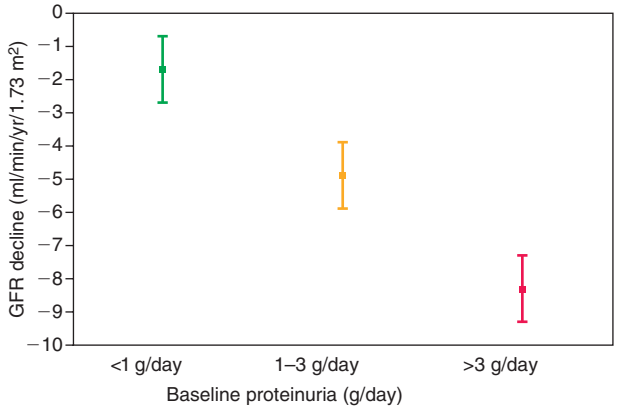

Figure 80-1 Relationship between baseline proteinuria and subsequent glomerular filtration rate (GFR) decline. *(Data from Study A of the Modification of Diet in Renal Disease study. Modified from reference 41.)*

Suggested Thresholds for Abnormal Serum Creatinine (S_{Cr})

- Large (e.g., >90 kg) nonobese men: S_{Cr} ≥1.30 mg/dl (1.40 mg/dl if African ancestry)
- Small (e.g., <60 kg) nonwasted men: S_{Cr} ≥1.10 mg/dl (1.20 mg/dl if African ancestry)
- Large (e.g., >70 kg) nonobese women: S_{Cr} ≥1.00 mg/dl (1.10 mg/dl if African ancestry)
- Small (e.g., <50 kg) nonobese women: S_{Cr} ≥0.80 mg/dl (0.90 mg/dl if African ancestry)

Box 80-1 Suggested thresholds for S_{Cr} according to body size, sex, and race. The estimates are based on experience with a clinical laboratory that reports a normal S_{Cr} range for men of 0.8 to 1.30 mg/dl, and for women of 0.60 to 1.10 mg/dl. The Modification of Diet in Renal Disease (MDRD) study estimated glomerular filtration rate (eGFR) that corresponds to each of the listed categories of S_{Cr} according to sex and race were calculated for persons aged 40 years. Each S_{Cr} value yielded an abnormal eGFR value (<90 ml/min/1.73 m²). For men the eGFR values ranged from 65 to 86 ml/min/1.73 m²; for women the eGFR values ranged from 65 to 79 ml/min/1.73 m². For persons older than 40 years, the corresponding eGFR values would be even lower.

Common Forms of Chronic Kidney Disease (CKD) in Which Important Progression Can Occur with Any Minimal Proteinuria

1. Early phase of diabetic nephropathy, type 1 or type 2 diabetes mellitus
2. Hypertensive nephrosclerosis in persons of African ancestry
3. Autosomal dominant polycystic kidney disease
4. Chronic NSAID (nonsteroidal anti-inflammatory drug) nephropathy
5. Obstructive uropathy
6. Nephropathy of aging

Box 80-2 Common forms of CKD in which important progression can occur with any minimal proteinuria. For example, S_{Cr} increases to above 2.0 mg/dl, but 24-hour protein urine is low—for example, albumin-creatinine ratio (ACR) below 0.2, protein-creatinine ratio (PCR) below 0.3. For conditions 1 through 6, see Chapters 29, 33, 44, 56, 62, and 65, respectively.

Recently, albuminuria measurement has gained favor over proteinuria measurement in CKD management. However, of the two studies that compared urine albumin-creatinine ratio (ACR) and urine protein-creatinine ratio (PCR) as predictors of GFR decline, one found ACR better than PCR,[6] and the other found PCR not inferior to ACR.[7] Kidney Disease: Improving Global Outcomes (KDIGO) recommends ACR. However, albumin assays are expensive compared with protein assays. Furthermore, above a proteinuria of 500 mg/day, ACR and PCR generally change in parallel.[7,8] If 24-hour proteinuria is below 500 mg/day, this parallelism is lost and ACR is more sensitive. On this basis, we recommend ACR for detection of early CKD progression. Thereafter, PCR is recommended. The recommended methods for monitoring proteinuria trends in individual patients are shown in Table 80-1. The key points are as follows:

- The gold standard for monitoring proteinuria is the protein content of an accurately collected 24-hour urine specimen. Unfortunately, in practice, nominal 24-hour urine collections often are largely undercollections or overcollections. For this reason we prefer the term "intended" 24-hour urine collection when such collections are made.[9,10]
- Creatinine should be measured in all intended 24-hour urine collection specimens. The PCR of the *intended* collection is a reliable estimate of the PCR of the complete 24-hour collection, if the intended 24-hour urine collection is at least 50% complete based on its total creatinine content.[9,10]
- In individual patients, the PCR of spot (single void) urine collections is an unreliable estimate of proteinuria magnitude given the large and inherent variability of the PCR (Fig. 80-2).
- Urine collections of intermediate duration (e.g., overnight collections) have merit. However, such collections may not be representative of the ACR or PCR of the entire 24-hour collection. For example, variations in diet, timing of antihypertensive medications, exercise on the day of the overnight collection, or contamination with semen may substantially alter the ACR or PCR, rendering the overnight collection nonrepresentative.
- Cost of ACR and PCR from spot collections is essentially the same as that of ACR and PCR from 24-hour urine collections. Given the high degree of unreliability of spot ACR and PCR, spot collections can be regarded as having an unfavorable cost-benefit ratio.
- The inconvenience of 24-hour urine collections can be lessened by the following:
  - It is acceptable if an occasional void is missed, but the gap should not be large (e.g., the entire work day).
  - A wide mouth "sports bottle" that is carried in a duffle bag can be used to collect urine when not at home. It is not necessary to refrigerate the collected urine unless it will be several days before the urine specimen is submitted to the clinical laboratory.

Dipstick testing for proteinuria is convenient but unreliable (see Chapter 4). It is not recommended for assessing proteinuria trends in individual CKD patients.[9]

Proteinuria testing in CKD is recommended every 6 to 12 months if proteinuria is low level (e.g., <500 mg/day, ACR <0.2, PCR <0.3 when expressed as mg/mg creatinine, in an average-sized person) and every 2 to 4 months for those with heavier proteinuria. If PCR increases from below 0.5 to 1.0 or higher, or from below 1.0 to 2.0 or higher, likely these are real changes.[11] Most of the measures that slow natural progression also reduce proteinuria.

Recommended and Nonrecommended Methods for Monitoring Proteinuria or Albuminuria	
Methods	**Comments**
Recommended	
PCR or ACR* of intended 24-h urine collections that are at least 50% complete based on creatinine content†	Most accurate method (see text). Can also be used to assess nutrient intake relevant to CKD management (e.g., Na, K, urea nitrogen, water). Inconvenient, but this can be lessened. See text.
PCR or ACR ratio from overnight collections (first morning void)	More convenient than 24-h collections but provides a lower estimate of proteinuria than 24-h collections and is more vulnerable to artifacts (see text).
Not Recommended	
Intended 24-h urine collection in which protein or albumin is measured but creatinine is not measured	Large overcollections and undercollections are common in intended 24-h urine collections. If creatinine content is not measured, the degree of overcollection or undercollection cannot be reliably assessed.
Spot PCR or ACR	Convenient but highly inaccurate estimate. Cost-benefit ratio is low because cost is about the same as 24-h urine testing, but often the results of spot testing are misleading.
Dipstick test for proteinuria (albuminuria)	Convenient and low-cost point-of-care measure but not reliable for monitoring CKD patients.

Table 80-1 Recommended and nonrecommended methods for monitoring proteinuria or albuminuria. E = (140 − Age) × Weight (nonobese) in kg × 0.2 × 0.85 if female. An M/E ratio exceeding 0.5 is evidence that the collection is more than 50% complete. *ACR,* Albumin-creatinine ratio; *CKD,* chronic kidney disease; *PCR,* protein-creatinine ratio. *ACR is recommended if 24-hour proteinuria is below 500 mg (PCR if below 0.3 for average-sized person). PCR is recommended if 24-hour proteinuria is above 500 mg. †Degree of completeness of an intended 24-hour urine collection = measured creatinine content *(M)*/expected creatinine content *(E).*

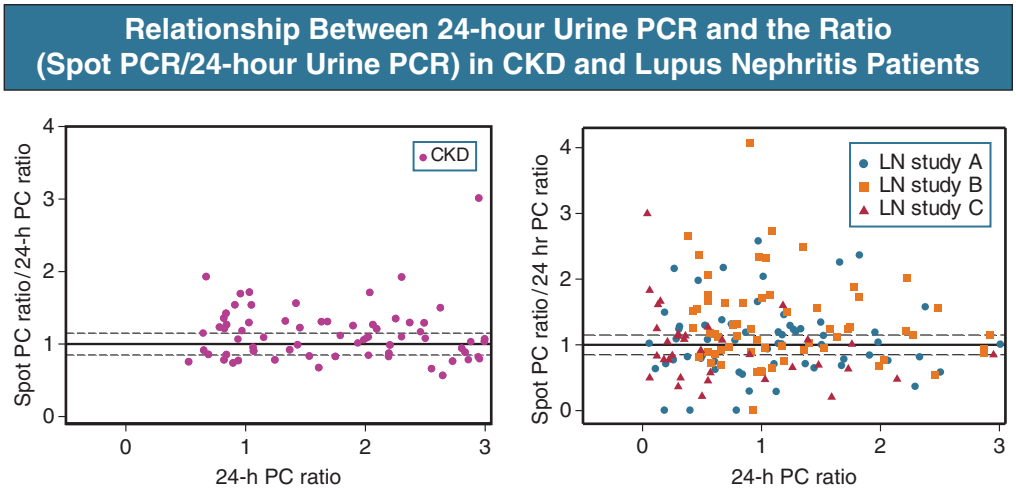

Figure 80-2 Relationship between 24-hour urine protein-creatinine ratio (PCR) and the ratio of spot PCR to 24-hour urine PCR in chronic kidney disease (CKD) and lupus nephritis (LN) patients. The *dashed line* indicates the expected limits of agreement if morning spot PCR provides the same results as testing an aliquot of the intended 24-hour collection. This figure shows that spot PCR is an unreliable estimate of 24-hour PCR, especially in lupus nephritis. *(From reference 8.)*

Monitoring Glomerular Filtration Rate Trends

In individual patients, it is usually sufficient to monitor GFR trends by serial S_{Cr} measurements. In interpreting S_{Cr} change, one must keep in mind the circumstances that can change S_{Cr} by mechanisms that do not involve a change in GFR, as follows: increased creatinine production (eating cooked meat, creatine ingestion, increased exercise, increasing muscle mass, fenofibrate therapy), or decreased creatinine production (vegetarian diet, muscle wasting, decreased exercise). Also, S_{Cr} can be increased spuriously by certain drugs and by increased serum ketones (from fasting or poor diabetes control) or actually increased by drugs that decrease tubular secretion of creatinine (cimetidine, trimethoprim). If a chronic progressive change in creatinine production is occurring (e.g., muscle wasting), GFR trends can be monitored by measuring serial 24-hour urine creatinine clearance. Creatinine clearance is not importantly affected by change in creatinine production. If creatinine clearance is used, an accurate 24-hour collection is essential.[1]

Glomerular filtration rate can also be monitored by the creatinine-based estimated glomerular filtration rate (eGFR) estimating equations—in particular, the Modification of Diet in Renal Disease (MDRD4) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations (see Chapter 3). These approaches to standardizing GFR assessment have greatly advanced the study of CKD epidemiology. In addition, they account for the influence of age on GFR. This is important in monitoring GFR trends over 10 years or more.[1] However, the eGFR equations have important limitations when applied to individuals, as follows:

- The MDRD4 and CKD-EPI equations assume that all patients of the same age, sex, and race have the same rate of creatinine production and the same body surface area. As a result, these equations substantially underestimate actual GFR in those with high creatinine production and substantially overestimate actual GFR in those with low creatinine production.[12]
- Because of inaccuracy, clinical laboratories generally do not report eGFR by MDRD4 or CKD-EPI equation if the eGFR is greater

than 60 ml/min/1.73 m^2. In this circumstance the clinician must determine whether the S_{Cr} is likely to be normal or abnormal. The following can be helpful:

- Large normal persons have higher S_{Cr} values than small normal persons.
- Men have higher S_{Cr} values than women.
- In North America, those of African ancestry have higher S_{Cr} values than those of non-African ancestry.

Box 80-1 provides specific numerical recommendations for interpretation of S_{Cr} when the eGFR is greater than 60 ml/min/1.73 m^2.

Glomerular Filtration Rate Trajectories in Chronic Kidney Disease

The chronic kidney disease GFR trajectory generally is well described as a linear decline; thus GFR loss per unit of time is approximately constant.[1,2] However, those of African ancestry deemed to have hypertensive nephrosclerosis can experience large unexplained changes in eGFR trends, especially decreases followed by stability. A concern is that increased variability of GFR decline over time is associated with increased mortality.[13]

Indexing Proteinuria and Albuminuria by Estimated Glomerular Filtration Rate to Predict Risk of Chronic Kidney Disease Progression

Recent work has emphasized that at any given level of albuminuria, the lower the eGFR, the greater the risk of CKD progression. This is referred to as *indexing* the risk of progression according to both proteinuria and eGFR.[14] Indexed GFR and albuminuria levels also are associated with increased cardiovascular mortality.

THERAPY FOR NATURAL PROGRESSION

Because of the benefit of even small decreases in CKD progression rate in delaying the onset of ESRD, an aggressive, multiple–risk factor intervention to slow GFR decline is warranted. This, however, does not apply to patients with low ESRD risk. Low-risk patients include those with corticosteroid-responsive minimal change disease (MCD); those with a solitary kidney that is normal, is acquired in adulthood, and is not accompanied by other CKD risk factors; normotensive adults with hereditary nephritis or thin basement membrane in whom the only renal manifestation is microscopic hematuria; and the elderly with idiopathic and moderately elevated S_{Cr} (1.30 to 2.00 mg/dl), a 24-hour urine PCR below 1.0, and whose renal parameters have been stable for at least 1 year. Patients in the last group are much more likely to die of cardiovascular disease (CVD) than to progress to ESRD.[2]

Therapies recommended in this chapter are listed in Box 80-3. A Level 1 (highest) recommendation is based on one or more large, high-quality randomized clinical trials (RCTs) that showed documented effects on GFR decline. A Level 2 recommendation is based on secondary analysis of the Level 1 RCT, RCTs that showed documented effects on proteinuria but not GFR decline, RCTs that appear to have been of adequate quality but may not have been definitive because of study size, and nonrandomized studies that were rigorous and confirmed by other rigorous studies.

The goals of progression therapy are to reduce proteinuria as much as possible, ideally to less than 500 mg/day, and to slow GFR decline as much as possible, ideally to about 1 ml/min/yr, which is the rate of GFR decline attributable to the nephropathy of aging (see Chapter 67).

Recommended Kidney Protective Therapies According to Level of Recommendation

Level 1 Recommendations

1. Control blood pressure (BP).
2. Administer angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), or renin inhibitor.
3. Avoid dihydropyridine calcium channel blockers (DHCCBs) unless needed for BP control.
4. Control protein intake.

Level 2 Recommendations

1. Restrict NaCl intake and diuretic therapy.
2. Administer NDHP-CCB therapy.
3. Control each component of the metabolic syndrome.
4. Administer aldosterone antagonist therapy.
5. Administer allopurinol therapy.
6. Control serum phosphorous.
7. Instigate smoking cessation.
8. Perform alkali therapy.
9. Administer β-blocker therapy.
10. Avoid overanticoagulation with warfarin.

Box 80-3 Recommended kidney protective therapies according to level of recommendation. The goal for the chronic kidney disease (CKD) patient is to implement all Level 1 recommendations and as many Level 2 recommendations as is feasible. *NDHP-CCB,* Nondihydroyridine calcium channel blocker.

Level 1 Recommendations to Slow Natural Progression

Control Blood Pressure

The low blood pressure (BP) goal (sitting systolic BP in the 120s or less, if tolerated) is recommended. However, the evidence supporting the low goal is not robust.[15] It is based largely on the subset of patients in the MDRD study whose baseline proteinuria was greater than 1.0 g/day; the African American Study of Kidney Disease and Hypertension (AASK), but only in the long-term cohort study; and the Effect of Strict Blood Pressure Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients (ESCAPE) trial in children.

Another reason to favor the low BP goal is that in both the MDRD study and AASK, those assigned to the low BP goal had a significantly lower risk of ESRD during long-term (post-trial) follow-up than those assigned to the usual (higher) BP goal. This is remarkable because during the post-trial follow-up the low BP goal was recommended to all patients.[15] In addition, in a meta-analysis of placebo-controlled randomized trials of antihypertensive drug therapy in which there was post-trial follow-up of at least 7 years, it was found that the mortality rate during post-trial follow-up was significantly lower in the group that had been randomized to the study drug than in the group that had been randomized to placebo—even though during the post-trial follow-up both groups were advised to receive the study drug. This benefit of having received the antihypertensive study drug during the randomized trial was independent of the class of the antihypertensive study drug.[16]

When these findings are taken together, it seems that the low BP goal is more beneficial than the usual BP goal, even though it may take several years for the benefit to be shown. These results also suggest that achieving the low goal BP sooner rather than later is important.

In CKD patients, in general, the greater the proteinuria, the greater the benefit of the low BP goal in slowing CKD progression.[1,17,18] The low BP goal was also better than the usual BP goal at slowing the progression of proteinuria during the trials.[1,2] This may be evidence of kidney protection.

Systolic BP is the recommended target because, in general, it correlates better with CKD progression than diastolic BP.[1,19,20] Also, specifying both a systolic and a diastolic BP goal can be confusing if one goal is met but the other is not, and could lead to overtreatment or undertreatment of BP.[1]

However, the low BP goal is not recommended for all CKD patients. The traditional (usual) BP goal, a sitting systolic BP in the 130- to 140-mm Hg range, is recommended for the CKD patient who is elderly (frail), has evidence of significant CVD, or is intolerant of the low BP goal. Intolerance can be manifested by lightheadedness, orthostatic symptoms, chest pain, fatigue, or progressively increasing S_{Cr} after achievement of the low BP goal.

Administration of antihypertensive medications at night may increase their efficacy in preventing cardiovascular events.

Whenever possible, BP control should be assessed with home BP monitoring (HBPM) rather than in the office or clinic. The latter is a poor predictor of risk compared with HBPM or ambulatory BP monitoring (ABPM). Among hypertensive CKD patients, masked hypertension (BP is normal in the office or clinic but hypertensive by HBPM or ABPM) and white coat hypertension are common and may be present in more than 50% of CKD patients.[20,21] The technique of HBPM is discussed in Chapter 33.

The optimum frequency of HBPM measurement has not been rigorously studied. We recommend that initially HBPM be measured twice daily—morning and evening—until the BP is at goal. The frequency of HBPM can then be decreased. The recommended minimum frequency of HBPM is every 1 or 2 weeks, including both morning and evening testing. The HBPM measures need to be recorded and averaged. The average BP should be used to determine the degree of BP control.

The classes of antihypertensive drugs used to achieve BP control importantly influence CKD progression.[1] Evidence-based and experience-based algorithms for BP control in CKD are shown in Figures 80-3 and 80-4. Although the algorithms recommend beginning with a single drug, if the systolic BP is more than 20 mm Hg above goal, two or more antihypertensive agents will usually be needed.[1]

Renin-Angiotensin System Blockers

Renin-angiotensin system (RAS) blockade with ACE inhibitors or angiotensin receptor blockers (ARBs) is recommended first-line therapy to reduce proteinuria, CKD progression, and cardiovascular risk (see Fig. 80-3). These benefits appear to be comparable between ACE inhibitors and ARBs. ARBs do not increase the risk of cancer. RAS blockade is recommended in CKD even if hypertension is not present, because the kidney and cardiovascular protection of RAS blockade is, at least in part, independent of BP control.[1] In general, the greater the ACE inhibitor or ARB dose, the greater the effect on control of hypertension and proteinuria.[1,22]

Renin-angiotensin system blockers are antiproteinuric even in inflammatory glomerulonephritis (GN), and should be continued even if GFR declines to stage 4 CKD (15 to 29 ml/min/1.73 m^2).[1] For prevention of hyperkalemia, dietary potassium restriction and the concomitant use of furosemide and sodium bicarbonate may be needed.[1]

Adipose tissue expresses all RAS components. Thus angiotensin II may play a greater role in obese CKD patients. Indeed, in the Ramipril in Non-diabetic Renal Failure (REIN) trial, ACE inhibitor therapy was significantly more effective in slowing GFR decline in the obese than in the nonobese.[23]

Combination Angiotensin-Converting Enzyme Inhibitor and Angiotensin Receptor Blocker Therapy

In general, combination ACE inhibitor and ARB therapy is more antihypertensive and more antiproteinuric than use of an ACE inhibitor or ARB alone. Therefore it is surprising that the randomized trials comparing ACE inhibitors, ARBs, and ACE inhibitors plus ARBs did not find benefit of the combination. However, in mice, severe blockade of the RAS can induce renal injury, so combination therapy might block the RAS too severely. Currently, combination therapy is not recommended in CKD management, particularly in the elderly.[24] However, there may be a role for combination therapy in the nonelderly with heavy proteinuria. Whether patients with very heavy proteinuria (e.g., 10 g/day, serum albumin 2.5 g/dl) are benefitted if the dose of combination therapy is pushed above the recommended levels has not been well studied. However, in our experience such high-dose therapy has not been helpful, even when combined with aldosterone antagonists, salt restriction, protein restriction, diuretic therapy, and statin therapy. Also, this aggressive antiproteinuria therapy often had to be abandoned because of overcontrolled BP.

Renin Inhibitor Therapy

Aliskiren, a direct renin inhibitor, is an effective antihypertensive agent and has been shown to reduce albuminuria in diabetic nephropathy and IgA nephropathy. However, when aliskiren was added to ACE inhibitor or ARB therapy in patients with type 2 diabetes and nephropathy, there was increased risk of renal impairment, hypotension, and hyperkalemia, without perceived benefit. Aliskiren may be a suitable alternative RAS blocker for those intolerant to either ACE inhibitors or ARBs.

Avoid Dihydropyridine Calcium Channel Blockers

There have been three randomized trials in CKD showing that those assigned to dihydropyridine calcium channel blocker (DHP-CCB) therapy experienced less kidney protection than those not assigned to DHP-CCB.[1,25] The mechanism may involve DHP-CCB–induced arteriolar vasodilation resulting in glomerular hypertension and thus promotion of proteinuria.[1] However, in the Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, ACE inhibitor plus amlodipine therapy protected kidney function better than ACE inhibitor plus diuretic therapy, especially in non-Blacks.[26] Possibly, the benefit of amlodipine in ACCOMPLISH was seen because the CKD patients had low-level proteinuria.[26] In addition, there is evidence that chronic thiazide therapy is nephrotoxic.[27] Thus, if a CCB is needed for BP control, the first choice should be a nondihydropyridine CCB (NDHP-CCB) (discussed later).

Control Protein Intake

Reducing dietary protein intake from the usual level (in developed countries about 1 to 1.5 g/kg ideal body weight per day) to about 0.7 g/kg ideal body weight per day (low-protein diet) slows GFR decline in those with proteinuria of more than 1 g/day.[1] Another benefit of the lower protein intake in CKD is that it slows proteinuria progression, even in those who at baseline have only low-level proteinuria.[1] Diets incorporating soy proteins may be more antiproteinuric than those composed of animal proteins only.[1] Dietary protein intake should be monitored periodically, for example, every 4 to 6 months, by measuring urine urea nitrogen (UUN) excretion in

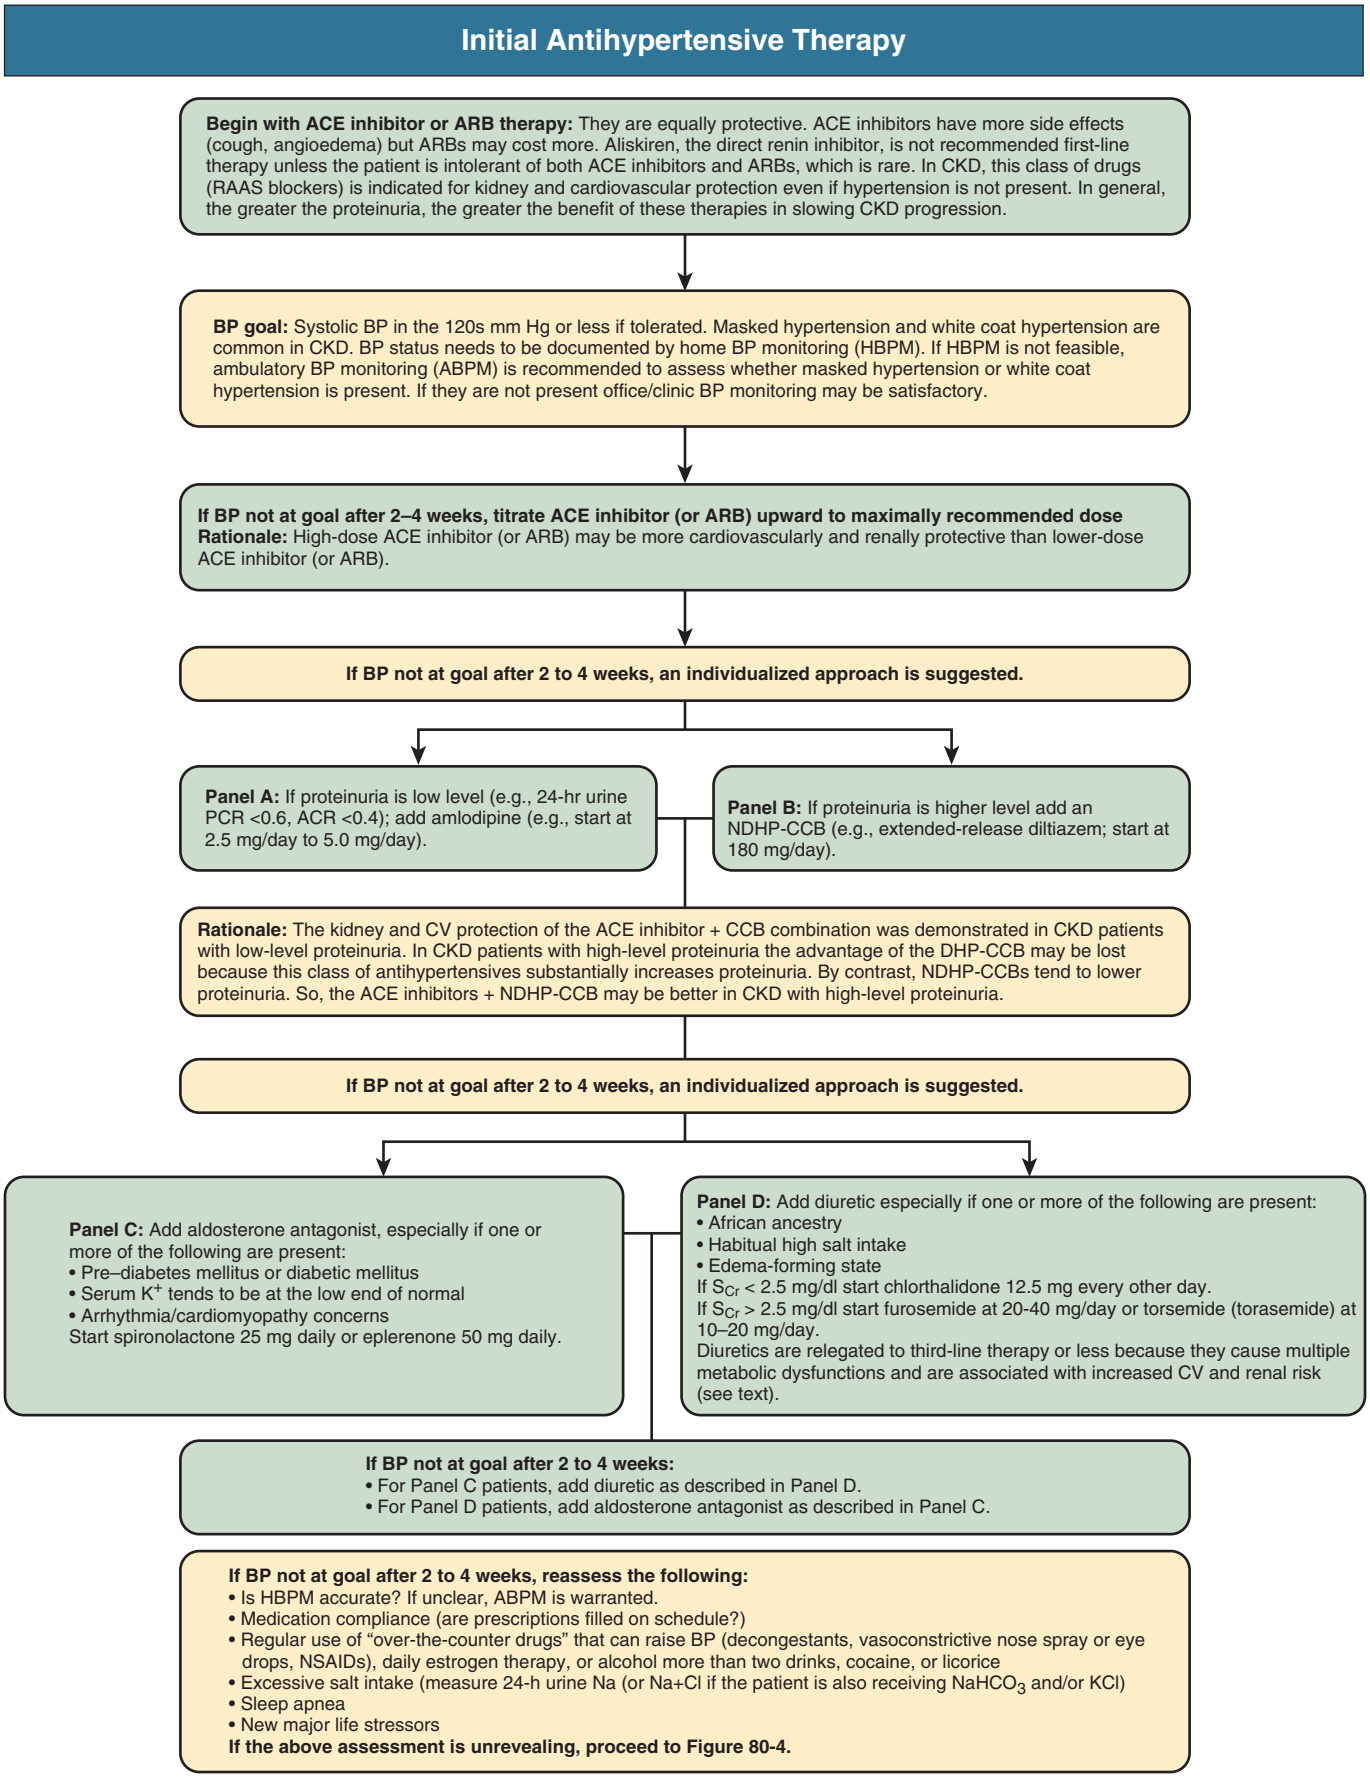

Figure 80-3 Initial antihypertensive therapy. The algorithm shown here assumes that nonpharmacologic therapy to control BP is in place (see text) and that the patient is not known to have renovascular hypertension, congestive heart failure, or ischemic or heart disease, and does not have hypertensive urgency. This approach focuses on BP control in proteinuric nephropathies, but is also appropriate for nephrosclerosis, polycystic kidney disease, and interstitial nephropathies. More details on each of the recommended drugs are provided in the text. *ACE,* Angiotensin-converting enzyme; *ACR,* albumin-creatinine ratio; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CKD,* chronic kidney disease; *CV,* cardiovascular; *NDHP-CCB,* nondihydropyridine calcium channel blocker; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *PCR*, protein-creatinine ratio; *RAAS,* renin-angiotensin-aldosterone system.

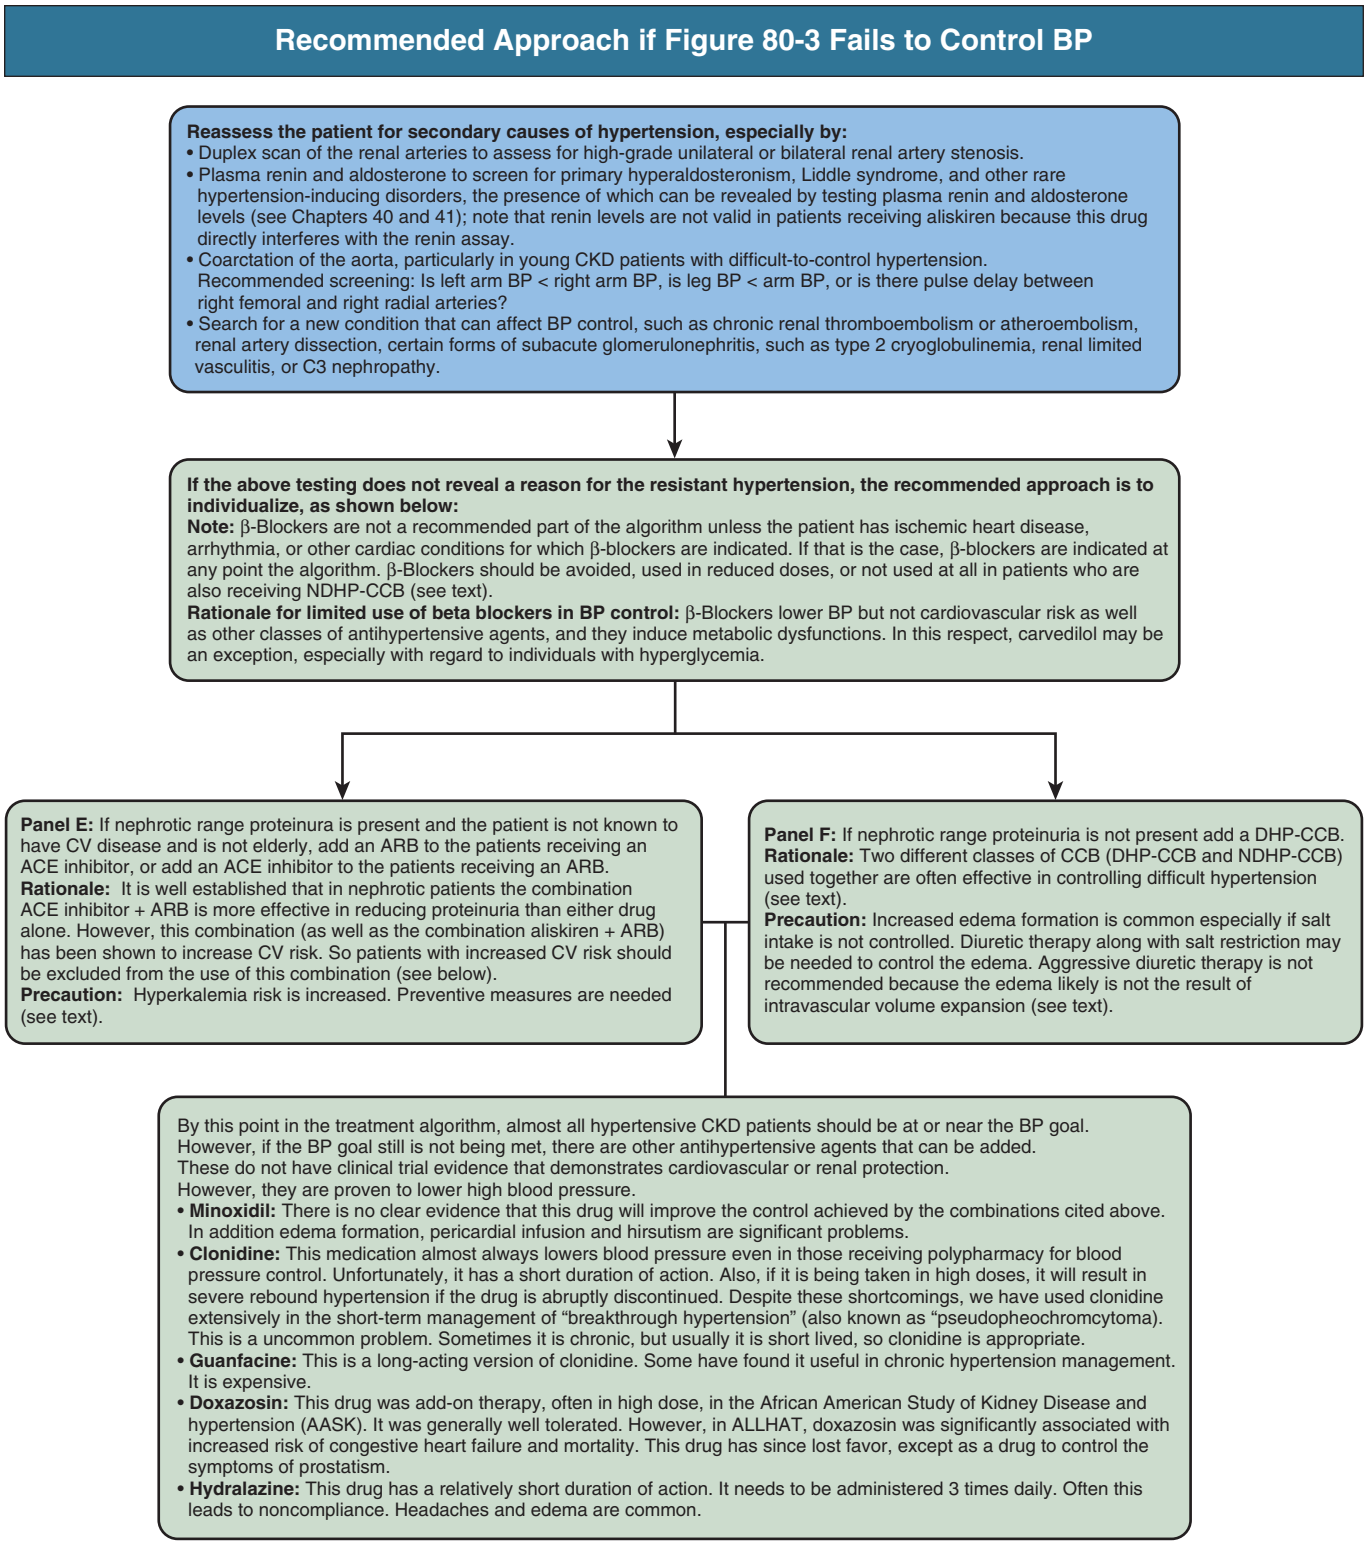

Figure 80-4 Recommended approach if Figure 80-3 fails to control BP. If patients are intolerant or allergic to the drugs recommended in the algorithms, suggested alternatives include ethacrynic acid for thiazide diuretics, aliskiren for ACE inhibitors or ARBs, and minoxidil for CCBs. Carvedilol or doxazosin may be appropriate at any point in patients in whom stress may play an important role in their hypertension, or in whom BP is particularly labile, in the absence of correctable factors to account for the lability. *ACE,* Antiotensin-converting enzyme; *ALLHAT,* Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack trial; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CCB,* calcium channel blocker; *CKD,* chronic kidney disease; *CV,* cardiovascular; *DHP-CCB,* dihydropyridine calcium channel blocker; *NDHP-CCB,* nondihydropyridine calcium channel blocker.

24-hour urine collections. For a 70-kg person, a 50-g protein diet would achieve the dietary goal of 0.7 g/kg ideal body weight per day. In such a patient, the 24-hour urine collection would contain about 8 g UUN. Monitoring protein intake is particularly important in those who are not achieving their proteinuria goal. Men and those with glomerular disease may particularly benefit from the low-protein diet.[2]

In the MDRD study, long-term follow-up of those on the very-low-protein intake (<0.6 g/kg/day) showed no further reduction in GFR decline, but these patients appeared to have an increased risk of death.[1] A risk of excessive protein restriction is protein-energy wasting. This occurs when protein catabolism does not appropriately compensate for decreased protein intake. Its consequences include muscle wasting and low serum albumin. The risk of protein-energy wasting increases with coexisting inflammatory disorders such as diabetes, severe atherosclerosis, or autoimmune diseases. Stage 4 and 5 CKD patients are particularly vulnerable to protein-energy wasting. Alkali therapy can mitigate protein-energy wasting (see the discussion of alkali therapy). Given the recent strong evidence that red meat and processed red meat are associated with increased risk of mortality, cancer, and CVD, it is reasonable that most of the reduction in protein intake should involve these protein sources.

Level 2 Recommendations to Slow Natural Progression

Restrict Salt Intake and Diuretic Therapy

A high salt intake (e.g., 200 mmol NaCl/day = 11.6 g NaCl and 4.6 g Na) can completely override the antiproteinuric effects of ACE inhibitor, ARB, or NDHP-CCB therapy. Also, high salt intake measured at baseline is a significant predictor of more rapid GFR decline.[28] In addition, it is well established that high salt intake worsens hypertension. Despite wide acceptance that salt restriction is important in CKD management, there have been no rigorous randomized trials of salt restriction in CKD.

The recommended NaCl intake in CKD (assuming that renal salt wasting is not present) is about 2 to 3 g Na (5-7.5 g NaCl). The NaCl intake of the average North American adult is about 10 g NaCl (4 g Na). Achievement of the CKD goal for salt intake would be documented by a 24-hour urine collection containing 80 to 120 mmol of sodium and is particularly important if the BP or proteinuria goal is not being met. Urine sodium should be measured each time 24-hour urine protein is measured (see the discussion of monitoring of proteinuria). In patients receiving NaHCO therapy, urine chloride rather than sodium should be monitored, taking into account whether the patient is also receiving KCl.[1] The rationale is that urine Cl is almost entirely derived from ingestion of NaCl, unless the patient is also receiving KCl therapy. So, if the patient is not receiving KCl, 24-hour urine chloride in milliequivalents is equal to 24-hour urine NaCl in millimoles.

High fructose intake (in the form of table sugar or high-fructose corn syrup used in sugar-sweetened beverages) should be avoided in CKD because it increases renal sodium reabsorption and can worsen BP control (see the discussion of metabolic syndrome).

In patients receiving RAS blockers, diuretic therapy improves BP control and decreases proteinuria. Nevertheless, the ideal is to avoid diuretics because of the evidence of nephrotoxicity[27] and its multiple metabolic dysfunctions, which include hypokalemia, hyperglycemia, hyperlipidemia, and stimulation of the RAS, all of which are known to increase cardiovascular risk.[1] Loop diuretics are more effective than thiazides if GFR is below 30 ml/min. If the GFR is higher, the preferred diuretic is chlorthalidone because of the evidence of superior protection against cardiovascular events compared with hydrochlorothiazide. The mechanism of the superior effect of chlorthalidone may be related to its more effective suppression of carbonic anhydrase and its ability to help regulate nitric oxide better than hydrochlorothiazide.[29]

Nondihydropyridine Calcium Channel Blocker Therapy

The NDHP-CCB class of agents, which includes diltiazem and verapamil, is antiproteinuric and may be renoprotective. An NDHP-CCB together with a DHP-CCB can be a potent antihypertensive combination when used along with other antihypertensive therapies (see Fig. 80-4).[1,2]

Control Each Component of the Metabolic Syndrome

The metabolic syndrome and each of its components are risk factors for CKD progression and are associated with the development of eGFR less than 60 ml/min, microalbuminuria, and overt proteinuria.[2] Also, the prevalence of microalbuminuria and CKD increases proportionately with the number of components of the metabolic syndrome.[30]

Each component of the metabolic syndrome has not been rigorously studied in randomized trials. Nevertheless, it is appropriate to discuss each component of the metabolic syndrome because, in general, an intervention that benefits any aspect of the metabolic syndrome likely benefits all of its aspects.

Obesity increases the risk of CKD and is associated with glomerulopathy, focal and segmental glomerulosclerosis, and proteinuria, which can be progressive. Reducing even moderate obesity can reduce proteinuria in CKD.[1,2] Bariatric surgery in morbidly obese patients reduces risk factors for CKD, including systolic BP and insulin resistance.

In CKD, increased intake of sugar-sweetened beverages, especially those sweetened by fructose, is an important contributor to metabolic syndrome. In CKD patients, lowering fructose intake lowers BP and inflammation.[31]

With regard to lipid control in CKD, the current KDIGO guidelines (www.kdigo.org) recommend a statin or a statin plus ezetimibe for all non-ESRD CKD patients 50 years of age or older, regardless of the lipid levels. Disregard of the lipid levels is based on the Study of Heart and Renal Protection (SHARP), which showed that the benefits of lipid therapy are not related to baseline lipid level. For non-ESRD CKD patients younger than 50 years, KDIGO does not recommend statin therapy unless there is increased cardiovascular risk. The KDIGO-recommended statin doses are low (e.g., atorvastatin 20 mg daily).

We suggest a less-restrictive policy for statin use than that of KDIGO. For example, all adult non-ESRD CKD patients, regardless of age and stage, should receive at least moderate-dose statin therapy (e.g., atorvastatin 40 mg daily). The rationale is that CKD itself is a strong cardiovascular risk factor, and the risk starts early in CKD (see Chapter 82). CVD has a long incubation period, so starting lipid therapy early in CKD patients may be prudent. Also, statins are well tolerated in CKD, even at high doses (e.g., atorvastatin 80 mg daily).[32] With regard to statin choice in CKD, atorvastatin may be better than simvastatin,[32] and rosuvastatin may have nephrotoxicity.[33] Also to be considered is the recent meta-analysis of randomized trials of fibrate therapy compared with placebo in mild to moderate CKD. Fibrate therapy reduced cardiovascular risk and albuminuria; however, ESRD risk was unchanged. S_{Cr} increased in patients taking fenofibrate, probably because of increased creatinine production. When fibrate was stopped after the trial, S_{Cr} decreased to below baseline values, suggesting that kidney function was protected during fibrate

therapy.[34] Fibrates decrease triglycerides significantly. Perhaps there is a role for add-on fibrate therapy for CKD patients at high cardiovascular risk whose triglycerides are not controlled by statin therapy or a statin-ezetimibe combination.

Aldosterone Antagonist Therapy

Spironolactone and the more selective aldosterone antagonist eplerenone have substantial antihypertensive, cardioprotective, and antiproteinuric effects even at low doses (e.g., spironolactone 25 mg/day) and in the presence of combined ACE inhibitor and ARB therapy.[35] The mechanism may involve blockade of aldosterone effects on endothelium and on fibrosis. Although there are no rigorous clinical trial data with hard end points such as ESRD, the available evidence supports the use of aldosterone antagonists in high-risk CKD patients who have not reached their BP and proteinuria goals despite other therapy (see Fig. 80-3). However, the use of aldosterone antagonists should be restricted to those with an eGFR above 30 ml/min. If spironolactone or eplerenone is used in patients receiving RAS blockers, it is especially important to prevent hyperkalemia. These measures include sodium bicarbonate therapy (see the discussion of alkali therapy), the avoidance of potassium-rich foods, and awareness of the symptoms of severe hyperkalemia. These include the relatively sudden onset of symmetric proximal muscle weakness (difficulty climbing stairs or rising from a chair) or muscle stiffness. This should prompt an immediate visit to the nearest emergency department. On arrival the patient should immediately advise the medical personnel that severely elevated serum potassium may be the problem.

β-Blocker Therapy

The AASK study showed that β-blocker therapy is more antiproteinuric and slows GFR decline better than DHP-CCB. However, β-blockers increase the likelihood of diabetes and, as monotherapy or when combined with diuretics, increase mortality compared with ACE inhibitors plus diuretics.[1,2] β-Blockers should be used in CKD to manage coronary heart disease or arrhythmia. However, in general, they should be avoided in the management of hypertension.[1,2] Carvedilol, which possesses both β-blocker and α_1-blocker effects, may be less likely to increase insulin resistance than metoprolol when it is used in combination with an ACE inhibitor.[1,2]

Control Serum Phosphorous

Serum phosphorus generally does not become abnormally elevated until stage 3 or 4 CKD. In CKD, there is a significant association between increased serum phosphorous and either CKD progression or incident CKD and ESRD. There is strong experimental evidence that hyperphosphatemia is harmful. However, there have been no high-quality randomized trials to test that hypothesis. To achieve phosphorus control (see Chapter 85), the following are suggested:

Phosphorus control should begin before the serum phosphorus is consistently greater than 4.0 mg/dl (1.3 mmol/l).

The first approach is to reduce phosphorous intake with the precaution that severely reducing meat and dairy products could lead to protein malnutrition. Proteins in grain (e.g., a vegetarian-type diet) have a lower phosphorus content than the proteins in meat or milk. If grains are substituted for meat and dairy products, better control of serum phosphorous can be achieved.

If dietary measures are ineffective, use of phosphate binders is generally recommended. Which type of phosphate binder is best is a subject of controversy. The evidence favors the notion that calcium-containing phosphorous binders are more likely to result in vascular calcification and increase cardiovascular risk than noncalcium phosphate binders (see Chapter 85).

Smoking Cessation

There are many compelling reasons for the CKD patient not to smoke. Cigarette smoking promotes progression of all forms of kidney disease in a dose-dependent manner, perhaps more in those of African American ancestry.[1] Cigarette smoking is associated with an increased risk of glomerular hyperfiltration and proteinuria and may cause a glomerulopathy that resembles diabetic nephropathy.

Allopurinol and Febuxostat Therapy

Three randomized trials[1,36] and one case-control study found that allopurinol therapy slows CKD progression. There is abundant experimental evidence that uric acid is proinflammatory and vasculotoxic[1] and that allopurinol is anti-inflammatory and cardioprotective by multiple mechanisms.

A major concern in recommending allopurinol to slow CKD is that the trials, although randomized, were open label. In addition, there is a risk, albeit very small, of severe and even fatal hypersensitivity reactions to allopurinol (e.g., Stevens-Johnson syndrome). However, given the likelihood that allopurinol has both kidney and cardiovascular protective properties and the likelihood that the severe risks can be avoided (see later), a cogent argument can be made that allopurinol has a favorable risk-benefit ratio in CKD, particularly in relationship to the traditional uses of allopurinol, which are to treat gout and kidney stones.

Reducing the risk of severe hypersensitivity reaction to allopurinol in CKD patients may be accomplished by reducing the dose[37] (see summary, later) and by advising patients who are about to start allopurinol to stop the drug immediately and call their physician should they develop rash, fever, or other signs of illness. This is practical advice because the risk of severe allopurinol reactions appears to be restricted to the first 8 weeks of therapy, and prompt withdrawal of the offending drug is associated with decreased mortality risk.[38] Also, allopurinol should be avoided in patients with high-risk alleles for severe allopurinol hypersensitivity. This is particularly seen in those of Asian ancestry. Testing Asians for these risk alleles has been recommended.

Another xanthine oxidase inhibitor, febuxostat, is now available. It is safe in patients intolerant of allopurinol. It does not need dose adjustment if eGFR is greater than 30 ml/min/1.73 m^2. Stevens-Johnson syndrome has been reported in postmarketing surveillance of febuxostat.

In summary, there is level 2 evidence that allopurinol therapy, properly approached, is prudent in hyperuricemic CKD patients to reduce cardiovascular risk and risk of CKD progression. For prevention of severe allergic reactions, the starting dose should be 1.5 mg × eGFR in ml/min/1.73 m^2. If after 8 weeks that dose is well tolerated, it can then be increased until the uric acid level is at goal (less than 7 mg/dl). Also, the patient should be strongly cautioned, when he or she starts allopurinol or when the dose is increased, to stop the allopurinol if rash, fever, or other signs of illness develop. The patient should then promptly seek medical advice. If allopurinol is being considered in those of Asian ancestry, testing for high-risk human leukocyte antigen (HLA) alleles is recommended. If they are present, allopurinol should not be used. Whether febuxostat is the appropriate next choice is not clear because there is no evidence from clinical trials that febuxostat is renal protective in hyperuricemic CKD, although that is plausible. Also, data on the long-term safety of febuxostat are lacking. Given these concerns, perhaps the most appropriate use of febuxostat in CKD is to treat gout or kidney stones in those allergic to allopurinol. Febuxostat might also be appropriate in the allopurinol-intolerant CKD patient who has severe hyperuricemia (e.g., >9.0 mg/dl). The rationale is that observational studies

show that the greater the uric acid level, the greater the risk of renal and cardiovascular end points.

Avoid Overanticoagulation with Warfarin

Warfarin-related nephropathy (WRN) is a newly recognized clinical syndrome. In this condition, patients with warfarin coagulopathy (international normalized ratio [INR] greater than 3.0) may have acute kidney injury (AKI) manifested by severe glomerular hemorrhage, even though the glomeruli are normal or nearly normal. WRN is particularly common in CKD.[39] Although most CKD patients recover from the AKI, the rate of CKD progression is increased.[39] Whether other classes of systemic anticoagulants can cause AKI is under investigation.

Alkali Therapy

The evidence that alkali therapy slows CKD progression is based on three randomized trials and one nonrandomized trial.[1] Alkali therapy may be kidney protective by blocking endothelin production, suppressing the alternative complement pathway, or reducing oxidative damage. Three different forms of alkali have been studied: sodium bicarbonate ($NaHCO_3$), sodium citrate, and diets high in fruits and vegetables (i.e., potassium citrate). If $NaHCO_3$ therapy is used, the recommended dose is three or four 650-mg tablets daily. They can be given twice daily. Taken together, the evidence favoring alkali therapy in CKD progression is plausible and prudent. Also, alkali therapy improves protein nutrition by suppressing protein catabolism and protects against hyperkalemia. Whether metabolic acidosis needs to be present for benefit to be derived from alkali supplementation is not clear. However, it appears that the benefit in slowing CKD progression is seen even in those whose pretreatment plasma bicarbonate level is within the normal range.

Correct Vitamin D Deficiency

Severe deficiency of 25-OH vitamin D is common in CKD. There is strong evidence from cross-sectional studies that severe vitamin D deficiency (25-OH vitamin D levels less than 15 ng/ml) is strongly associated with increased risk of CVD, infection, thrombotic disease, autoimmune disease, diabetes mellitus, bone disease, and progression of CKD. Vitamin D_3 supplementation is recommended for those with 25-OH vitamin D levels less than 30 ng/ml.[40] Vitamin D_3 doses of 1000 or 2000 IU daily or 50,000 IU monthly will usually restore 25-OH vitamin D levels to normal.

CHAPTER 81

Clinical Evaluation and Management of Chronic Kidney Disease

Laurie A. Tomlinson and David C. Wheeler

Although many patients with chronic kidney disease (CKD) progress to end-stage renal disease (ESRD) and require renal replacement therapy (RRT), the majority die of nonrenal causes, particularly premature cardiovascular events.[1] Early diagnosis of CKD is therefore important because it provides opportunities to delay progression of CKD (see Chapter 80) and to prevent cardiovascular complications (see Chapter 82).

DEFINITIONS

Chronic kidney disease is defined as abnormalities of kidney structure or function, present for at least 3 months, with implications for health (Table 81-1). The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend classification of CKD based on cause, category of glomerular filtration rate (GFR), and albuminuria (see Fig. 79-1).[2] Because of the impracticalities of using radioisotopes and 24-hour urine collections, the KDIGO classification system recommends that kidney function be assessed by estimating the GFR (eGFR) from the serum creatinine level through use of an appropriate equation, except in circumstances in which eGFR estimations are known to be less accurate, such as when there is significant muscle wasting. The Modification of Diet in Renal Disease (MDRD) equation has been in common use in clinical laboratories until recently, but KDIGO has recommended that this be replaced by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, which more accurately categorizes the risk of mortality and progression to ESRD (see Chapter 3).[3] Although staging systems for CKD based on eGFR have limitations, they have proven to be useful in many clinical settings and are now deeply embedded into guidelines developed for CKD management.

The evidence base for the management of CKD is constantly evolving, and guidelines are updated in light of this. Although every effort has been made to ensure that this chapter reflects current recommendations, the reader is advised to check for any relevant guideline updates.

CLINICAL PRESENTATION

Chronic kidney disease is usually asymptomatic until late stage 4 or stage 5 and is commonly detected by routine blood testing. There is some evidence that early diagnosis with appropriate management may slow the rate of decline of kidney function and reduce cardiovascular risk.[4] Screening of the general population for CKD is not recommended, but in the United Kingdom the National Institute for Health and Care Excellence (NICE) proposes offering testing to people with conditions associated with an increased prevalence—those with diabetes, hypertension, cardiovascular disease (CVD), structural renal tract disease, renal calculi, prostatic hypertrophy, multisystem diseases with potential kidney involvement (e.g., systemic lupus), a family history of category G5 CKD, or hereditary kidney disease—and after opportunistic detection of hematuria or proteinuria.[5]

Evaluation of Chronic Kidney Disease

Establishing Chronicity

When an eGFR of less than 60 ml/min/1.73 m^2 is detected in a patient, careful attention needs to be paid to previous blood and urine test results and the clinical history to determine if this is a result of acute kidney injury (AKI), an abrupt decrease in kidney function, or CKD that has been present but asymptomatic for some time.

A detailed medical history covering issues, including other medical conditions, family history of kidney disease, prescribed medication, and illicit drug use, may suggest an underlying cause. There may be hints of a past history of kidney problems (e.g., hypertension, proteinuria, microhematuria) or symptoms suggestive of prostatic disease. The physical examination findings are not usually helpful, although skin pigmentation, scratch marks, left ventricular hypertrophy, and hypertensive fundal changes favor a chronic presentation (Fig. 81-1). Details of the social and personal circumstances are also crucial, particularly for patients with progressive kidney disease in whom RRT is likely to be required.

Blood tests for other conditions can be helpful if the findings indicate evidence of an acute illness that may be the cause of kidney failure, such as systemic vasculitis or multiple myeloma. A normochromic normocytic anemia is usual in CKD but may also be a feature of acute systemic illnesses and therefore is not discriminatory. Low serum calcium and raised phosphate levels also have little discriminatory value, but normal levels of parathyroid hormone (PTH) are more in keeping with AKI. Patients with grossly abnormal biochemical values—for example, blood urea nitrogen higher than 140 mg/dl, serum creatinine above 13.5 mg/dl (>1200 µmol/l), or blood urea greater than 300 mg/dl (>50 mmol/l)—who appear relatively well and are still passing normal volumes of urine are much more likely to have chronic than acute kidney disease.

Assessment of Glomerular Filtration Rate

For patients in whom the distinction between AKI and CKD is unclear, repeat testing of kidney function should be performed within 2 weeks of the initial finding of an eGFR below 60 ml/min/1.73 m^2. However, if previous results confirm that this is a

Criteria for Definition of Chronic Kidney Disease (CKD)	
CKD is defined as abnormalities of kidney structure or function, present for more than 3 months, with implications for health. These may include the following.	
Markers of kidney damage	Albuminuria (AER ≥ 30 mg/24 h; ACR ≥ 30 mg/g [≥ 3 mg/mmol]) Urine sediment abnormalities Electrolyte and other abnormalities caused by tubular disorders Abnormalities detected through histology Structural abnormalities detected through imaging History of kidney transplantation
Decreased GFR	GFR <60 ml/min/1.73 m^2

Table 81-1 Criteria for definition of chronic kidney disease. *ACR,* Albumin-creatinine ratio; *AER,* albumin excretion rate; *GFR,* glomerular filtration rate. *(From reference 2.)*

chronic finding, or if repeated blood test results over a 3-month period are consistent, CKD is confirmed. Other tests (such as cystatin C or an isotope-clearance measurement) may be required for confirmation of CKD in circumstances when eGFR based on serum creatinine is known to be less accurate.

Assessment of Proteinuria

Dipstick testing of the urine and urine culture are important.[6] This may reveal microhematuria, which can be a useful pointer toward an underlying diagnosis. Workup of hematuria is discussed in Chapter 4. Whether or not proteinuria is detected by dipstick, further measurement of urinary protein excretion should be conducted. Proteinuria is an important diagnostic and prognostic marker, and its presence indicates a higher risk for both progression of kidney disease and cardiovascular complications.[7] KDIGO recommends that the preferred method of assessing proteinuria is by measurement of the urinary albumin-creatinine ratio (ACR) using an early morning urine sample.[2] The degree of albuminuria is graded by the A1 to A3 category system, replacing previous terms such as *microalbuminuria* (see Fig. 79-1). However, it is important to be aware that some patients will excrete proteins other than albumin, and a urine protein-creatinine ratio (PCR) may be more useful for certain conditions.[8] Serial PCR measurements may be particularly useful in glomerular disease because of the higher variability of ACR and the greater cost of determining albumin in urine. Where appropriate, urine tests for Bence-Jones protein (immunoglobulin light chains) may be required because this is not detected by standard proteinuria or albuminuria testing.

Kidney Imaging

Imaging of the kidneys with ultrasound is useful for a number of reasons. Small kidneys with reduced cortical thickness, showing increased echogenicity, scarring, or multiple cysts, suggest a chronic process. Structural abnormalities such as autosomal dominant polycystic kidney disease (ADPKD), hydronephrosis caused by obstruction, or coarse renal scarring may be detected. NICE states that kidney ultrasound scanning is important only in certain circumstances and suggests counseling patients if ADPKD is suspected before imaging.[5] In some situations, imaging with computed tomography, magnetic resonance, or angiography may be useful, taking into account the risks of administering contrast media (see Chapter 5).

Further Investigations

Establishing the cause of CKD is important when possible, and further specific testing, as indicated by the history and results of initial investigations, may be required. There may be an underlying treatable condition that requires appropriate management, or there may be a genetic cause such as ADPKD, for which counseling should be offered. Furthermore, some kidney diseases may recur after transplantation (see Chapter 108), and an accurate diagnosis may therefore influence later management. Despite thorough investigation, however, the cause of CKD is often unclear, with an unhelpful past medical history, minimal abnormalities on urinalysis, and small kidneys on ultrasound. In such patients, investigation should not be pursued relentlessly because the implications for treatment are often minimal. Attempting to obtain biopsy material from small kidneys is associated with risk, and even if a biopsy is performed, histologic assessment may simply show nonspecific chronic scarring rather than diagnostic features that explain the cause of kidney damage.

PREDICTING PROGNOSIS

With the cause of CKD established if possible, the GFR and the level of proteinuria measured, and other comorbidities categorized, it may be possible to estimate the risk of CKD progression and likely future need for RRT. KDIGO recommends consideration of the GFR and the albuminuria categories according to a "heat map" of risk (see Fig. 79-1).[2] Other factors associated with CKD progression will also help inform prognosis. These include cause of CKD, age, sex, ethnicity, dyslipidemia, smoking, obesity, history of CVD, ongoing exposure to nephrotoxic agents, and degree of control of hypertension and hyperglycemia. However, often the best guide to future change in kidney function is the previous pattern of decline, highlighting the importance of considering results of previous blood and urine testing during the initial assessment.

Monitoring and Defining Progression

Once a diagnosis of CKD has been established, arrangements need to be put in place to ensure regular monitoring of kidney function and proteinuria. In patients at low risk of decline, this could be done annually. However, assessment should be undertaken more regularly

if the trajectory of the disease is not clear, and in patients at higher risk of progression.

Determining a true change in kidney function may be difficult because small fluctuations in eGFR are common and not necessarily indicative of progression. They may be caused by reversible factors, such as intravascular depletion or high meat intake, so repeat testing may be required. NICE defines progression as a decline in eGFR of more than 5 ml/min/1.73 m^2 within 1 year or more than 10 ml/min/1.73 m^2 within 5 years.[5] KDIGO refers to a sustained decline in eGFR of more than 5 ml/min/1.73 m^2 within 1 year as rapid progression and also specifies a drop in GFR category accompanied by a 25% or greater drop in eGFR from baseline as defining progression.[2] In patients with CKD progression, current management should be reviewed to detect reversible causes, and specialist referral should be considered.

When to Refer to the Nephrologist

Although management of patients with early nonprogressive CKD is increasingly becoming the responsibility of primary care physicians, nephrologists need to assess those individuals likely to progress to ESRD and to require RRT. Substantially similar criteria for referral have been developed by NICE and KDIGO (Table 81-2). Such criteria are not absolute but should provide a guide to the primary care physician as to which patients are likely to benefit from specialist care. For example, many patients with stable category G4 CKD are successfully managed in the community, often after initial assessment by or with advice from secondary care colleagues.

Unfortunately, a substantial proportion of patients with advanced CKD are referred late, often when they need dialysis. Late referral is often avoidable, although in some cases, patients may have had a truly silent illness or an acute presentation of a disease with rapid decline in kidney function.[9] There is evidence that over recent years the introduction of routine reporting of eGFR, which has facilitated better communication between primary and secondary care providers, has led to a substantial fall in late referrals.[10]

Late presentation is disadvantageous to the patient because it limits the time to select the mode of dialysis or to be listed for "preemptive" kidney transplantation. There may be increased psychological stress, making it difficult for the patient to come to terms with the illness. Furthermore, because an arteriovenous fistula takes several weeks to mature, patients presenting late start hemodialysis with central venous catheters. Catheters are prone to infectious complications and inevitably damage central veins, leading to thromboses and stenoses, which may manifest at a later stage when venous return from one or the other arm is increased by the subsequent construction of an arteriovenous fistula (see Chapter 91).[11] Late presentation of CKD also precludes effective treatment of complications such as hypertension and anemia, which may contribute to cardiovascular damage and ultimately limit life span.[12] Most important, late referral is associated with greater subsequent costs of medical care and a worse prognosis.[13]

PREVENTION OF CHRONIC KIDNEY DISEASE PROGRESSION

Management of CKD should be aimed at slowing the rate of decline of kidney function and minimizing the effects of other complications of CKD. Except for specific management of the underlying kidney disease where possible, the most effective intervention is control of blood pressure, including, in patients with proteinuric CKD, use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). Control of glycemia for patients with diabetes and CKD is covered in Chapter 32.

Hypertension

Hypertension is very common in patients with CKD, and the level of blood pressure is associated with the rate of loss of kidney function.[14] Control of blood pressure slows the rate of decline of kidney function (see Chapter 80), and until recently this led to a focus on "the lower, the better" targets for hypertension management. However, in light of growing evidence about the adverse effects of hypotension, the paradigm has moved toward less-intensive and individualized blood pressure control.[15] Recently, guidelines by both NICE and KDIGO have considered management of hypertension in patients with CKD in depth.[5,16] Both sets of guidelines emphasize the

Suggested Criteria for Referral of Patients with Chronic Kidney Disease (CKD) to a Nephrologist

	NICE 2008	KDIGO 2012
Advanced CKD	Stage 4 and 5 CKD	Category G4 and G5 CKD
Proteinuria	High proteinuria: ACR ≥ 70 mg/mmol unless known to be caused by diabetes and appropriately treated	Consistent proteinuria: ACR ≥ 300 mg/g (≥30 mg/mmol)
Hematuria	Proteinuria (ACR ≥ 30 mg/mmol) together with hematuria	Urinary red cell casts, RBCs > 20 per high-power field sustained; not readily explained
Progression of CKD	Rapidly declining eGFR: >5 ml/min/1.73 m^2 in 1 yr >10 ml/min/1.73 m^2 in 5 yr	Progression of CKD: Sustained decline in eGFR > 5 ml/min/1.73 m^2 in 1 yr Drop in GFR category with a ≥25% drop in eGFR from baseline
Uncontrolled hypertension	Hypertension that remains poorly controlled despite the use of at least four antihypertensive drugs at therapeutic doses	CKD and hypertension refractory to treatment with four or more antihypertensive agents
Hereditary kidney disease	Known or suspected rare or genetic causes of CKD	Hereditary kidney disease
Other conditions	Suspected renal artery stenosis	Recurrent or extensive nephrolithiasis Persistent abnormalities of serum potassium

Table 81-2 Suggested criteria for referral of patients with CKD to a nephrologist. *ACR,* Albumin-creatinine ratio; *eGFR,* estimated glomerular filtration rate; *KDIGO,* Kidney Disease: Improving Global Outcomes; *NICE,* National Institute for Health and Care Excellence; *PTH,* parathyroid hormone; *RBC,* red blood cell. *(Data from references 2 and 5.)*

importance of considering coexistent CVD, other comorbidities, and side effects when choosing medications and blood pressure targets, particularly for elderly patients. Lifestyle modifications, including maintenance of a healthy weight, reductions in salt and alcohol intake, and regular exercise, should be encouraged (see Chapter 35).

Although current recommendations are based on office blood pressure recordings, recent studies suggest that readings obtained from home and ambulatory monitoring correlate better with cardiovascular and kidney outcomes.[17] It is alarming to note that up to 30% of CKD patients who were thought to have hypertension have normal blood pressures at home, and 40% of patients who were thought to be normotensive (or to have adequately treated hypertension) were hypertensive at home.[18] Although ambulatory monitoring is not yet universally recommended, there should be a very low threshold for undertaking 24-hour monitoring or asking patients to undertake self-measurements at home if they prefer.

Target blood pressure levels and antihypertensive therapy in CKD patients are discussed in Chapter 80. ACE inhibitors or ARBs are recommended as first-line agents for patients with evidence of proteinuria, but usually multidrug regimens are required to obtain good control. During intercurrent illness, patients with CKD are vulnerable to drug side effects, particularly hyperkalemia and AKI.[19] The KDIGO guidelines recommend the temporary discontinuation of potentially nephrotoxic and renally excreted drugs (including ACE inhibitors, ARBs, aldosterone inhibitors, direct renin inhibitors, diuretics, nonsteroidal anti-inflammatory drugs [NSAIDs], metformin, lithium, and digoxin) in patients with a GFR below 60 ml/min/1.73 m^2 (CKD categories G3a to G5) who have serious intercurrent illness.

Dietary Advice

Detailed dietary advice and education, along with ongoing support from an appropriately trained professional, are important in the management of patients with CKD. Obesity is associated with a more rapid decline of kidney function, so in early CKD, weight loss may be appropriate. However, in advanced CKD, malnutrition is common (see Chapter 87). The causes are multifactorial but include anorexia, acidosis, insulin resistance, inflammation, oxidative stress, and urinary protein loss. Biochemical indicators may demonstrate a decrease in serum albumin, transferrin, and cholesterol. Weight should be monitored in patients who progress to CKD categories G4 and G5. Serum creatinine concentrations, which in part reflect muscle mass, may stop rising despite a progressive loss of kidney function, because of compromised nutritional status.

In light of this, recommendations to restrict protein intake have been controversial. Although there is evidence that reduced protein intake may slow progression of decline of kidney function, many patients develop protein-calorie malnutrition on a low-protein diet.[20] KDIGO has recommended that protein intake should be lowered to 0.8 g/kg/day in adults with CKD and GFR below 30 ml/min/1.73 m^2, whereas high protein intake (>1.3 g/kg/day) should be avoided in adults with CKD at risk of progression. When this recommendation is followed, detailed dietary assessment and supervision are needed to ensure that malnutrition is prevented.

One of the earliest effects of CKD is to limit the ability of the kidney to compensate for large changes in sodium and water intake (see Chapter 7). Salt and water retention are major factors contributing to hypertension in CKD patients and, in more advanced stages, to morbidity and mortality through systemic or pulmonary edema. Therefore sodium intake should ideally be restricted to less than 90 mmol/day (5 g/day of sodium chloride), except in salt-wasting conditions. Advice about optimal fluid intake at each stage of CKD is needed to prevent volume overload. Salt substitutes containing potassium should be avoided because of the risk for hyperkalemia. In categories G4 and G5 CKD, education and advice about restriction of potassium and phosphate may be required.

MANAGEMENT OF COMPLICATIONS OF CHRONIC KIDNEY DISEASE

A detailed discussion of the complications of CKD is provided in Chapters 82 to 89. With the exception of hypertension, there are usually few clinical manifestations associated with CKD categories G1 and G2 (GFR > 60 ml/min/1.73 m^2). Other complications (discussed in the following sections) tend to develop progressively as GFR declines below 60 and in particular below 30 ml/min/1.73 m^2 (i.e., during CKD categories G4 and G5).

Anemia

Anemia is common in CKD categories G3a to G5 and is caused by a relative deficiency of erythropoietin (EPO), although reduced availability of iron and chronic inflammation are frequent contributory factors (see also Chapter 83). Anemia may have multiple adverse effects, including worsening cardiac dysfunction by increasing cardiac output and exacerbating left ventricular hypertrophy, exacerbating the decline of kidney function, and reducing cognition and concentration. However, clear evidence that reversal of anemia using erythropoiesis-stimulating agents (ESAs) is associated with improved clinical outcomes is lacking, and randomized trials have suggested that in some circumstances these agents may cause harm. This has led to reconsideration of anemia management in CKD in recent years.

A recent KDIGO guideline recommends that all patients identified as having CKD categories G3a and below should have their hemoglobin (Hb) levels monitored annually, increasing to twice a year for categories G4 and G5.[2] Anemia in adults is diagnosed when the Hb concentration falls below 13.0 g/dl in men and below 12.0 g/dl in women. NICE recommends that management of anemia should be considered in patients with CKD when the Hb level is 11 g/dl or lower.[5] In anemic patients, investigations for other causes should be conducted, including measurement of iron stores and serum vitamin B_{12} and folate levels. ESAs should not be started until treatment of iron deficiency or other underlying causes has been addressed, and only then after considering the balance of benefits (from the reduced requirement for blood transfusions and abrogation of anemia-related symptoms) against the potential harms, which may include an increased risk of stroke and malignancy.

If anemia does not respond to correction of underlying causes, such as iron deficiency, KDIGO recommends that ESAs be commenced when Hb concentrations are below 10.0 g/dl, if indicated.[21] Hb target ranges are discussed in Chapter 83.

Bone and Mineral Metabolism

Hyperphosphatemia, together with a deficiency of 1,25-dihydroxyvitamin D_3, contribute to secondary hyperparathyroidism and ultimately to the development of renal bone disease. These biochemical and endocrine changes, in association with the closely related histologic abnormalities of bone and soft tissue calcification, are collectively termed the *CKD–mineral and bone disorder* (see Chapter 85).[22] Bone disease may already be manifested in CKD category G3b and is well established in ESRD, even though patients may

remain asymptomatic. In addition to the need to prevent bone complications, active management of CKD–mineral and bone disorder may help to prevent some of the cardiovascular complications of CKD.[23]

Kidney Disease: Improving Global Outcomes recommends measuring serum levels of calcium, phosphate, PTH, and alkaline phosphatase activity in adults with GFR below 45 ml/min/1.73 m^2 (GFR categories G3b through G5). Determining the optimal level of PTH in CKD has been controversial. For patients with levels of intact PTH above the upper normal limit of the assay, efforts should be made to correct hyperphosphatemia, hypocalcemia, and vitamin D deficiency if present. KDIGO recommends that serum phosphate concentrations be maintained in the normal range according to local laboratory reference values,[24] whereas NICE supports a level between 0.9 and 1.5 mmol/l for patients with category G4 and G5 CKD.[25] Early advice on dietary phosphate management by a specialist dietician or other professional is important in helping patients to achieve this. Phosphate-binding drugs may be required, and their choice is discussed in Chapter 85. Prescription of vitamin D supplements or analogues, in the absence of documented deficiency, to suppress elevated PTH concentrations in patients with CKD not on dialysis is not routinely recommended.

Metabolic Acidosis

The metabolic acidosis associated with CKD is caused by failure of hydrogen ion excretion and may be compounded by the accumulation of organic acids and bicarbonate loss, particularly in interstitial kidney diseases. Clinical symptoms resulting from acidosis are rare until patients reach CKD category G5, when dyspnea may occur as a result of respiratory compensation. Other causes of dyspnea in advanced CKD, such as anemia and pulmonary edema, should always be considered. Acidosis aggravates hyperkalemia, inhibits protein anabolism, and accelerates calcium loss from bone where the hydrogen ions are buffered.[26] Correction of metabolic acidosis may also slow progression of kidney disease.[27]

Kidney Disease: Improving Global Outcomes recommends that in patients with CKD and serum bicarbonate concentrations below 22 mmol/l, oral bicarbonate supplementation should be given to maintain serum bicarbonate within the normal range, unless contraindicated. However, the associated sodium loading may aggravate hypertension and fluid retention, and severe metabolic acidosis associated with symptoms in a patient with CKD category G5 may be an indication to start dialysis.[2]

Cardiovascular Risk

Patients with CKD have an increased prevalence of CVD and are far more likely to die from a CVD-related cause than to progress to ESRD (see Chapter 82). Therefore, appropriate management of existing CVD and minimization of future CV risk is vital for all patients with CKD.

Unfortunately, many trials of interventions for CVD have excluded patients with CKD,[28] and a recent KDIGO update highlights doubt about the relevance of existing standards of care of CVD to patients with CKD.[29] Nonetheless, KDIGO recommend that the level of care for coronary heart disease offered to patients with CKD should not be prejudiced by their CKD. NICE suggests that antiplatelet drugs should be offered to patients with CKD for the secondary prevention of CVD, and KDIGO extends this recommendation to primary prevention for those at risk of atherosclerotic events. However, there is an increased risk of minor bleeding, and a recent systematic review of antiplatelet agents for patients with CKD found that although the incidence of myocardial infarction is reduced, major bleeding is increased. Thus the risks may outweigh benefits among individuals with low risk for cardiovascular events, including those with early stages of CKD, who do not have clinically evident occlusive arterial disease.[30]

For management of dyslipidemia, KDIGO recommends that cholesterol-lowering treatment be routinely offered for the prevention of CVD in patients with CKD who are older than 50 years and to younger patients with additional risk factors, irrespective of baseline lipid values.[31]

Risk of Infections

Infection is the second most common cause of death after CVD in patients with ESRD. This is in part because of defects in both cellular and humoral immunity, which make CKD a state of chronic immunosuppression (see Chapter 84).[32] T-cell responses to *de novo* antigens are deficient, partly because of impaired antigen presentation by monocytes. Neutrophil activation is defective, and although serum immunoglobulin levels are normal, antibody responses to immunization may be poor. Patients with CKD have an increased susceptibility to bacterial infection (particularly staphylococcal), increased risk of reactivation of tuberculosis (typically with a negative tuberculin skin test response), and failure to eliminate hepatitis B and C viruses after infection.

In view of these increased risks, KDIGO recommends that all adults with CKD be offered annual vaccination with influenza vaccine unless contraindicated and that all adults with eGFR below 30 ml/min/1.73 m^2 (GFR categories G4 to G5) and those at high risk of pneumococcal infection (e.g., patients with nephrotic syndrome, with diabetes, or who are receiving immunosuppression) receive vaccination with polyvalent pneumococcal vaccine unless contraindicated.[2] Patients who have received pneumococcal vaccination are offered revaccination within 5 years. In addition, those at high risk of progression of CKD with eGFR below 30 ml/min/1.73 m^2 (GFR categories G4 and G5) should be immunized against hepatitis B and the response confirmed by appropriate serologic testing. This should happen as early as possible to maximize the chances of seroconversion.[33]

CARE OF THE PATIENT WITH PROGRESSIVE CHRONIC KIDNEY DISEASE

To optimize the care of patients with progressive CKD, optimal management is provided in a multidisciplinary setting where a range of professionals are able to provide education and information about diet, different RRT modalities, transplant options, vascular access surgery, and social care. Psychological comorbidity is common among patients with CKD. Health care professionals working with patients with CKD should take account of the psychological aspects of coping with the condition and offer access to support groups, counseling, or a specialist nurse. The aim is to create an environment in which patients can become informed and proactive in their care.

Chronic Kidney Disease and Risk of Acute Kidney Injury

All patients with CKD are at increased risk of AKI, and AKI may be associated with more rapid progression to ESRD.[34] Imaging studies that require iodinated radiocontrast media carry a risk of AKI, and the benefit of a diagnostic scan needs to be balanced against the risks.

If the investigation is needed, the lowest dose of radiocontrast should be used, the patient should be adequately hydrated, and potentially nephrotoxic agents should be withdrawn before and after the procedure; however, the fear of radiocontrast-induced AKI should not prevent or impair a necessary diagnostic workup. The potential risk of nephrogenic systemic fibrosis from gadolinium-based contrast media and measures to reduce it are discussed in Chapter 5.

Many commonly used medications increase the risk of AKI, and the level of GFR should be considered when any drug is prescribed or its dosage determined. As discussed earlier, the need for temporary cessation of all medications should be considered during periods of severe intercurrent illness. Other causes of reduction in kidney perfusion can also lead to AKI, including volume depletion from excessive diuretics, insufficient fluid intake in hot weather, diarrhea or vomiting, heart failure, myocardial infarction, and tachyarrhythmias. Severe hypercalcemia, resulting from either coadministration of high doses of vitamin D and calcium-containing phosphate binders or from underlying disease, can also cause AKI.

Clinicians should always consider whether acceleration of loss of kidney function is a result of relapse of the underlying disease or of a superimposed problem such as acute interstitial nephritis (see Chapter 62), obstructive uropathy (see Chapter 60), or renal vein thrombosis.

Timing the Initiation of Renal Replacement Therapy

Despite all attempts to optimize the management of CKD, many patients will progress to needing RRT. All patients with eGFR below 20 ml/min/1.73 m^2 and/or who are likely to progress to ESRD within 12 months should receive education and counseling to aid their selection of the most appropriate RRT modality. If hemodialysis is the preferred option, an arteriovenous fistula should be constructed, remembering that it may take 8 to 12 weeks for veins to become adequately arterialized before needling can be attempted (see Chapter 91). Similar plans need to be made for preemptive insertion of a peritoneal dialysis catheter to allow time for healing and training before any acute need for commencement of dialysis (see Chapter 96). Peritoneal dialysis catheters can be inserted and completely buried subcutaneously some time before patients require dialysis, then superficialized for use once clinical circumstances dictate.

Early kidney transplantation may be associated with improved long-term outcome,[35] so patients should be assessed for their suitability and, when feasible, activated on the waiting list before dialysis is commenced. This maximizes the chances of the potential recipient remaining in reasonable health. The availability of a living donor should be explored to increase the chances of preemptive transplantation before the patient begins dialysis. KDIGO recommends that living donor preemptive kidney transplantation in adults be considered when the GFR is below 20 ml/min/1.73 m^2 and there is evidence of progressive and irreversible CKD over the preceding 6 to 12 months.[2]

Planned early initiation of dialysis is not associated with improvement in outcomes compared with commencement when indicated by signs and symptoms of uremia.[36] KDIGO suggests that dialysis be initiated when one or more of the following are present: symptoms or signs attributable to kidney failure (serositis, acid-base or electrolyte abnormalities, pruritus); inability to control volume status or blood pressure; a progressive deterioration in nutritional status refractory to dietary intervention; or cognitive impairment.[2] These problems often but not invariably occur when the GFR is below 15 ml/min/1.73 m^2 (see Chapter 90).

Conservative Management

The potential burden of commencing RRT in terms of high short-term mortality rates, recurrent hospitalizations, time spent travelling, and limited improvement in quality of life for some elderly patients and those with multiple comorbid disease is increasingly recognized. This has led to the practice of offering patients approaching ESRD the additional option of choosing not to start dialysis, but to maintain ongoing follow-up and symptomatic support through conservative management. Although dialysis may offer longer survival, those choosing conservative management may have as many hospital free-days as those who choose hemodialysis.[37] The symptoms of advanced uremia can be distressing, and it is important to ensure that patients who choose this pathway have access to members of the multidisciplinary team with expertise in palliative care to facilitate a death free of suffering.

CHAPTER 82

Cardiovascular Disease in Chronic Kidney Disease

Peter Stenvinkel and Charles A. Herzog

The life span of patients with chronic kidney disease (CKD), particularly those with end-stage renal disease (ESRD), is reduced. In the United States, the all-cause mortality rate of prevalent dialysis patients in 2010 was 193 deaths per 1000 patient-years, 38% attributable to cardiac causes.[1] Diminished estimated glomerular filtration rate (eGFR) is a powerful graded, independent predictor of cardiovascular morbidity and mortality[2] and all-cause mortality (Fig. 82-1).[3] Even subtle kidney dysfunction, as suggested by albuminuria, increases cardiovascular risk[4] because it may reflect microvasculature health, including endothelial function. There is a strong association between urinary albumin excretion and other cardiovascular risk factors.[5] ESRD patients face an extraordinary risk for premature death, largely as a result of cardiovascular complications. However, the numbers of patients with non–dialysis-dependent CKD are much larger, and those with eGFR below 60 ml/min/1.73 m^2 are much more likely to die than to develop ESRD,[6] reflecting the burden of cardiovascular disease (CVD) in this high-risk population. The most effective strategy for reducing cardiovascular morbidity and mortality would be to target patients with mild renal impairment for prevention and treatment before severe CKD develops.

Unfortunately, CKD patients were often excluded from randomized controlled trials targeting CVD, or renal function was poorly described,[7] possibly reducing acceptance of evidence-based therapies (validated in nonrenal patients) and fostering "therapeutic nihilism" in clinicians who treat CKD patients.

Like conventional atheromatous occlusive vascular disease, CKD is characterized by generalized vasculopathy with other characteristics, including left ventricular hypertrophy (LVH), vascular calcification, and vascular noncompliance. Numerous CVD risk factors are specific for CKD and operate in addition to conventional risk factors found in the general population.

EPIDEMIOLOGY

Prevalence of Cardiovascular Complications in Chronic Kidney Disease

Interpretation of epidemiologic studies of CVD in CKD is problematic because of the difficulty in defining cause of death, but this difficulty is not limited to renal disease patients. Unexpected sudden death is most likely a result of arrhythmia, but a subarachnoid hemorrhage, massive embolic stroke, or aortic dissection might be indistinguishable from a primary arrhythmic event without an autopsy. The real conundrum, however, is defining "coronary heart disease" (CHD). In the general population, sudden cardiac death is rightly considered a primary complication of CHD; evidence-based interventions (e.g., statins) aimed at quelling the progression of atherosclerotic disease reduce the incidence of sudden death. However, in dialysis patients, sudden cardiac death is likely not to be a surrogate for CHD. Even use of a history of angina to classify a patient as having CHD is problematic because angina (as a result of supply-demand mismatch) can occur in patients with LVH and angiographically pristine coronary arteries. This probably relates to the increased myocardial fibrosis, diminished relative capillary density, and increased thickening of the intramyocardial vessel walls in uremia.

Of incident ESRD patients, 75% have LVH. Hypertension prevalence increases progressively with falling GFR; 75% to 85% of dialysis patients have hypertension. With hypertension, anemia, vascular noncompliance, and volume overload contribute to LVH. Based on echocardiography, 85% to 90% of patients have a left ventricular (LV) ejection fraction (EF) of 50% or higher, despite frequent congestive heart failure (CHF).[8] Because CHF is diagnosed in about 40% of incident ESRD patients within the first year,[9] many volume overload episodes may be attributable to diastolic dysfunction or circulatory congestion. CHF hospitalizations are associated with high long-term mortality.[10] Although occlusive CHD is common in CKD patients, acute myocardial infarction (AMI) accounts for only 13% of cardiac deaths; 69% of deaths in the United States Renal Data System (USRDS) database are attributable to arrhythmias.[11] In incident elderly dialysis patients, new atrial fibrillation (AF) occurs at an annual rate of 15%, with 59% mortality in the first year after incident AF.[12] Figure 82-2 provides a snapshot of CVD event rates in prevalent ESRD patients.

Congestive heart failure results from pressure overload, volume overload, and nonhemodynamic factors altering the myocardium.[13] Figure 82-3 summarizes cardiorenal syndrome pathophysiology leading to cardiomyopathy and CHF.

Cardiovascular Disease Is Present Before the Start of Renal Replacement Therapy

In elderly CKD patients at stage 2 or 3, traditional risk factors seem to be the major contributors to cardiovascular mortality. Atherosclerosis Risk in Communities (ARIC) data suggest that both traditional and novel risk factors are relevant at CKD stage 4,[14] and studies of dialysis patients suggest that novel risk factors are far more prevalent than in the general population (Fig. 82-4).[15] The Framingham predictive instrument does not accurately predict coronary events in CKD.[16] Mild to moderate CKD is associated with increased risk of venous thromboembolism,[17] supporting the concept of hypercoagulability in CKD. A Kidney Disease: Improving Global Outcomes (KDIGO) collaborative meta-analysis provides estimates of cardiovascular and all-cause mortality risk stratified by eGFR and urinary albumin-creatinine ratio (Fig. 82-5).[18] Figure 82-6 shows the burden of CVD in elderly patients with and without non–dialysis-dependent CKD.

Racial and International Differences in Cardiovascular Disease Prevalence

In the United States, African American dialysis patients have better survival than Caucasian dialysis patients. However, overall

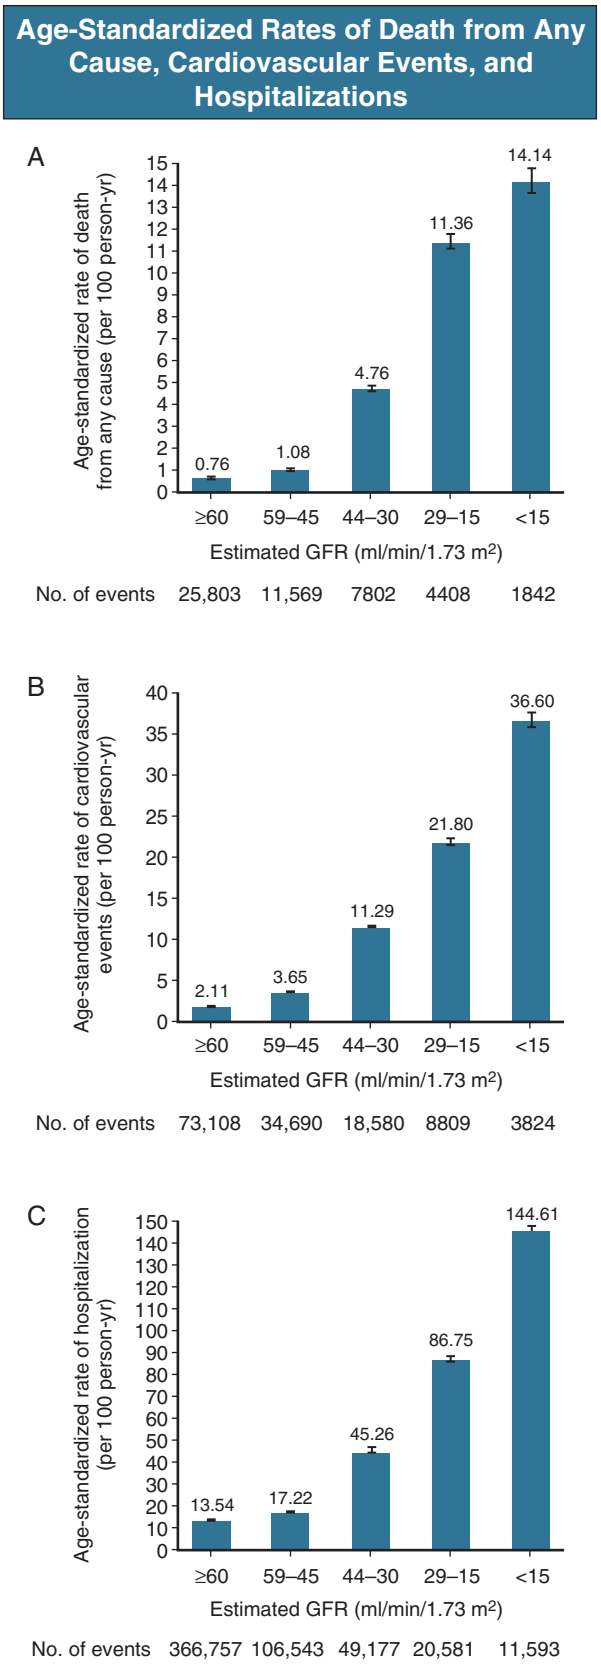

Figure 82-1 Age-standardized rates of death from any cause (A), cardiovascular events (B), and hospitalization (C) according to estimated glomerular filtration rate (GFR) among 1,120,295 ambulatory adults. A cardiovascular event was defined as hospitalization for coronary heart disease, heart failure, ischemic stroke, or peripheral arterial disease. Error bars represent 95% confidence intervals. The rate of events is listed above each bar. *(From reference 2.)*

cardiovascular mortality among dialysis patients from the United States is significantly greater than is observed in Japan and Europe,[19] even after adjustment for standard risk factors and dialysis dose. Higher mortality rates in U.S. dialysis patients may be related to higher prevalence of sicker or diabetic patients or to differences in dialysis practice patterns; however, cultural habits, differences in diet, or genetic variations may also contribute.

Reverse Epidemiology

Reverse epidemiology refers to the paradoxical observation that the association among hypercholesterolemia, hypertension, obesity, and poor outcomes, including cardiovascular death, in the general population does not exist and may be reversed in the CKD population.[20] This concept is needlessly confusing and should be replaced by *confounded epidemiology.* Causality must not be confused with association. It is assumed (but open for debate) that patients with wasting and inflammation mostly account for poor survival and confounded epidemiology.

ETIOLOGY AND RISK FACTORS

Traditional Risk Factors

Age, Gender, and Smoking

The U.S. National Health and Nutrition Examination Surveys (NHANES) show the prevalence of cardiovascular risk factors and CVD prevalence in relation to age and CKD stage. In the United States, the average age at renal replacement therapy initiation is 63 years, when CVD is common. An individual-level meta-analysis including more than 2 million participants showed that low eGFR and high albuminuria were independently associated with mortality and ESRD regardless of age.[21] Female gender is associated with a 4% independent increased risk of mortality in incident dialysis patients,[5] and smoking with a 52% increased risk of death in dialysis patients.[22]

Diabetes Mellitus

Diabetes accounted for 44% of incident U.S. ESRD patients in 2010[1] and is the most common cause of ESRD in many countries. Diabetic patients starting renal replacement therapy have numerous cardiovascular risk factors, including dyslipidemia, hypertension, persistent inflammation, increased oxidative stress, and protein-energy wasting. Not surprisingly, diabetes at dialysis initiation is an independent risk factor for all-cause and CVD-related deaths, including after coronary revascularization or AMI; diabetic ESRD confers a 34% mortality risk after AMI compared with nondiabetic ESRD. Despite diabetes being a "CHD equivalent," the rate of incident AMI is even higher for patients with CKD stages 3b to 4 without diabetes than for patients with diabetes and eGFR of 60 ml/min/1.73 m^2 or higher.[23]

Hypertension

Hypertension is common but variably treated in CKD patients. Of NHANES[5] participants with CKD stages 3 and 4, 80% were hypertensive (defined as blood pressure ≥130/≥80 mm Hg for CKD patients), and only 20% were aware of it and treated, with the blood pressure adequately controlled. Of participants with CKD stages 1 and 2, 63% were hypertensive and only 11% of these were treated, with blood pressure adequately controlled. More recent data from NHANES 2001 to 2010 suggest modest improvement in hypertensive people with CKD stages 3 to 4.[24] Low blood pressure is correlated with mortality in some dialysis patients (see the discussion of reverse epidemiology). However, as in the general population,

Summary of Relative Risks for All Causes and Cardiovascular Death Based on eGFR and Albumin-Creatinine Ratio

All-cause mortality

	ACR <10	ACR 10–29	ACR 30–299	ACR ≥300
eGFR >105	1.1	1.5	2.2	5.0
eGFR 90–105	Ref	1.4	1.5	3.1
eGFR 75–90	1.0	1.3	1.7	2.3
eGFR 60–75	1.0	1.4	1.8	2.7
eGFR 45–60	1.3	1.7	2.2	3.6
eGFR 30–45	1.9	2.3	3.3	4.9
eGFR 15–30	5.3	3.6	4.7	6.6

Cardiovascular mortality

	ACR <10	ACR 10–29	ACR 30–299	ACR ≥300
eGFR >105	0.9	1.3	2.3	2.1
eGFR 90–105	Ref	1.5	1.7	3.7
eGFR 75–90	1.0	1.3	1.6	3.7
eGFR 60–75	1.1	1.4	2.0	4.1
eGFR 45–60	1.4	2.2	2.8	4.3
eGFR 30–45	2.2	2.7	3.4	5.2
eGFR 15–30	14	7.9	4.8	8.1

hypertension predicts mortality in CKD patients before or at dialysis initiation. Isolated systolic hypertension with increased pulse pressure is by far the most prevalent blood pressure anomaly in dialysis patients, resulting from arterial medial sclerosis with secondary stiffening. Stiff vessels cause increased pulse wave velocity, resulting in increased systolic peak pressure by a prematurely reflected pulse wave, progressive LV dysfunction, and finally CHF. This may subsequently result in decreased mean arterial and diastolic pressure and increased risk for cardiovascular death. The relationship between blood pressure and mortality is U shaped; isolated systolic hypertension and increased pulse pressure probably indicate high long-term risk in dialysis patients, whereas low mean and diastolic blood pressures predict early mortality. The invisible hypertension danger relates to numerous CKD patients being "nondippers" (see Chapter 33). CKD patients frequently also experience sleep apnea associated with nondipping, sympathetic nervous system activation, and cardiovascular risk.

Dyslipidemia

The relationship among hypercholesterolemia, CVD, and mortality in CKD patients is weak because some major cardiovascular abnormalities, such as cardiomyopathy and arteriosclerosis, may be less dependent on dyslipidemia than on other factors. Paradoxically, low rather than high serum cholesterol level is associated with poor survival in hemodialysis (HD) patients,[20] confounded epidemiology likely related to protein-energy wasting and inflammation. After adjustment for C-reactive protein (CRP) levels, high cholesterol level predicted risk in relatively healthy ESRD patients without inflammation.[25]

Progressive CKD leads to changes in blood lipids associated with vascular disease, including decreased levels of apolipoprotein A (apoA)–containing lipoproteins and increased levels of apoB-containing lipoproteins (Table 82-1). Plasma triglyceride levels are elevated in most ESRD patients, whereas total serum cholesterol levels may be elevated, normal, or low, depending on nutritional status and presence of inflammation. High-density lipoprotein (HDL) cholesterol is typically reduced, and low-density lipoprotein (LDL), intermediate-density lipoprotein, and very low-density lipoprotein cholesterol as well as lipoprotein(a) levels tend to be increased. Because of specific changes in its molecular composition, HDL anti-inflammatory activities are defective in the uremic milieu.[26] Compared with long-term HD patients, peritoneal dialysis (PD) patients more often have both hypercholesterolemia and hypertriglyceridemia. Both groups are characterized by low HDL and elevated oxidized LDL cholesterol levels; elevated lipoprotein(a) levels are associated with increased CVD mortality.

Insulin Resistance and Atherosclerosis

In the general population, impaired insulin-stimulated glucose disposal in muscle is often part of a metabolic syndrome that includes dyslipidemia, hypertension, endothelial dysfunction, and sympathetic overactivity. Many of these abnormalities are present in CKD.

Although insulin resistance was found to be an independent predictor of cardiovascular mortality in dialysis patients,[27] its contribution to CKD patient mortality is uncertain.

Nontraditional and Uremia-Specific Risk Factors

Several large prospective population studies have shown that even mild CKD is an independent risk factor for CVD, independent of hypertension, diabetes, and albuminuria, and similar in magnitude to diabetes and hypertension.[28,29] The uremic milieu may affect both quality and quantity of the atherosclerotic plaques. Coronary lesions in uremic patients, compared with nonrenal controls, are characterized by increased media thickness, infiltration, and activation of macrophages and marked calcification.[30] The mechanism by which a uremic milieu may accelerate atherosclerosis is not well established, but prevalence and magnitude of several nontraditional risk factors, such as oxidative stress, inflammation, vascular calcification, and advanced glycation end products (AGEs), increase as renal function deteriorates. Other uremic retention solutes, such as asymmetric dimethylarginine (ADMA), guanidine, indoxyl sulfate, and *p*-cresol, which accumulate in CKD, may have proatherogenic properties.[31] Finally, the kidneys produce substances that may inhibit CVD and atherogenesis—for example, renalase, a soluble monoamine oxidase that regulates cardiac function and blood pressure.[32]

Oxidative Stress

Oxidative stress may be implicated in the pathogenesis of atherosclerosis and the increased risk of atherosclerotic cardiovascular events and in other CKD complications, such as protein-energy wasting and anemia.[33] Increased production of reactive oxygen species in the vascular wall is a characteristic feature of atherosclerosis.[33] Early CKD (stage 3), and in particular uremia, is a pro-oxidant state resulting from reduced antioxidant systems (vitamin C and selenium deficiency, reduced intracellular vitamin E levels, reduced glutathione system activity) and increased pro-oxidant activity associated with advanced age, diabetes, chronic inflammation, retained uremic solutes, and dialysis membranes and solutions.[33] Four oxidative stress pathways can be hypothesized in CKD: carbonyl stress, nitrosative stress, chlorinated stress, and classical oxidative stress (Fig. 82-7).

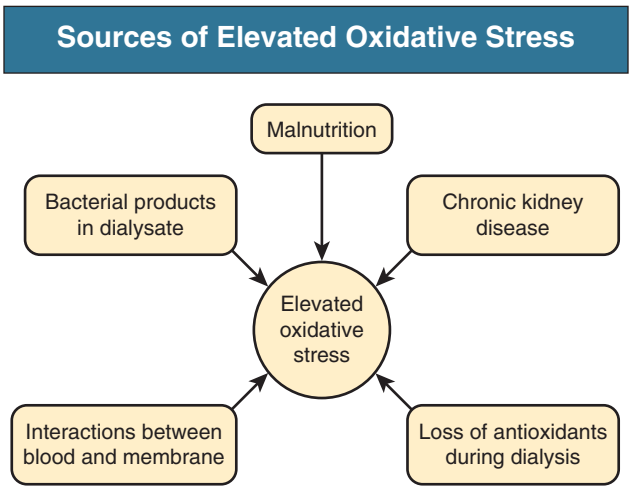

Figure 82-7 Sources of elevated oxidative stress.

Inflammation

Most dialysis patients are in a state of chronic inflammation; inflammatory biomarkers, such as CRP, interleukin (IL)-6, pentraxin 3 (PTX3), fibrinogen, and white blood cell count, are robust and independent predictors of mortality in CKD patients. Hypoalbuminemia, a biochemical factor strongly associated with systemic inflammation, is another strong outcome predictor in CKD. Whereas both dialysis-related factors and non–dialysis-related factors (infection, comorbidity, genetic factors, diet, renal function loss) may contribute to chronic inflammation, its primary causes are not always evident. As in the general population, it is unclear in CKD patients whether the acute-phase response reflects only established atherosclerotic disease or is involved in the initiation and progression of atherosclerosis. Some inflammatory biomarkers, such as IL-6, PTX3, and tumor necrosis factor, may have proatherogenic properties, such as promoting vascular calcification, oxidative stress, and endothelial dysfunction (Fig. 82-8). Evidence also suggests associations between inflammation and development of albuminuria. The link between septicemia and subsequent increased risk of death and cardiovascular events, including AMI, in observational studies further supports inflammation as a trigger for cardiovascular events.[34]

Endothelial Dysfunction

Endothelial dysfunction (as evaluated by impaired endothelium-dependent vasodilation) is a prominent feature of CKD. Reasons include inflammation, ADMA retention, oxidative stress, dyslipidemia, hyperglycemia, and hypertension. Plasma ADMA concentrations are associated with endothelial function in uremic resistance vasculature.[35] Surrogate markers of endothelial dysfunction, such as ADMA, PTX3, and adhesion molecules, independently predict death.[15] Detached circulating endothelial cells serve as potential markers of endothelial damage in renal and nonrenal patients and have prognostic value in HD patients.[15] Normally, in response to ischemic insult and cytokine stimulation, endothelial progenitor cells are mobilized from the bone marrow to act as repair cells for the endothelial injury. Because CKD patients seem to have reduced numbers or functional impairment of endothelial progenitor cells as a result of inflammation or uremic toxins, they seem predisposed to endothelial dysfunction. An independent association exists between circulating fibroblast growth factor 23 (FGF23) and endothelial dysfunction.[36]

Anemia

Anemia is a major cause of LVH and LV dilation in CKD. Although partial correction of anemia with erythropoiesis-stimulating agents (ESAs) results in LVH regression, current information suggests no cardiovascular outcome benefit of normalized hemoglobin (see Chapter 83).

Secondary Hyperparathyroidism and Mineral Metabolism

Disturbances of calcium and phosphate metabolism starting as early as CKD stages 3 and 4 might accelerate calcifying atherosclerosis and arteriosclerosis. Recent evidence suggests that chronically elevated FGF23 levels contribute directly to high rates of LVH and mortality in CKD.[37] In registry data, a strong independent mortality risk is predicted by hyperphosphatemia, an intermediate risk by elevated serum calcium levels, and a weak but significant risk by high or low serum intact parathyroid hormone levels. The overall mortality risk prediction attributable to mineral metabolism disorders is estimated to be about 17% in HD patients.[38]

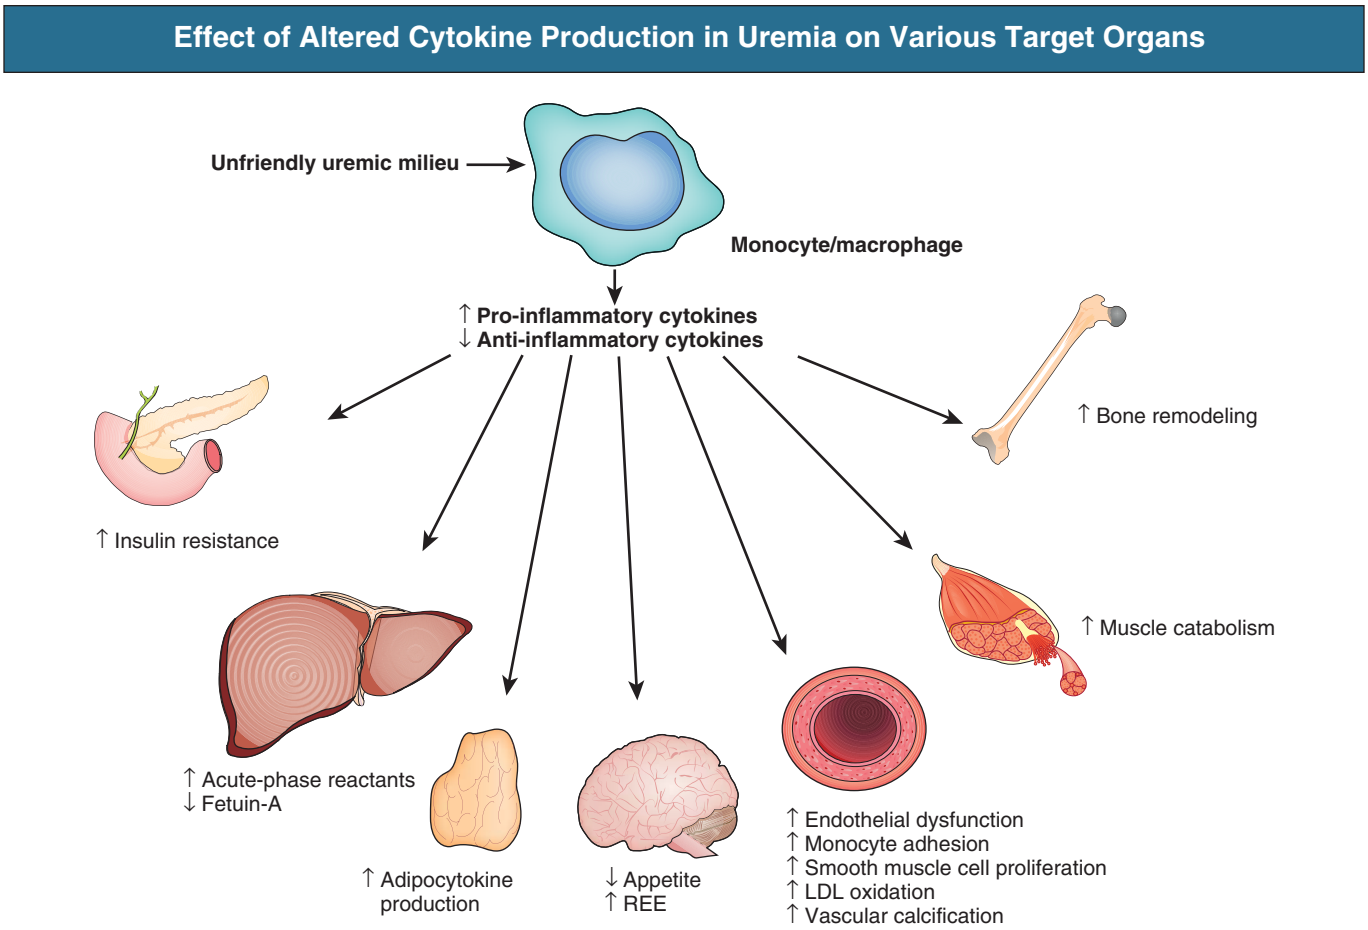

Figure 82-8 Potential mechanisms by which elevated circulating levels of proinflammatory and anti-inflammatory cytokines may promote accelerated atherosclerosis, other uremic complications, and wasting. *LDL,* Low-density lipoprotein; *REE,* resting energy expenditure. *(From reference 31).*

Cardiovascular Calcification

Cardiovascular calcification may affect the arterial media, atherosclerotic plaques, myocardium, and heart valves. Medial calcification causes arterial stiffness and, consequently, increased pulse pressure. The pathophysiologic role of plaque calcification is less clear because soft plaques are assumed to rupture and to cause AMI; atherosclerotic calcification is a potent risk marker of cardiovascular events, but its utility as a risk marker for clinical management of CKD patients remains controversial. Valvular calcification mostly affects the aortic and mitral (annulus) valves in dialysis patients and contributes to progressive stenosis and associated morbidity; mitral annular calcification is associated with increased mortality.[39] In dialysis patients, extensive vascular, especially coronary artery, calcification can occur at young ages. Calcium and phosphate metabolism disturbance is an important factor in cardiovascular calcification in ESRD. A serum phosphate level of 5.0 mg/dl or higher (≥1.62 mmol/l) is associated with increased risk of valvular heart surgery in HD patients.[40] Calciphylaxis (calcific uremic arteriolopathy), characterized by severe calcifications of cutaneous arterioles and tissue necrosis, is discussed in Chapter 88.

Vascular calcification is not derived only from passive calcium and phosphate precipitation. Rather, it is a highly regulated active process involving differentiation of vascular smooth muscle cells toward osteoblasts induced by phosphate, calcium, and other factors, such as calcitriol and proinflammatory cytokines. One way by which chronic inflammation promotes vascular calcification may involve downregulation of fetuin-A, the most potent circulating inhibitor of extraosseous calcification and formation of calciprotein particles.[41] In cross-sectional studies, dialysis patients with low serum fetuin-A levels showed significantly poorer survival than those with normal values.[42] Apart from fetuin-A, other inhibitors probably counteract unwanted calcification. Leptin, matrix GLA protein, FGF23, pyrophosphates, bone morphogenic proteins (e.g., BMP-2 and BMP-7), and osteoprotegerin may be related to accelerated vascular calcification in ESRD. Recent studies indicate that deficiency of vitamin K and/or treatment with vitamin K antagonists (warfarin) may accelerate the vascular calcification process in the uremic milieu.[43]

Advanced Glycation End Products

Advanced glycation end products accumulate in CKD patients as a result of nonenzymatic glycation, oxidative stress, and diminished clearance of AGE precursors. Stable AGE residues of long-lived proteins are biomarkers of cumulative metabolic, inflammatory, and oxidative stress; carbonyl stress is speculated to contribute to tissue aging and long-term CKD complications. Whether AGE inhibition may be a useful intervention to reduce cardiovascular events, progression, and mortality in CKD is unknown.

Dialysis Modality

Reports from dialysis registries are inconsistent with regard to whether HD or PD is associated with better outcomes.[44] Valid mortality comparisons between modalities would require stratification

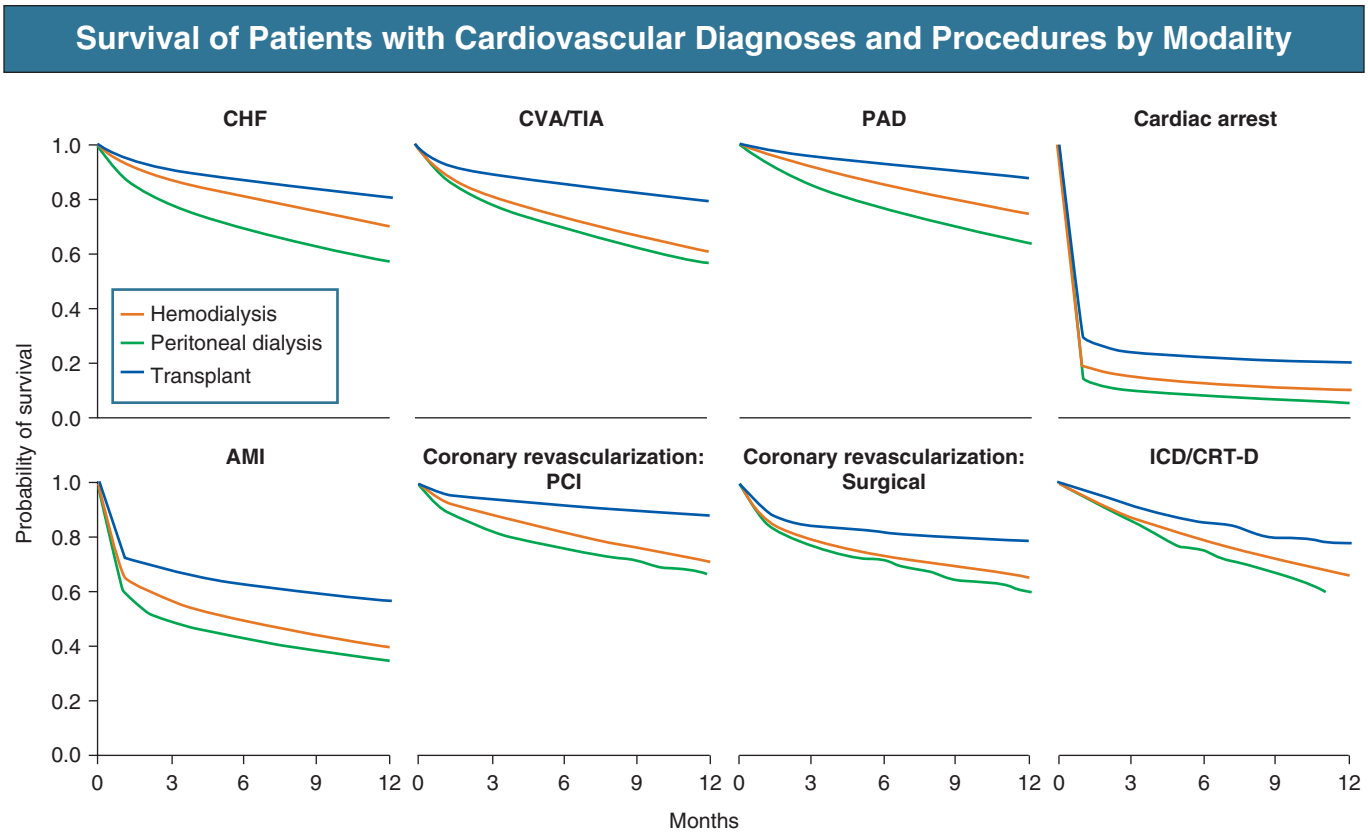

Figure 82-9 Survival of patients with cardiovascular diagnoses and procedures, by modality. January 1, 2005, point prevalent ESRD patients, age 20 and older, with a first cardiovascular diagnosis or procedure in 2005-2007. *AMI,* acute myocardial infarction; *CHF,* congestive heart failure; *CRT-D,* cardiac resynchronization therapy defibrillator; *CVA,* cerebrovascular accident; *ICD,* implantable cardioverter-defibrillator; *PAD,* peripheral arterial disease; *PCI,* percutaneous coronary intervention; *TIA,* transient ischemic attack. *(Modified from reference 166.)*

of patients according to underlying ESRD cause, age, and level of baseline comorbidity.[44] Such data are currently not available.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Figure 82-9 shows survival of patients with cardiovascular diagnoses and procedures, by renal replacement therapy modality.

Chest Pain, Coronary Heart Disease, and Acute Myocardial Infarction

Acute myocardial infarction in dialysis patients is associated with poor long-term survival. The unadjusted 73% 2-year mortality rate has changed minimally in 25 years[45] despite dramatic improvements in AMI outcomes in the general population (Fig. 82-10). This heightened mortality is not restricted to ESRD patients; in-hospital deaths increase with decreasing GFR (Fig. 82-11).[46-48] Furthermore, the likelihood of prescribing evidence-based therapies, including aspirin and β-blockers, in CKD patients is historically diminished[46-49] (but recently increased),[1] although these therapies decrease mortality in such patients.

Prior speculations have attributed this poor outcome to underrecognition resulting from "atypical" presentations,[49] underuse of appropriate diagnostic investigations, and undertreatment (therapeutic nihilism).[49,50] The collaborative USRDS/National Registry of Myocardial Infarction study[50] of dialysis patients hospitalized for AMI found that:

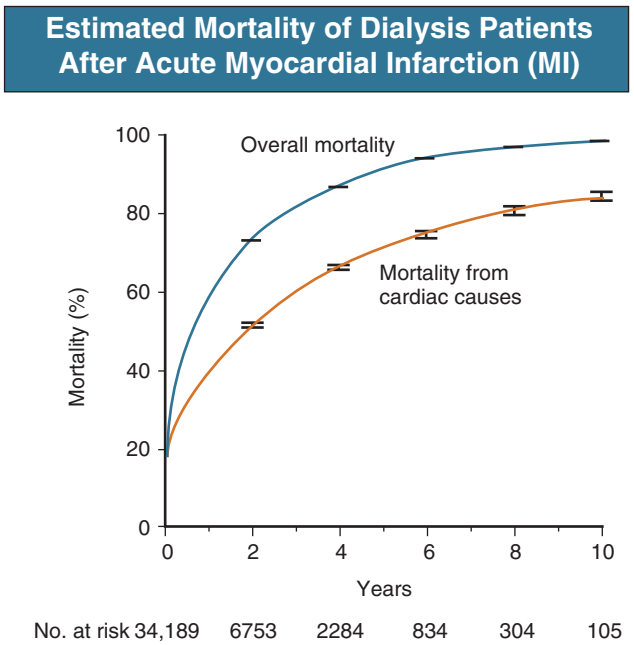

Figure 82-10 Estimated mortality of dialysis patients after acute myocardial infarction. *(Reprinted with permission from reference 167. Copyright © 2003 American Society of Nephrology.)*

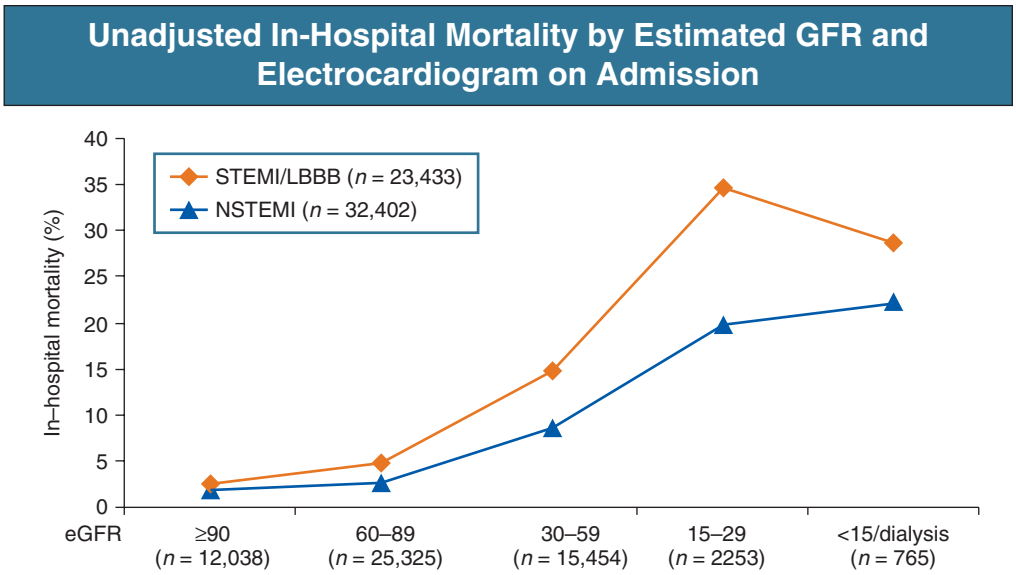

Figure 82-11 Unadjusted in-hospital mortality by estimated glomerular filtration rate (GFR) and electrocardiogram on admission. *LBBB,* Left bundle branch block; *NSTEMI,* non–ST-segment elevation myocardial infarction; *STEMI,* ST-segment elevation myocardial infarction. *(From reference 46.)*

- 45% of dialysis patients, versus 21% of nondialysis patients, were diagnosed incorrectly with respect to acute coronary syndrome.
- 44% of dialysis patients, versus 68% of nondialysis patients, experienced chest pain.
- 19% of dialysis patients, versus 36% of nondialysis patients, had ST-segment elevation.
- After other clinical exclusions, only 10% of dialysis patients, versus 25% of nondialysis patients, were eligible for acute coronary reperfusion.
- Of those who were eligible, 47% of dialysis and 75% of nondialysis patients actually received reperfusion.
- In-hospital death was 21% for dialysis and 12% for nondialysis patients. In-hospital cardiac arrest occurred twice as frequently in dialysis as in nondialysis patients (11% vs. 5%).

Similar findings occur across the CKD spectrum; the likelihood of increased mortality and lower prevalence of both ST-segment elevation myocardial infarction (STEMI) and chest pain are correlated with severity of non–dialysis-dependent CKD in patients with AMI.[47,48,51] Patients with eGFR below 45 ml/min/1.73 m^2 are three times as likely to present with AMI as with stable angina as the initial manifestation of CHD.[52]

Peripheral Arterial Disease

Risk of peripheral arterial disease (PAD) is highest for dialysis patients with diabetes or preexisting atherosclerosis. In HD patients, PAD is also associated with time on dialysis, hypoalbuminemia, low parathyroid hormone levels, and low predialysis diastolic blood pressure. Vascular medial calcification of large peripheral arteries may not indicate presence of occlusive disease, and peripheral gangrene is often caused by diabetic or other small-vessel disease or rarely by calcific uremic arteriolopathy (see Chapter 88). PAD is associated with increased mortality; outcomes after revascularization are worse than for the general population,[53] in part reflecting advanced vasculopathy. About one fourth of CKD patients and half of HD patients have PAD,[1,54] and the knowledge gaps regarding treatment of PAD in CKD patients are large.[13]

Cerebrovascular Disease and Atrial Fibrillation

Cognitive impairment is severe in more than a third of dialysis patients, and only 15% have normal cognition.[55] Cognitive impairment prevalence increases approximately 10% per 10 ml/min/1.73 m^2 of eGFR less than 60 ml/min/1.73 m^2.[56] Microalbuminuria and stage 3 CKD increased stroke risk 1.5-fold to 2-fold in a multivariate model.[57,58] Incident dialysis patients have a sixfold age-adjusted relative risk of stroke compared with the general population; the unadjusted rate for stroke hospitalization for dialysis patients was 48 per 1000 patient-years, and 11% of these hospitalizations were attributed to hemorrhagic stroke.[59] Dialysis initiation is associated with a fourfold to sevenfold increased stroke incidence compared with the rate 12 months before initiation.[60] Stroke accounts for 3% of ESRD deaths in the USRDS registry[1] (see Chapter 86 for more details).

Atrial fibrillation is the most common dysrhythmia in CKD patients; the prevalence among dialysis patients is 15% to 20%, and AF is associated with an increased stroke rate. Incident AF is an independent risk factor for development of ESRD in patients with CKD.[61] The incidence of AF is high and apparently increasing in older patients initiating dialysis in the United States.[12] Among warfarin-treated AF patients with stage 3 CKD, the hazard of stroke doubled versus lower CKD stages, and adjusted-dose warfarin was associated with a 76% reduction in the relative risk of ischemic stroke or systemic embolism.[63] In AMI patients with AF, warfarin treatment was associated with a lower 1-year risk for the composite outcome of death, AMI, and ischemic stroke without a higher risk of bleeding, irrespective of CKD severity was observed.[63a] In contrast, the usefulness of warfarin for primary prevention of stroke in dialysis patients with AF is controversial; because of observational studies suggesting harm, current KDIGO recommendations do not include routine warfarin therapy for primary prevention of stroke in AF patients with CKD stage 5D (however, warfarin for secondary prevention of stroke is recommended).[13,64]

Left Ventricular Remodeling and Hypertrophy

Left ventricular hypertrophy is a potent predictor of mortality in ESRD patients. LVH is associated with a 60% increased risk of sudden death and a more than twofold increased risk of stroke.[65] LVH occurs early in progressive CKD, probably because of high hypertension prevalence, including frequent nocturnal hypertension. Pressure overload, caused by hypertension and arterial stiffness, results in concentric hypertrophy. Volume overload manifests as eccentric hypertrophy. LV dilation strongly predicts poor outcome.

It may be an end result of severe LVH, diffuse ischemic damage, or recurrent volume overload; a high-output arteriovenous fistula may contribute. Diastolic dysfunction is strongly associated with LVH and with increased risk for intradialytic hypotension because relatively small reductions in left atrial filling have significant effects on cardiac output in these stiff, hypertrophied preload-sensitive hearts, together with Bezold-Jarisch reflex activation through stimulation of LV posterior wall stretch receptors in underfilled, hypercontractile, hypertrophied ventricles.

The term "uremic cardiomyopathy" is misleading; "cardiomyopathy of advanced CKD" more accurately describes the structural heart disease that occurs before ESRD onset. The Chronic Renal Insufficiency Cohort (CRIC) Study found no change in LV mass index in patients serially imaged with echocardiograms with eGFR below 20 ml/min/1.73 m^2 (not on dialysis) and subsequently imaged after dialysis initiation (i.e., after incident ESRD), a finding corroborated by the Initiating Dialysis Early and Late (IDEAL) trial.[66] In the CRIC study, dialysis initiation was associated with a small drop in left ventricular ejection fraction (LVEF; mean 53% to 50%), compared with no change in the IDEAL trial. In CRIC patients with stage 4 CKD (and no clinical heart failure), 75% had LVH and only about 10% had normal LV geometry.[67]

Conventional HD delivery can produce repetitive myocardial injury, leading to global and segmental reduction in LV systolic function[68]; the occurrence of HD-induced myocardial stunning is associated with 1-year mortality.[69] Even pediatric HD patients can experience HD-induced myocardial stunning, indicating that large-vessel obstructive CHD is not a prerequisite for this pathologic finding.[70] Biofeedback dialysis or reduced dialysate temperature both help reduce intradialytic hypotension and severity of HD-induced myocardial stunning.[71]

Extracellular Volume Overload

Extracellular volume overload resulting from loss of sodium excretory capacity is the major cause of hypertension in dialysis patients. Whether prevention of recurrent hypervolemia reduces cardiovascular morbidity and mortality remains unproved. If adjustments are made for comorbidity and advanced age, a strong, incremental risk of all-cause and cardiovascular mortality is associated with interdialytic weight gains.[72] Recurrent hypervolemia may result in LVH and LV dilation, peripheral or pulmonary edema, raised jugular vein pulse, or a third heart sound, or it may be largely asymptomatic. Tolerance of large ultrafiltration volumes may indicate that the dry weight target (see Chapter 94) has not been reached. Reaching an optimal dry weight, however, does not necessarily lead to immediate blood pressure correction; a lag phase of some weeks can precede improvement.

Pericarditis

Pericarditis from untreated uremia is rare today. Dialysis-associated pericarditis may be related to intercurrent illnesses (including viral infections), fistula recirculation leading to underdialysis, or underlying diseases such as systemic lupus, but the exact pathogenesis remains obscure. Fever with pericardial pain or a rub on heart auscultation, unexplained cardiomegaly on chest films, or hemodynamic instability should prompt echocardiography. An effusion causing overt hemodynamic compromise (i.e., pericardial tamponade) or large pericardial effusions judged unlikely to resolve with conservative measures require echocardiographically guided or computed tomography (CT)–guided pericardiocentesis or surgical drainage. Intensive dialysis is indicated for true uremic pericarditis; the optimal treatment of dialysis-associated pericarditis is much less clear in patients without hemodynamic compromise.[73] Aggressive anticoagulation should be avoided because of increased (but not well defined) risk for development of hemorrhagic pericarditis and pericardial tamponade.

Autonomic Dysfunction

Chronic kidney disease involves decreased baroreflex sensitivity, which has been linked to increased risk of sudden death.[74] Increased sympathetic nerve activity, including secondary to sleep apnea, is a common alteration in CKD patients and associated with adverse outcome.[75]

Valvular Disease

The rate of progression of calcific aortic stenosis is approximately three times faster in dialysis patients than in the general population.[76] Annual echocardiographic follow-up is recommended for asymptomatic dialysis patients who are suitable candidates for valve replacement with an aortic valve area of 1.0 cm^2 or less.[77] A USRDS study and a meta-analysis of dialysis patients undergoing valve replacement surgery found no difference in survival for patients receiving tissue versus mechanical valves and fewer valve-related complications with tissue valves.[78,79] The overall mortality is high, with in-hospital mortality of about 20% (four times higher than in non-CKD patients) and 2-year survival of 40%. In kidney transplant patients, in-hospital mortality was 11% for tissue and 15% for mechanical valve patients, and 2-year mortality rates were 62% and 60%, respectively. In the entire cohort of kidney transplant patients, the rate of endocarditis after valve surgery was 5% per year.[80]

Infective Endocarditis

Estimated incidence of infective endocarditis in U.S. dialysis patients is 267 cases per 100,000 patient-years.[81] Vascular access, including temporary and semipermanent catheters, is an important source of infection; heightened risk of bacteremia related to HD therapy is likely an important aspect of endocarditis risk. Dialysis patients with bacterial endocarditis have poor long-term survival. In-hospital mortality was 24% and 1-year survival only 38% for patients hospitalized in 1997 to 2000.[82]

A risk model for operative mortality may be helpful in managing these high-risk patients.[83]

Sudden Cardiac Arrest

In the USRDS database, two-thirds of all cardiac deaths and one quarter of all-cause mortality in dialysis patients are attributable to arrhythmias.[1] Although obstructive CHD is likely to be an important cause of sudden cardiac death, it is probably not the major one (unlike in the general population). Statin therapy has no impact on sudden death,[84] and a USRDS study found that coronary revascularization does not nullify the risk of sudden cardiac death for dialysis patients.[85] However, in the Hemodialysis (HEMO) trial the strongest multivariable predictors of sudden cardiac death were history of CHD, PAD, and diabetes.[86] Sudden cardiac death is independently associated with inflammatory biomarkers.[87] Myocardial fatty acid imaging might identify patients at risk for sudden death.[88] Factors probably contributing to the special vulnerability of ESRD patients to sudden cardiac arrest include LVH; rapid electrolyte shifts and hyperkalemia in HD; autonomic dysfunction and sympathetic

overactivity, including sleep apnea; and abnormalities in myocardial ultrastructure and function, including endothelial dysfunction, interstitial fibrosis, decreased perfusion reserve, and diminished ischemia tolerance.[49,89-91] Low-potassium dialysate (<2 mEq/L) is associated with a twofold independent risk for cardiac arrest and is thus a modifiable risk factor.[92] The rate of cardiac arrest is 50% higher for HD than for PD patients 3 months after initiation of dialysis but is higher for PD patients at 3 years.[93] The highest rate of sudden cardiac death occurs 2 months after HD initiation.[94] Reduced LVEF is a powerful independent predictor of cardiovascular death: ninefold for LVEF below 30% (versus 60% or higher) in incident HD patients.[94] Even a modest reduction in LVEF is prognostically important; in both HD (2.5-fold risk of cardiovascular death for LVEF 40% to 50%)[8] and PD patients, LVEF below 49% was the cutpoint for predicting sudden cardiac death in a prospective cohort of PD patients in Hong Kong.[95] One study of cardiac arrests occurring in HD centers found that the predominant rhythm was ventricular fibrillation (66%), followed by pulseless electrical activity (23%) and asystole (10%).[96]

Non–dialysis-dependent CKD is also associated with increased risk of sudden cardiac death. In women with CHD, eGFR below 40 ml/min/1.73 m^2 was associated with a 2.3-fold increased risk of sudden cardiac death. Despite a graded, incremental risk of arrhythmic death and impaired renal function, the overall magnitude of risk in stage 3 CKD patients is small compared with dialysis patients.

The reported rate of cardiac arrest in HD centers is 3.8 to 7.1 events per 100,000 dialysis sessions.[96-98] On-site defibrillation capability (preferably with automatic external defibrillators) was recommended as a U.S. practice guideline in 2005.[77]

The role that implantable cardioverter-defibrillators (ICDs) may play in reducing mortality in CKD patients is controversial, particularly regarding primary prevention of sudden death in patients with LVEF of 35% or lower (comparable general population patients receive ICDs under current U.S. implant guidelines). CKD may attenuate the survival advantage of ICDs for primary prevention of sudden cardiac death,[99,100] but older age and medical comorbidity should not routinely exclude patients from receiving ICDs. In dialysis patients who survived cardiac arrest, ICD implantation was associated with a 14% to 42% reduction in long-term mortality.[101,102] The role of ICDs in dialysis patients remains uncertain because they were never enrolled in clinical trials for either primary or secondary prevention of sudden death. The Wearable External Defibrillator in Hemodialysis Patients (WED-HED) trial, a large randomized controlled trial, will enroll patients who do not qualify for ICDs under current guidelines for primary prevention of sudden death (but who constitute the majority of patients at risk for it): dialysis patients with LVEF exceeding 35%.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Key issues in the diagnosis of CVD are under-recognition of symptoms, underuse of appropriate diagnostic investigations, and interpretation of those investigations.

Blood Pressure Measurements

Outcome prediction by ambulatory blood pressure monitoring is not necessarily better than by office blood pressure measurements. However, ambulatory monitoring is useful to identify high-risk nondippers and inverted dippers, allowing consequent treatment adjustments.

Electrocardiography and Echocardiography

Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines for CVD in dialysis patients recommend a baseline electrocardiogram at dialysis initiation and at annual intervals.[77] Diabetic HD patients presenting without sinus rhythm (11% of the cohort) were 89% more likely to die (based on multivariate analysis) and 164% more likely to sustain a stroke.[65] CKD patients (eGFR < 60 ml/min/1.73 m^2) with increased QRS duration had 15% greater risk of incident CHF, 13% greater risk of incident CHD, and 17% greater risk of mortality per 10-millisecond increase; prolongation of the QT interval was also independently associated with adverse outcome.[103]

KDOQI guidelines recommend routine echocardiograms in all dialysis patients after they achieve "dry weight" targets, preferably 1 to 3 months after dialysis initiation on an interdialytic day for HD patients and at 3-year intervals thereafter.[77] The rationale for this guideline is that diminished LV systolic function is independently associated with incident CHF, recurrent CHF, incident CHD, and increased mortality,[77] and it is not accurately diagnosed by history, physical examination, or chest radiography. Detection of unsuspected cardiomyopathy is also important, given that carvedilol therapy in such patients improved LV systolic function, decreased hospitalization, and reduced mortality.[104] As in the general population, CKD patients with LVEF below 40% should be evaluated for CHD (exceptions are pediatric or young adult patients with nondiabetic renal failure and other patients known to be at low risk for CHD).

Stress Tests and Screening Renal Transplant Candidates

End-stage renal disease patients are poorly suited for conventional exercise stress electrocardiography because of limited exercise tolerance and frequent resting electrocardiographic abnormalities. Accuracies of pharmacologic stress echocardiographic and nuclear scintigraphic techniques are remarkably variable over the world; they clearly are operator dependent, and the approach of individual sites to cardiac screening should rely on institutional expertise. Moreover, prediction of the likelihood of future events may differ considerably from prediction of coronary anatomy. In severe CKD, dobutamine stress echocardiography is an independent predictor of long-term mortality.[105] Sensitivities and specificities for detection of CHD in renal transplant candidates have been reported to range from 44% to 90%.[106] A meta-analysis[107] concluded that presence of inducible myocardial ischemia by any stress imaging test is independently predictive of increased AMI risk and cardiac death, whereas a fixed or resting defect or abnormality is predictive of cardiac death but not AMI. A subsequent meta-analysis by the Cochrane Collaboration concluded that dobutamine stress echocardiography is probably more accurate than myocardial stress nuclear scintigraphy for noninvasive detection of CHD in renal transplant candidates.[108]

The major problem with "screening" is use of test results for clinical management. The evidence for prophylactic revascularization of asymptomatic renal transplant candidates (or any other patient group) is weak.[49,109] The best observational data supporting the usefulness of preemptive coronary revascularization (in 184 of 657 renal transplant candidates screened with coronary angiography) showed 3-year cardiac event–free survival of 90% for wait-listed revascularized patients.[110] Optimal medical therapy (which should constitute the treatment strategy for all patients) may potentially attenuate the putative benefit of prophylactic coronary revascularization. One algorithm for screening and management of CHD in renal transplant candidates is presented in Figure 82-12. All patients undergo resting

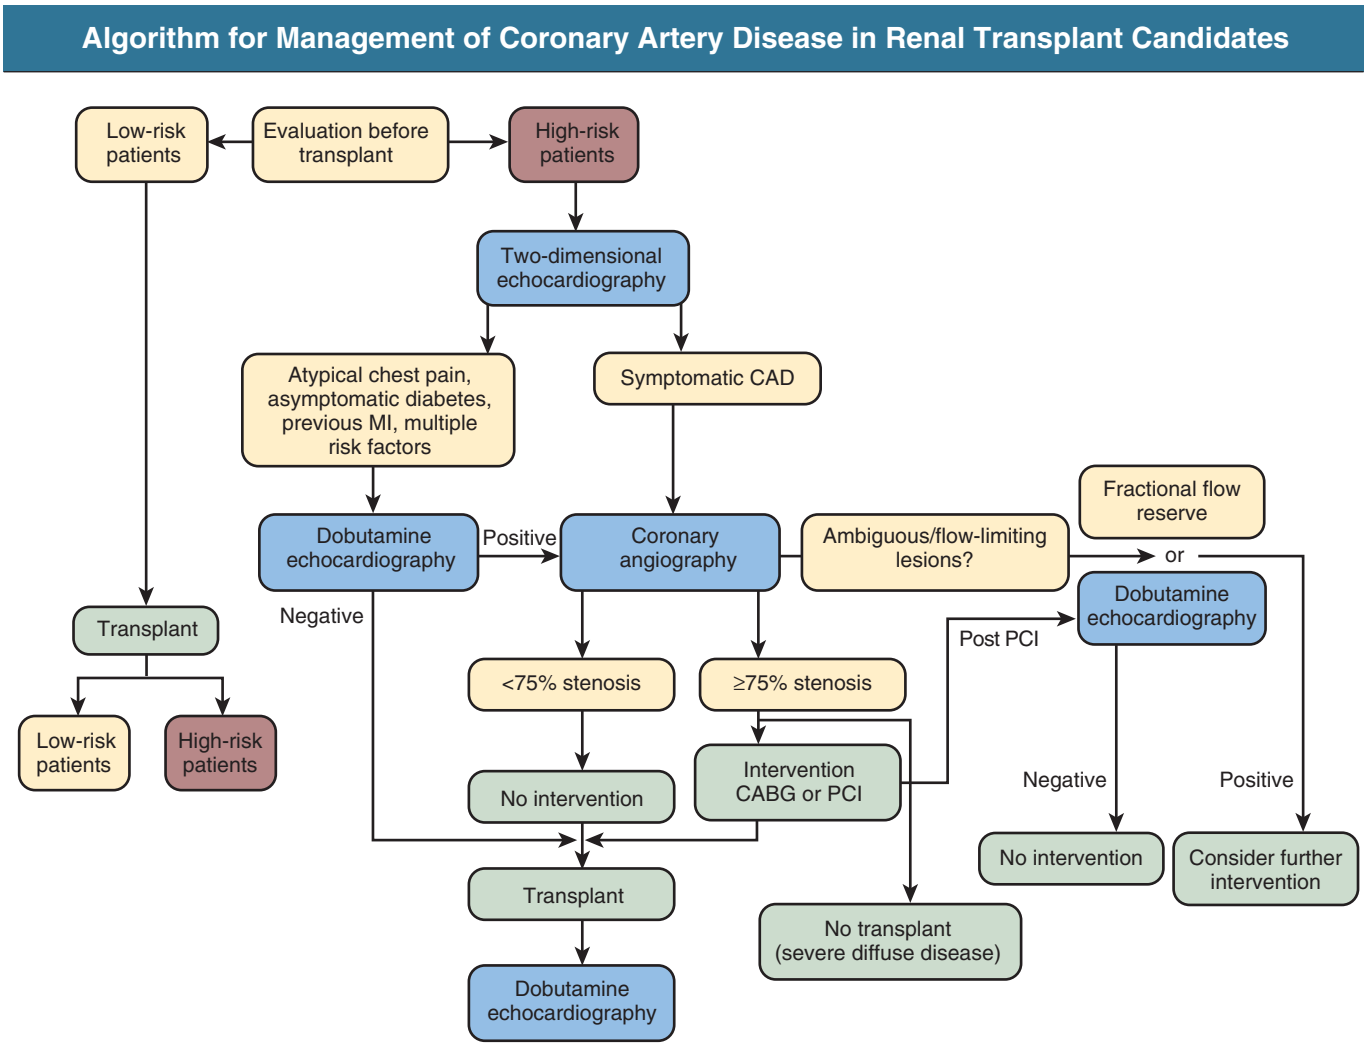

Figure 82-12 Algorithm for management of coronary heart disease (CHD) in renal transplant candidates. *CABG,* Coronary artery bypass graft surgery; *CAD,* coronary artery disease; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention. *(Modified from reference 168.)*

echocardiography, and high-risk patients (e.g., with diabetic ESRD, any age; history of CHD or angina; or two or more classic CHD risk factors [asymptomatic] and age older than 45 years) undergo stress echocardiography. For patients subsequently found to have angiographically indeterminate lesions, measurement of fractional flow reserve is used to make decisions about revascularization.[111]

Coronary Angiography

Coronary angiography, the gold standard in evaluating CHD in CKD, should be considered in stable ESRD patients with evidence for inducible myocardial ischemia, unstable patients with acute coronary syndrome (performed urgently for STEMI), and patients with LVEF below 40%. Some reports suggest a predilection for more proximal CHD in CKD patients, which may predict worse outcome.[112,113]

In CKD and ESRD patients with residual renal function, fear of contrast nephropathy may restrain use of coronary angiography (see Chapter 73 for preventive measures); one retrospective study of 76 nondialysis patients with mean eGFR of 12.5 ml/min/1.73 m^2 found no significant postangiographic deterioration in renal function.[114] However, patients sustaining acute kidney injury (AKI) after coronary angiography are at heightened risk for long-term mortality, ESRD, and hospitalization.[115] Echocardiography should be performed before any nonemergent coronary angiography in CKD patients to diagnose clinically unsuspected valvular disease or cardiomyopathy, to gauge preprocedure volume status, and to assess LV function (to avoid excessive exposure to radiocontrast media through unwarranted ventriculography).

Noninvasive coronary CT angiography may be problematic in dialysis patients because of medial calcification interfering with angiographic interpretation. Another problem may be the requirement for a large-bore intravenous line for rapid injection of radiocontrast media. Noninvasive gadolinium-based magnetic resonance angiographic imaging in patients with severe CKD remains problematic because of lingering concerns about nephrogenic fibrosing dermopathy; the usefulness of imaging without contrast media is uncertain.

Imaging of Vascular Calcification

Vascular calcification can be visualized by conventional x-ray techniques and by multislice spiral CT or electron-beam CT. Valvular and large-artery calcification can be visualized by ultrasound

techniques. Detection of any cardiovascular calcification predicts worse outcome in dialysis patients. The value of routine imaging of vascular calcifications in CKD patients is currently not defined. The diagnostic significance of coronary artery calcification in dialysis patients as a surrogate for CHD severity has been questioned.[116]

Biomarkers

Plasma brain natriuretic peptides (BNP and NT-proBNP), cardiac troponins (cTnT, cTnI), and high-sensitivity CRP are prognostic risk markers in the evaluation of heart disease in ESRD.[117-119] BNP reflects cardiac filling pressures (not limited to the left side of the heart), troponins reflect myocardial cell death (but not necessarily ischemia), and high-sensitivity CRP is an inflammatory marker. Elevation of cTnT occurs in pediatric CKD patients and is associated with cardiac dysfunction.[120] Elevation of plasma troponin levels in ESRD patients is not a false positive; the origin is myocardial, but the interpretation is incorrect if it is uncritically attributed to myocardial ischemia caused by obstructive coronary artery disease. Elevated levels of cTnT are associated with the presence and severity of HD-induced myocardial stunning.[121] The cardiac biomarker-based diagnosis of acute coronary syndrome requires a time-appropriate rise and fall of the biomarker. The most cost-effective combination of biomarkers for risk stratification in dialysis patients might be cTnT and high-sensitivity CRP, but this is controversial. In CKD, NT-proBNP and BNP are equivalent predictors of decompensated heart failure, but NT-proBNP is a better predictor of survival.[122] Figure 82-13 graphically displays the relationship of cTnT and cTnI levels in asymptomatic dialysis patients and long-term survival. On the basis of these data, the U.S. Food and Drug Administration approved the measurement of cTnT in dialysis patients for the indication of risk stratification (mortality prediction) in 2004.[77] FGF23 has also proven to be a strong outcome predictor in CKD patients,[123] but further studies are needed to demonstrate its role as an additional clinical biomarker.

TREATMENT AND PREVENTION OF CARDIOVASCULAR DISEASE

Risk Factor Reduction

Lifestyle Factors and Smoking

Because physical inactivity is associated with albuminuria[124] and cardiovascular mortality,[125] CKD patients should be advised to stay as physical active as possible. It is clearly imperative to strongly encourage smoking cessation at any CKD stage.

Weight and Diet

Lifestyle changes, including balanced diets with regard to saturated fat and carbohydrates (in diabetic patients), probably reduce cardiovascular morbidity and should be encouraged. However, in all CKD stages, protein-energy wasting must be avoided; especially in dialysis patients, increased body mass index has been associated with improved outcomes,[126] possibly reflecting confounded epidemiology. Correction of obesity should be encouraged. Low-salt diet and phosphate restriction are discussed in Chapter 87.

Hypertension and Coronary Heart Disease

Arterial hypertension is undertreated in many CKD and ESRD patients, and despite controversial data about the risk prediction by diastolic and systolic blood pressure in dialysis patients, antihypertensive treatment is associated with improved survival. Blood pressure targets for CKD patients, in particular those with diabetes or proteinuria exceeding 1 g/day, are discussed in Chapter 80. Hallmarks of therapy are volume control (see Chapter 94) and prevention of sodium overload, particularly through dietary sodium restriction. Longer or more frequent HD sessions may be beneficial in controlling hypertension. Because of their parallel cardioprotective effects, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and vasodilating β-blockers (e.g., carvedilol) are the first-line drugs to treat CKD- and ESRD-related hypertension. Calcium channel blockers and most other antihypertensive drugs, including centrally acting sympathetic inhibitors, are useful when administered complementarily. Pure vasodilators (e.g., minoxidil) must be used with caution because they may increase volume overload or occasionally cause pericardial effusions. Novel approaches to drug-resistant hypertension, such as renal sympathetic denervation, potentially offer an alternative to patients with refractory hypertension; however, the recent and surprising negative results of the SYMPLICITY HTN-3 (Renal Denervation in Patients With Uncontrolled Hypertension) trial refutes the efficacy of renal sympathetic denervation therapy.[127] Because sleep-disordered breathing occurs in about 50% of CKD stage 4 and 5 patients and is associated

with hypertension, sleep apnea should be considered in therapy-resistant hypertension.

Coronary heart disease and CHD-related events should be treated with the same medications and active interventions indicated in the general population in the absence of convincing CKD-specific data to the contrary. Medical treatment includes use of antiplatelet agents, ACE inhibitors, ARBs, β-blockers, nitroglycerin, and statins. There is no rationale for a less aggressive therapeutic approach in CKD and ESRD patients than in the nonrenal population.

Diabetes Mellitus

Optimal glycemic control (see Chapter 32), reaching blood pressure target levels, and lipid monitoring (with subsequent dyslipidemia treatment) are crucial in managing diabetic CKD patients. CHD and other CVD should be treated aggressively in this high-risk group. Because recent data show that the harm associated with severe hypoglycemia might counterbalance the potential benefit of intensive glucose-lowering treatment, treating to a hemoglobin A1c (HbA1c) level below 7.0% is not recommended.[128]

Dyslipidemia

Because CKD, like diabetes and hypertension, is considered a cardiovascular risk equivalent,[28,29] CKD patients should be treated to secondary prevention LDL cholesterol target guidelines (<100 mg/dl or 2.6 mmol/l). However, this goal was unsupported by clinical trials targeting dialysis patients.[84,129] *Post hoc* subgroup analyses in the Heart Protection Study,[130] Cholesterol and Recurring Events (CARE) study,[131] and Treating to New Targets (TNT) study,[132] together with a meta-analysis,[133] provide inferential support for the role of statins in improving outcomes in CKD stage 1 or 2 patients. The Study of Heart and Renal Protection (SHARP) showed that reducing LDL cholesterol with simvastatin 20 mg plus ezetimibe 10 mg daily safely reduced the incidence of major atherosclerotic events in patients with advanced CKD.[134] Thus, statin treatment is recommended in CKD patients older than 20 years, with LDL cholesterol level goals below 130 mg/dl (3.4 mmol/l) or below 100 mg/dl (2.6 mmol/l) for secondary prevention; however, the negative results from the 4D study and A Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events (AURORA) do not support this guideline in dialysis patients.

Volume

In predialysis CKD, sodium restriction and diuretics are important to counteract fluid retention. In ESRD, longer and more frequent HD sessions may permit more effective volume control. In the HD center in Tassin, France, more than 90% of patients were normotensive with 8 hours of dialysis three times per week, with dietary salt restriction and no antihypertensive drugs. In the Frequent Hemodialysis Network (FHN) trial, frequent (six times per week) HD (versus conventional three times per week) led to better hypertension control, a drop in LV mass index over 12 months,[135,136] and less myocardial stunning.[135,136] Episodes of dialysis-related hypotension should prompt reevaluation of dry weight, antihypertensive treatment, and exclusion of pericardial effusions, valvular disease, cardiomyopathy, and silent myocardial ischemia (see Chapter 95).

Anemia

Partial correction of severe anemia with ESAs results in regression of LVH. Treatment of severe anemia is also associated with fewer ischemic symptoms in CHD patients. However, evidence for reduction of cardiovascular mortality by ESAs is based on observational data only. To date, randomized controlled trials in HD[137] and CKD patients[138] have shown no benefit of normalized anemia on mortality as a primary endpoint (see Chapter 83). Thus, anemia correction in CKD patients to a hemoglobin level of 11 to 12 g/dl appears logical.

Inflammation

Anti-inflammatory treatment strategies, such as statins and aspirin, have beneficial effects on cardiovascular mortality in the general population. Data from the 4D study[84] show that whereas CRP baseline levels were not significantly different between treated and placebo groups and remained stable at 6 months with atorvastatin, they increased significantly in the placebo group.[139] Although high-sensitivity CRP levels were elevated at baseline and were decreased by rosuvastatin in the AURORA study,[129] there was no reduction in cardiovascular events. Meanwhile, a careful search for infectious processes, such as periodontal disease, and use of ultrapure water are recommended in dialysis patients with inflammation. Restriction of catheter use is also important; short daily dialysis with better fluid status was associated with decreasing CRP levels compared with conventional HD.[140] Volume status should be carefully monitored to avoid inflammation. Altered intestinal microbial flora is a potential novel risk factor for systemic uremic inflammation, which merits further study.

Oxidative Stress

Oxidative stress probably plays a role in mediating CVD in CKD. Two placebo-controlled interventional studies showed that vitamin E[141] and *N*-acetylcysteine[142] decreased the number of cardiovascular events in HD patients. Unfortunately, both studies were small and of limited duration. Because *N*-acetylcysteine administration led to reduced atheromatous lesions in an apoE knockout model of CKD-enhanced atherosclerosis, adequately powered randomized trials with antioxidative treatment strategies are warranted. A recent meta-analysis showed that use of ultrapure dialysate results in decreased markers of inflammation and oxidative stress in HD patients.[143] However, administration of mixed tocopherols and α-lipoic acid did not influence biomarkers of inflammation and oxidative stress or the erythropoietic response in a recent randomized trial of 353 HD patients.[143a]

Chronic Kidney Disease–Mineral Bone Disorder

In a randomized Japanese trial, sevelamer, as compared with calcium carbonate treatment, slowed the increase in coronary artery calcification score.[144] Based on this and other studies, nephrologists should reduce oral calcium loading in CKD patients, in particular if cardiovascular calcifications have already been documented.[145] Because vitamin D treatment is associated with improved survival in dialysis patients,[146] vitamin D insufficiency should also be considered. However, results from the Dialysis Outcomes and Practice Patterns Study (DOPPS)[147] call into question the survival advantage for HD patients taking vitamin D. The PRIMO (Paricalcitol Capsules Benefits Renal Failure Induced Cardiac Morbidity in Subjects With Chronic Kidney Disease Stage 3/4) study showed that 48 weeks of paricalcitol therapy did not alter LV mass index or improve certain measures of diastolic dysfunction in CKD patients.[148] With respect to calcimimetics, the Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) study[149] showed that cinacalcet did not significantly reduce the risk of death or major cardiovascular events in dialysis patients with moderate to severe secondary hyperparathyroidism unless the groups were adjusted for age. A randomized study to evaluate the effects of cinacalcet plus low-dose vitamin D on vascular calcification in subjects with chronic kidney disease receiving hemodialysis (ADVANCE)[150] showed that cinacalcet plus low-dose

vitamin D sterols may attenuate vascular and cardiac valve calcification in HD patients with moderate to severe secondary hyperparathyroidism. KDOQI and KDIGO targets for parathyroid hormone, calcium, and phosphate are discussed in Chapter 85.

FGF23 is a bone hormone that has attracted much recent interest as a putative player in the calcification process. FGF23 is cardiotoxic and induces LVH[37] but does not induce vascular calcification.[151]

Revascularization

Chronic kidney disease is a strong risk factor for death after coronary revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG).[152,153] Coronary revascularization complicated by AKI is associated with excess mortality; operative mortality for non-ESRD patients who require acute dialysis after cardiac surgery is 44%.[154]

Data comparing coronary revascularization with medical therapy in CKD are limited by their retrospective, observational nature and lack of optimal medical therapy, including β-blockers. Observational studies suggest lower mortality in CKD (including dialysis) patients undergoing coronary revascularization compared with no revascularization.[155,156] A *post hoc* analysis of CKD patients in the FRISC II (Fast Revascularization During Instability in Coronary Artery Disease) trial indicated a superior outcome with an early invasive strategy in acute coronary syndrome compared with conservative management.[157]

The optimal coronary revascularization method for CKD patients remains controversial because of absence of adequate clinical trial data. A *post hoc analysis* of CKD patients enrolled in ARTS (Arterial Revascularization Therapies Study)[158] found similar outcomes for CABG or multivessel PCI with non–drug-eluting stents (DESs) for death, myocardial infarction, or stroke; unsurprisingly, CABG was associated with less repeated revascularization. In elderly non–dialysis-dependent CKD patients, incidence of ESRD is lower after PCI (5.4% at 3 years vs. 6.8% for CABG), but long-term risk of death (28% 3-year mortality with CABG, 33% with PCI) or the combined event of death or ESRD is lower after CABG. The relative survival advantage of CABG (vs. PCI) occurs only more than 6 months after revascularization.[159] Dialysis patient survival after CABG is better than after PCI with non-DESs[160] and DESs,[161] but 2-year mortality remains high at 44% (vs. 52% for PCI).[160] Based on two large observational studies,[160,161] we recommend the following:

1. Patients with multivessel CHD (including the left anterior descending coronary artery [LAD]) who are anatomically suitable candidates for internal mammary artery grafts should undergo CABG surgery.
2. The CABG survival advantage occurs more than 6 months after revascularization. Patients with limited life expectancy or who are concerned about perioperative morbidity (higher with CABG) might choose PCI (better outcomes at less than 6 months).
3. If the left internal mammary graft (to the LAD) is not part of the surgical strategy, CABG likely provides no advantage.

In the general population, one proven advantage of DESs (compared with non-DESs) is lower incidence of in-stent restenosis. In dialysis patients, reliance on clinical surrogates (e.g., chest pain) for detection of restenosis can be problematic and lead to underestimation of the true incidence. The most complete angiographic follow-up of DESs (performed in Japanese dialysis patients) noted a 22% to 31% angiographically detected incidence of restenosis with DESs and 24% to 43% with non-DESs.[162-165] Clinically inapparent restenosis is a rationale for surveillance stress imaging to detect occult restenosis as part of our management strategy for dialysis patients undergoing PCI (see Fig. 82-12).

CHAPTER 83

Anemia in Chronic Kidney Disease

Iain C. Macdougall and Kai-Uwe Eckardt

Anemia is an almost universal complication of chronic kidney disease (CKD). It contributes considerably to reduced quality of life of patients with CKD and has been associated with a number of adverse clinical outcomes. Before the availability of recombinant human erythropoietin (rHuEPO, or epoetin), patients on dialysis frequently required blood transfusions, exposing them to the risks of iron overload, transmission of viral hepatitis, and HLA sensitization, which reduced the chances of successful transplantation. The advent of rHuEPO in the late 1980s changed this situation completely. The ability to correct anemia has suggested that its consequences may go beyond general fatigue and reduced physical capacity to affect a broad spectrum of physiologic functions. Thus, there is a strong rationale for managing anemia in CKD patients, and yet the optimal treatment strategies are still incompletely defined. Apart from therapy with erythropoiesis-stimulating agents (ESAs), iron replacement is essential for anemia management. It is important to note that CKD patients require target thresholds of iron parameters different from those for normal individuals to ensure optimal rates of red cell production. The costs of anemia management are considerable, and it has also become apparent that full anemia correction may cause harm; therefore a rational and careful consideration of the risks and benefits is mandatory.

PATHOGENESIS

Renal anemia is typically an isolated normochromic, normocytic anemia with no leukopenia or thrombocytopenia. Both red cell life span and the rate of red cell production are reduced, but the latter is more important. The normal bone marrow has considerable capacity to increase the rate of erythropoiesis, and the reduction in erythrocyte life observed in association with CKD would normally be easily compensated for. However, this erythropoietin (EPO)–induced compensatory increase in erythrocyte production is impaired in CKD. Serum EPO levels remain within the normal range and fail to show the inverse exponential relationship with blood oxygen content characteristic of other types of anemia. EPO is normally produced by interstitial fibroblasts in the renal cortex, in close proximity to tubular epithelial cells and peritubular capillaries.[1,2] In addition, hepatocytes and perisinusoidal Ito cells in the liver can produce EPO (Fig. 83-1). Hepatic EPO production dominates during fetal and early postnatal life but does not compensate for the loss of renal production in adult organisms. Subtle changes in blood oxygen content induced by anemia, reduced environmental oxygen concentrations, and high altitude stimulate the secretion of EPO through a widespread system of oxygen-dependent gene expression.[2-4] Central to this process is a family of hypoxia-inducible transcription factors (HIFs). The two most important members of this family, HIF-1 and HIF-2, are composed of an oxygen-regulated α subunit (HIF-1α or HIF-2α) and a constitutive β subunit. The production of HIF-1α and HIF-2α is largely independent of oxygen, but their degradation is related to cellular oxygen concentrations. Hydroxylation of specific prolyl and asparagyl residues of HIF-α, for which molecular oxygen is required as a substrate, determines HIF proteasomal destruction and inhibits its transcriptional activity. Apart from EPO, far more than 100 HIF target genes have been identified. HIF-2, rather than HIF-1, is the transcription factor primarily responsible for the regulation of EPO production.[5,6]

The role of renal EPO production in the pathogenesis of renal anemia is supported by the observation that anemia is particularly severe in anephric individuals. However, the mechanisms impairing renal EPO production in diseased kidneys remain poorly understood. The production capacity for EPO remains significant, even in end-stage renal disease. Thus, patients with anemia and CKD can respond with a significant increase in EPO production to an additional hypoxic stimulus.[1] The main problem therefore appears to be a failure of EPO production in response to chronically reduced hemoglobin (Hb) concentrations. In line with this view, endogenous EPO production can be induced in CKD patients by pharmacologic inhibition of HIF degradation (see later discussion).

Erythropoietin is a glycoprotein hormone consisting of a 165–amino acid protein backbone and four complex, heavily sialylated carbohydrate chains.[1,2] The latter are essential for the biologic activity of EPO *in vivo* because partially or completely deglycosylated EPO is rapidly cleared from the circulation. This is also why rHuEPO has to be manufactured in mammalian cell lines; bacteria lack the capacity to glycosylate recombinant proteins.

Erythropoietin stimulates red cell production by binding to homodimeric EPO receptors, which are primarily located on early erythroid progenitor cells, the burst-forming units erythroid (BFU-e) and the colony-forming units erythroid (CFU-e). Binding of EPO to its receptors salvages these progenitor cells and the subsequent earliest erythroblast generation from apoptosis, thereby permitting cell division and maturation into red blood cells.[7] Inhibition of red cell production by uremic inhibitors of erythropoiesis may also contribute to the pathogenesis of renal anemia, although they have so far not been identified. Nevertheless, dialysis *per se* can improve renal anemia and the efficacy of ESAs. Moreover, the interindividual dose requirements for ESAs vary significantly among CKD patients, and the average weekly dose is much higher than estimated production rates of endogenous EPO in healthy individuals. An alternative view to the accumulation of inhibitors of erythropoiesis in CKD is that in many patients there is overlap between renal anemia and the anemia of chronic disease, which is characterized by inhibition of EPO production and EPO efficacy as well as by reduced iron availability, mediated through the effects of inflammatory cytokines.[8] The hepatic release of hepcidin, the key regulator of iron metabolism, is upregulated in states of inflammation; it simultaneously blocks iron absorption from the gut and promotes iron sequestration in macrophages.[9]

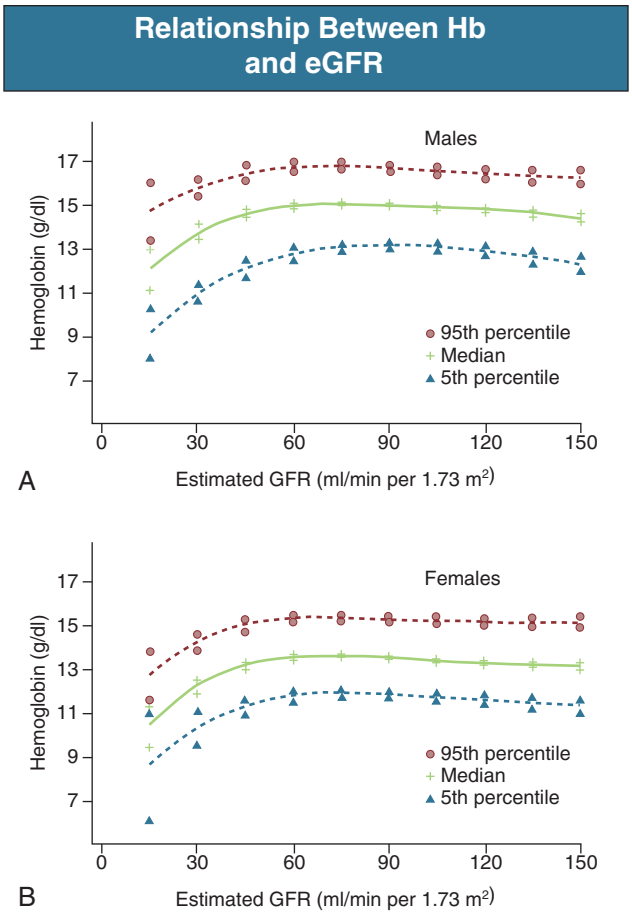

Figure 83-2 Relationship between hemoglobin (Hb) concentration and estimated glomerular filtration rate (eGFR). Data are from a cross-sectional survey of individuals randomly selected from the general U.S. population (Third National Health and Nutrition Examination Survey [NHANES III]). Results and 95% confidence interval are shown for males **(A)** and females **(B)** at each estimated GFR interval. *(From reference 11.)*

EPIDEMIOLOGY AND NATURAL HISTORY

In general, there is a progressive increase in the incidence and severity of anemia with declining renal function. The reported prevalence of anemia by CKD stage varies significantly and depends to a large extent on the definition of anemia and whether study participants are selected from the general population, are at high risk for CKD, are diabetic, or are already under the care of a physician. Data from the National Health and Nutrition Examination Survey (NHANES) showed that the distribution of Hb levels starts to fall at an estimated glomerular filtration rate (eGFR) of less than 75 ml/min/1.73 m^2 in men and 45 ml/min/1.73 m^2 in women (Fig. 83-2).[10] The prevalence of Hb values below 13 g/dl increases below a threshold eGFR of 60 ml/min/1.73 m^2 in men and 45 ml/min/1.73 m^2 in women in the general population. Among patients under regular care and known to have CKD, the prevalence of anemia was found to be much greater, with mean Hb levels of 12.8 ± 1.5 (CKD stages 1 and 2), 12.4 ± 1.6 (CKD stage 3), 12.0 ± 1.6 (CKD stage 4), and 10.9 ± 1.6 (CKD stage 5).[11] Although anemia develops largely independently of the cause of kidney disease, there are two important exceptions. Diabetic patients develop anemia more frequently, at earlier stages of CKD, and more severely at a given level of renal impairment.[12,13] Conversely, in patients with polycystic kidney disease, Hb is on average higher than in other patients with similar degrees of renal failure, and polycythemia may occasionally develop.[1]

With the advent of rHuEPO and its derivatives, Hb values in patients with CKD have changed. In particular, in patients on dialysis, average Hb values have steadily increased for many years, and then declined again in view of new evidence suggesting lower target levels.[12] The average Hb value, however, still varies considerably among countries, reflecting considerable variability in practice patterns (Table 83-1).[13] Moreover, Hb values vary considerably among patients in the same treatment setting as well as within patients over time, mainly reflecting persistent and time-dependent changes in responsiveness (see later discussion).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of anemia and the assessment of its severity are best made by measuring the Hb concentration rather than the hematocrit. Hb is a stable analyte that is measured directly in a standardized fashion, whereas the hematocrit is relatively unstable, indirectly derived by automatic analyzers, and lacking in standardization. Within-run and between-run coefficients of variation in automated analyzer measurements of Hb are one half and one third those for hematocrit, respectively.[12]

There is considerable variability in the Hb threshold used to define anemia. According to the most recent definition in the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines, anemia should be diagnosed at Hb concentrations of less than 13.0 g/dl in men and less than 12.0 g/dl in women.[14] These values represent the World Health Organization (WHO) definition of anemia. In children, age-dependent differences in the normal values have to be

Hemoglobin Levels in Patients on Dialysis						
	Among Patients on Dialysis for Longer Than 180 Days			Among Patients New to ESRD, at Start of Dialysis		
Country	n	Mean Hb (g/dl)	Hb <11 g/dl (% of patients)	n	Mean Hb (g/dl)	Hb <11 g/dl (% of patients)
Sweden	456	12.0	23	168	10.7	55
United States	1690	11.7	27	458	10.4	65

Japan	1210	10.1	77	131	8.3	95

Table 83-1 Mean hemoglobin (Hb) levels and percentage of patients with Hb levels below 11 g/dl who have been on dialysis therapy for more than 180 days and at the time of starting dialysis, by country. Data are from the Dialysis Outcomes and Practice Patterns Study, Phase II (DOPPS 2), and are derived from 308 randomly selected, representative dialysis facilities. Note that there are marked differences among countries, but at least one fourth and up to three fourths of dialysis patients, and, in most countries, more than two thirds of patients starting chronic dialysis have Hb values below the recommended lower target of 11 g/dl. *ESRD,* End-stage renal disease. *(Modified from reference 13.)*

taken into account. Normal Hb values are increased in high-altitude residents. It is important to note that thresholds for the diagnosis of anemia and evaluation of the causes should not be interpreted as being thresholds for treatment of anemia.[14]

In addition to the Hb value, the evaluation of anemia in CKD patients should include a complete blood count with red blood cell indices (mean corpuscular Hb concentration [MCHC], mean corpuscular volume [MCV]), white blood cell count (including differential), and platelet count. Although renal anemia is typically normochromic and normocytic, deficiency of vitamin B_{12} or folate may lead to macrocytosis, whereas iron deficiency or inherited disorders of Hb formation (such as thalassemia) may produce microcytosis. Macrocytosis with leukopenia or thrombocytopenia suggests a generalized disorder of hematopoiesis caused by toxins, nutritional deficit, or myelodysplasia. Hypochromia probably reflects iron-deficient erythropoiesis. An absolute reticulocyte count, which normally ranges between 40,000 and 50,000 cells/μl of blood, is a useful marker of erythropoietic activity.

Iron status tests should be performed to assess the level of iron in tissue stores or the adequacy of iron supply for erythropoiesis. Although serum ferritin is so far the only available marker of storage iron, several tests reflect the adequacy of iron for erythropoiesis, including transferrin saturation, the percentage of hypochromic red blood cells (PHRC), the content of Hb in reticulocytes (CHr), and the MCV and MCHC. Storage time of the blood sample may elevate PHRC, and MCV and MCHC are below the normal range only after longstanding iron deficiency.

It is important to identify anemia in CKD patients because it may signify nutritional deficits, systemic illness, or other conditions that warrant attention, and even at modest degrees, anemia reflects an independent risk factor for hospitalizations, cardiovascular disease, and mortality.[12] The diagnosis of renal anemia, that is, an anemia caused by CKD, requires careful judgment of the degree of anemia in relation to the degree of renal impairment and exclusion of other or additional causes. Because there is significant variability in the degree of anemia in relation to the impairment in renal function, no simple diagnostic criteria can be applied. Causes of anemia other than EPO deficiency should be considered when (1) the severity of anemia is disproportionate to the impairment of renal function, (2) there is evidence of iron deficiency, or (3) there is evidence of leukopenia or thrombocytopenia. Concomitant conditions such as sickle cell disease may exacerbate the anemia, as can drug therapy. For example, inhibitors of the renin-angiotensin system may reduce Hb levels by (1) direct effects of angiotensin II on erythroid progenitor cells,[15] (2) accumulation of *N*-acetyl-seryl-lysyl-proline (Ac-SDKP), an endogenous inhibitor of erythropoiesis in patients treated with angiotensin-converting enzyme (ACE) inhibitors,[16] and (3) reduction of endogenous EPO production, possibly because of the hemodynamic effects of angiotensin II inhibition. Myelosuppressive effects of immunosuppressants may further contribute to anemia.[17] The measurement of serum EPO concentrations is usually not helpful in the diagnosis of renal anemia because there is relative rather than absolute deficiency, with a wide range of EPO concentrations for a given Hb concentration that extends far beyond the normal range of EPO levels in healthy, nonanemic individuals. Abnormalities of other laboratory parameters should be looked for, such as a low MCV or MCHC (may indicate an underlying hemoglobinopathy), a high MCV (may indicate vitamin B_{12} or folate deficiency), or an abnormal leukocyte or platelet count (may suggest a primary bone marrow problem, such as myeloma or myelodysplastic syndrome), and further tests should be performed as indicated to explore these potential conditions. However, when there are no such pointers to other confounding causes of anemia, and iron deficiency has been excluded, a trial with rHuEPO or its derivatives is warranted, even when the eGFR is only moderately reduced.

CLINICAL MANIFESTATIONS

In the early clinical trials of rHuEPO performed in the late 1980s, the mean baseline Hb concentration was about 6 to 7 g/dl, and this progressively increased to about 11 or 12 g/dl after treatment.

Secondary Effects of Anemia Correction on the Cardiovascular System
Reduction in high cardiac output
Reduced stroke volume
Reduced heart rate
Increase in peripheral vascular resistance
Reduction in anginal episodes
Reduction in myocardial ischemia
Regression of left ventricular hypertrophy
Stabilization of left ventricular dilation
Increase in whole blood viscosity

Box 83-1 Secondary effects of anemia correction on the cardiovascular system.

Other Secondary Effects of Anemia Correction
Reduced blood transfusions
Increased quality of life
Increased exercise capacity
Improved cognitive function
Improved sleep patterns
Improved immune function
Improved muscle function
Improved depression
Improved nutrition
Improved platelet function
(Hypertension)
(Vascular access thrombosis)

Box 83-2 Other secondary effects of anemia correction. Parentheses indicate negative and adverse effects.

Patients subjectively felt much better, with reduced fatigue, increased energy levels, and enhanced physical capacity, and there were also objective improvements in cardiorespiratory function.[18] Thus, it is now clear that many of the symptoms previously attributed to the "uremic syndrome" may have been caused by severe anemia associated with CKD (Boxes 83-1 and 83-2). Although the avoidance of blood transfusions and improvement in quality of life are obvious early changes, there are also possible effects on the cardiovascular system (see Box 83-1). The physiologic consequences of longstanding anemia are an increase in cardiac output and a reduction in peripheral vascular resistance. Anemia is associated with the development of left ventricular hypertrophy in CKD patients and is thought to exacerbate left ventricular dilation. Sustained correction of severe anemia in CKD patients tends to reverse most of these cardiovascular abnormalities, with the notable exception of left ventricular dilation. Once the left ventricle is stretched beyond the limits of its elasticity, correction of anemia cannot reverse this.[19] It may, however, prevent further progression in some patients. Other effects of anemia correction reported in clinical trials include improvements in quality of life, cognitive function, sleep patterns, nutrition, sexual function, menstrual regularity, immune responsiveness, and platelet function. The majority of these trials, however, have not been placebo-controlled, so the spectrum and extent of possible benefits remain uncertain.

Over the years, there has also been considerable debate about the optimal target range of Hb in CKD patients. A presumed improvement in quality of life and expectations of positive effects on cardiovascular function and renal disease progression with increasing Hb concentrations led to suggestions of a level above 10 to 11 g/dl in all CKD patients,[12,13] but several studies have indicated increased risks associated with attempts to completely correct anemia. In particular, no survival benefit is evident at a higher level of anemia correction,[20-23] and attempts to normalize Hb concentrations have shown various risks, including increased rates of thromboembolic events, strokes, and possibly death. Thus there is a possible tradeoff among improved quality of life, reduced transfusion requirements, and risk for harm (see discussion later), and a target Hb level of above 13 g/dl should be avoided.[12, 14]

TREATMENT

Erythropoiesis-Stimulating Agents

Epoetin Therapy

Manufacture of rHuEPO is achieved by gene transfer into a suitable mammalian cell line such as Chinese hamster ovary (CHO) cells or induction of the human gene in a hepatoma cell line. The early clinical trials of rHuEPO were conducted with both EPO alfa and EPO beta, both produced in CHO cells. Like the endogenous hormone, rHuEPO consists of a 165–amino acid backbone with one *O*-linked and three *N*-linked glycosylation chains. Invariably, however, there are some differences in the glycosylation pattern among different preparations of rHuEPO and the endogenous hormone. Several formulations of EPO are now available, including "biosimilar" EPO preparations, which have been developed after patent expiry of the innovator compounds.[24] Other "copy" EPOs are available elsewhere in the world (e.g., China, India, Peru, Argentina, Russia, and Cuba) and are not necessarily produced to the same regulatory standards as the EPO preparations marketed in the United States and Europe. Another EPO that was initially developed for the European market was EPO delta, which differed from other EPOs in its glycosylation pattern because it was produced in a human fibrosarcoma cell line.

Before 1998, EPO alfa in Europe was formulated with human serum albumin, but because of a change in European regulations, this was replaced with polysorbate 80. EPO beta is formulated with polysorbate 20, along with urea, calcium chloride, and five amino acids as excipients. The importance of the formulation of the EPO products was highlighted in 2002 with an upsurge in cases of antibody-mediated pure red cell aplasia in association with the subcutaneous use of EPO alfa after its change of formulation. Patients affected by this complication develop neutralizing antibodies against both rHuEPO and the endogenous hormone, which result in severe anemia and transfusion dependence.[25] The cause of this serious complication in which there is a break in B cell tolerance remains obscure, although it seems likely that factors such as a breach of the cold storage chain are relevant, and the subcutaneous application route is a prerequisite; circumstantial evidence also suggests that rubber stoppers of prefilled syringes used in one of the albumin-free EPO alfa formulations may have released organic compounds that acted as immunologic adjuvants.[26] Although this unfortunate combination of adverse factors was specific for one compound, a low baseline rate of pure red cell aplasia also occurs with EPO beta and darbepoetin alfa.

The EPOs are administered either intravenously or subcutaneously. The bioavailability after intraperitoneal administration (in peritoneal dialysis patients) is too low. The earliest clinical trials of EPO used intravenous injections two or three times per week. This was partly because of the short half-life of EPO (6 to 8 hours after intravenous administration)[27] and partly because of the convenience

for the patient on dialysis. With use of this regimen, 90% of patients show a significant increase in Hb concentration. Good iron management is pivotal for the success of EPO therapy (see later discussion). Although the bioavailability of subcutaneous EPO is 20% to 30%, the prolonged half-life after subcutaneous compared with intravenous administration allows less frequent injections. Furthermore, the dose required to achieve the same Hb response is about 30% lower with subcutaneous than with intravenous administration.[27] There appears to be little difference between the thigh, arm, or abdomen as injection sites.

Darbepoetin Alfa

Darbepoetin alfa is a second-generation ESA that is a supersialylated analogue of EPO, possessing two extra *N*-linked glycosylation chains. This property confers greater metabolic stability and a lower clearance rate *in vivo*, and the elimination half-life of this compound in humans after a single intravenous administration is three times greater than that of epoetin alfa (25.3 hours vs. 8.5 hours). Thus, this agent can generally be given less frequently than the standard epoetins, with administration intervals of once weekly and once every alternate week.[28] In contrast to the epoetins, dosage requirements for darbepoetin alfa for the correction of anemia and maintenance of Hb concentration in CKD patients are the same for intravenous and subcutaneous administration. The conversion factor for switching patients from epoetin alfa or beta to darbepoetin alfa is usually quoted as 200:1, but there may be considerable variability in this, depending on the patient population, the dose, and the route of administration.

C.E.R.A. (Methoxy Polyethylene Glycol–Epoetin Beta)

Alternative bioengineering techniques to prolong the half-life of EPO further resulted in the development of C.E.R.A., which is a pegylated derivative of epoetin beta with an elimination half-life of around 130 hours when it is administered either intravenously or subcutaneously. A number of randomized controlled Phase III studies suggested that many patients are able to be maintained with once-monthly administration of C.E.R.A., and a superiority study (Comparator Study of C.E.R.A. and Darbepoetin Alfa in Patients Undergoing Dialysis [PATRONUS]) suggested greater efficacy with this frequency of administration compared with once-monthly dosing of darbepoetin alfa when it is administered intravenously to hemodialysis patients.[29]

Adverse Effects of the Erythropoiesis-Stimulating Agents

Adverse effects of ESA therapy include a moderate increase in blood pressure and an increased rate of thromboembolic events, including vascular access thrombosis. Whereas these effects are probably dependent to a large degree on the increase in Hb concentrations, there are some concerns that ESA therapy may enhance thrombogenicity and tumor growth in patients with malignant disease, as well as exacerbate vascular events in CKD independently of Hb concentrations. Thus, attempts should be made to use the lowest doses of ESA possible to avoid the presumed pleiotropic effects of this class of drugs. Similarly, because no "safe" upper dose level has been determined, it is advisable to avoid repeated dose escalations.[14] In the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), patients with a history of malignancy were found to have an increased rate of cancer-related deaths when treated with darbepoetin.[23] Although no study has investigated anemia management in patients with CKD and active cancer, ESAs should be used only with great caution in such patients, in particular when cure from cancer is the anticipated outcome.[14] Similarly, in patients with a history of stroke or recent venous thromboembolic event, careful consideration should be given to the benefit-risk ratio of using ESA therapy.

Other Erythropoiesis-Stimulating Agents

In addition to the original epoetins and the two long-acting derivatives, several other approaches to stimulating erythropoiesis have been explored,[24] and more recent ESAs include peginesatide and the HIF stabilizers.[24]

Peginesatide (previously called Hematide) is an EPO-mimetic peptide, the amino acid sequence of which is completely unrelated to native or recombinant EPO,[24] although it shares the same functional and biologic properties as EPO. It has been shown to be an effective treatment for anti-EPO antibody–mediated pure red cell aplasia because of a lack of cross-reactivity with anti-EPO antibodies.[30] Peginesatide was also shown to be equivalent to epoetin and darbepoetin in raising Hb concentrations in dialysis and nondialysis patients, respectively, but in nondialysis patients, a higher rate of cardiovascular events was observed.[31,32] Therefore it was approved in the United States for use in only dialysis patients. Approximately a year after its introduction, peginesatide had to be withdrawn from the market because of severe hypersensitivity reactions, including fatal anaphylactic events.

The HIF stabilizers are competitive inhibitors of HIF prolyl hydroxylases[24] and asparagyl hydroxylase, enzymes involved in the metabolism of HIF and its transcriptional activity. The HIF stabilizers therefore cause an increase in endogenous EPO production.[33] Such prolyl hydroxylase inhibitors are orally active, and several of these drugs, manufactured by different companies, are currently being tested in Phase II and III clinical trials.[24] There is much discussion about whether these agents will upregulate not only EPO gene expression but also the expression of other HIF target genes, such as those involved in iron metabolism and neoangiogenesis. Whereas some of these effects may facilitate an increase in Hb concentrations, the long-term consequences of these potential additional effects have not been established and merit careful monitoring.[24]

Initiation of and Maintenance Therapy with Erythropoiesis-Stimulating Agents

Before ESA therapy is considered in CKD patients, it is essential to exclude and to correct causes of anemia other than EPO deficiency, such as hematinic deficiencies (Fig. 83-3). If the ferritin concentration is below 100 µg/l, iron supplementation should be administered first. Iron is best given by intravenous administration, although oral iron can be considered in patients not yet on dialysis. Some patients may respond to intravenous iron alone (see later discussion). If the ferritin level is above 100 µg/l (in the absence of systemic inflammation) or there is a suboptimal response to iron, ESA therapy is an option. However, the Hb level at which ESAs should be initiated remains controversial, mainly because the topic has not been rigorously studied. TREAT, the largest ESA trial performed so far, compared darbepoetin therapy with a target Hb level of 13 g/dl versus placebo, with a rescue protocol when a patient's Hb dropped below 9 g/dl.[23] In the darbepoetin arm, the number of patients transfused was lower, and there was a small increase in quality of life, but the stroke rate was twice as high, so that the risk-benefit relationship was clearly negative. Whereas these data argue strongly against the initiation of ESA therapy in patients with mild anemia, there is only one, much smaller randomized controlled trial that tested two different target ranges of 9.5 to 11.0 g/dl and 11.5 to 13.0 g/dl against placebo in patients with severe anemia.[34] Patients in both EPO treatment arms experienced improved quality of life and exercise capacity, but

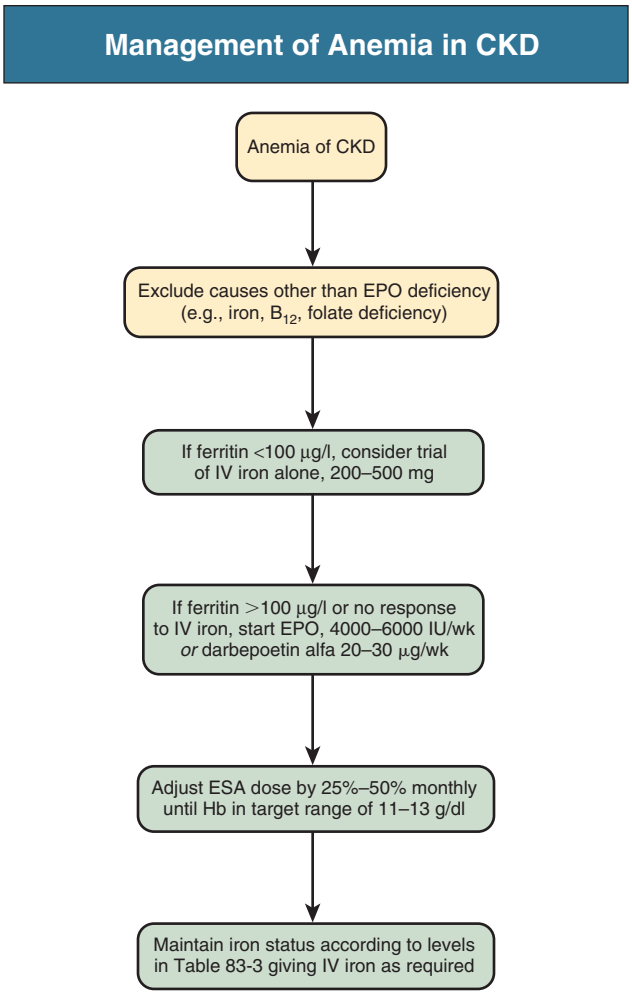

Figure 83-3 Management of anemia in patients with chronic kidney disease (CKD). *EPO,* Erythropoietin; *ESA,* erythropoiesis-stimulating agent; *Hb,* hemoglobin; *IV,* intravenous.

there was no difference between the arms. Based on these findings, the KDIGO guidelines recommend use of ESAs to prevent the Hb level from falling below 9 g/dl.[14] However, individualization is possible, acknowledging the fact that some patients have improved symptoms at higher Hb levels and are prepared to take increased risks.

The usual starting dose of epoetin is about 25 to 50 IU/kg (e.g., 2000 IU) two or three times weekly, either by intravenous or subcutaneous administration. A possible starting dose of darbepoetin alfa is 20 to 30 µg once weekly intravenously or subcutaneously; an appropriate starting dose of C.E.R.A. is 30 to 60 µg once every 2 weeks intravenously or subcutaneously. Within 3 to 4 days after treatment initiation, an increase in the reticulocyte count is seen, and within 1 to 2 weeks, there is a significant rise in the Hb concentration, usually on the order of 0.25 to 0.5 g/dl/wk. Thus, during the course of 1 month, a significant increase of 1 to 2 g/dl in the Hb concentration is usually achieved. If a patient fails to respond satisfactorily to ESAs, the dose is increased in stepwise upward titrations of 25% to 50%, and if there is still an inadequate response, causes of resistance to ESA therapy should be investigated (see later discussion).

Given the risks observed in trials aiming at Hb normalization, it is recommended that the Hb level should not be intentionally increased to 13 g/dl or higher and should generally not be maintained above 11.5 g/dl.

Causes of a Poor Response to Erythropoiesis-Stimulating Agent Therapy

Major (Frequent)	Minor (Less Common)
Iron deficiency	Poor compliance, poor adherence to ESA therapy
Infection, inflammation	Blood loss
Underdialysis	Hyperparathyroidism
	Aluminum toxicity (now rare)
	Vitamin B_{12} or folate deficiency
	Hemolysis
	Primary bone marrow disorders (e.g., myelodysplastic syndrome)
	Hemoglobinopathies (e.g., sickle cell disease)
	ACE inhibitors, angiotensin receptor blockers
	Carnitine deficiency
	Anti-EPO antibodies causing PRCA

Table 83-2 Causes of a poor response to erythropoiesis-stimulating agent (ESA) therapy. *ACE,* Angiotensin-converting enzyme; *EPO,* erythropoietin; *PRCA,* pure red cell aplasia.

Hyporesponsiveness to Erythropoiesis-Stimulating Agents

There is no absolute definition of hyporesponsiveness to ESA therapy, but according to the most recent guidelines, it is identified when the Hb concentration does not increase from baseline after the first month of ESA treatment on appropriate weight-based dosages or if after treatment with stable doses, patients require two increases in ESA doses up to 50% beyond the dose at which their condition had previously been stable.[14] Patients who are hyporesponsive have a worse prognosis than those who do respond.[35] The causes of resistance to ESA therapy are listed in Table 83-2, and it is important to correct them when possible. The major causes include iron deficiency (see later discussion), infection or inflammation, and underdialysis.[12,14] If the patient is self-administering (e.g., for peritoneal dialysis patients), poor adherence to or compliance with therapy must be excluded. If there is any doubt about the possibility of iron deficiency, a trial of intravenous iron may be useful. Vitamin B_{12}, folate, and thyroxine deficiency may be excluded easily by the appropriate laboratory tests, as may severe hyperparathyroidism. Aluminum toxicity is no longer a significant cause of ESA resistance. Depending on the ethnic origin of the patient, a hemoglobinopathy should be excluded by performance of Hb electrophoresis. Some patients taking ACE inhibitors or angiotensin receptor blockers may require higher doses of ESA therapy, although it is rarely necessary or indeed advisable to stop these drugs. The possibility of a primary bone marrow disorder, such as myelodysplastic syndrome, should be investigated by a bone marrow examination (aspirate and trephine) if all other causes have been excluded. A bone marrow test may also be necessary in the diagnosis of antibody-mediated pure red cell aplasia, although measurement of the reticulocyte count and anti-EPO antibodies may provide an earlier clue.[25] If a patient receiving ESA therapy has a high reticulocyte count, the bone marrow is generating more than adequate quantities of new red cells, and bleeding or hemolysis should be investigated by means of upper gastrointestinal endoscopy, colonoscopy, or hemolysis screen (Coombs test, serum bilirubin, lactate dehydrogenase, and haptoglobin levels).

There is no defined upper dose limit of ESA, and doses of 60,000 IU of EPO per week have not uncommonly been used in the United States, but there is recent concern that high doses of ESA may increase side effects independently of Hb concentrations, as described earlier. In patients with acute illness requiring hospitalization, Hb frequently falls despite continued ESA therapy, indicating increased

blood loss and temporary hyporesponsiveness. The optimal management of anemia under these conditions remains unclear. Whereas cost considerations may speak for withholding of ESA therapy until responsiveness is reestablished, it has also been proposed that doses should be increased in an attempt to overcome hyporesponsiveness. Very high doses can be effective even in critically ill patients in intensive care units, but a pivotal trial[36] failed to demonstrate a reduction in transfusion requirements and observed an increase in deep vein thrombosis. From a practical point of view, and pending evidence to the contrary, it seems sensible to continue the same dose of ESA.

Iron Management

Iron is an essential ingredient for heme synthesis, and adequate amounts of this mineral are required for the manufacture of new red cells. Thus, under enhanced erythropoietic stimulation, greater amounts of iron are used, and many CKD patients (particularly those on hemodialysis) have inadequate amounts of available iron to satisfy the increased demands of the bone marrow.[37] Even before the introduction of ESA therapy, many CKD patients were in negative iron balance as a result of poor dietary intake, poor appetite, and increased iron losses from occult and overt blood losses (see Chapter 87). Losses in hemodialysis patients are up to 5 or 6 mg/day, compared with 1 mg in healthy individuals, and this may exceed the absorption capacity of the gastrointestinal tract, particularly when there is any underlying inflammation. Iron absorption capacity in patients with CKD is considerably lower than in nonuremic individuals, particularly in the presence of systemic inflammation, and this is probably mediated by hepcidin upregulation (see earlier discussion).[9] For this reason also, oral iron is ineffective in many CKD patients, and parenteral iron administration is required, particularly in those receiving hemodialysis.[37] However, even with these limitations of oral iron absorption, the cheap costs of using this route, along with convenience for the patient, often persuade physicians to try oral iron supplementation first in nondialysis patients; if, however, there is insufficient response after 2 to 3 months, intravenous iron should be administered.

An inadequate supply of iron to the bone marrow may be caused by an absolute or a functional iron deficiency.[37] Absolute iron deficiency occurs when there are low whole-body iron stores, as indicated by a serum ferritin level less than 30 µg/l. Functional iron deficiency occurs when there is ample or even increased storage iron but the iron stores fail to release iron rapidly enough to satisfy the demands of the bone marrow. Several markers of iron status are available, but none of them is ideal (Table 83-3). Serum ferritin is a marker of storage iron but is spuriously raised in inflammatory conditions and liver disease. Transferrin saturation is a function of the circulating serum iron in relation to the total iron-binding capacity and is often regarded as a better measure of available iron; however, levels can be highly fluctuant because of significant diurnal variation in the measurement of serum iron.[37] The percentage of hypochromic red cells and the reticulocyte hemoglobin content (CHr) are red cell and reticulocyte parameters, respectively, that are indirect measures of how much iron is being incorporated into the newly developing or mature red cell. No one measure of iron status is usually adequate to exclude iron deficiency, and the recommended levels for these measures are based on limited scientific evidence. Functional iron deficiency is usually diagnosed when there is a normal or increased ferritin level and a reduced transferrin saturation (<20%) or increased hypochromic red cells (>10%). The KDIGO guidelines on renal anemia management suggest a trial of iron in CKD patients with anemia who are not on iron and ESA therapy and in whom an increase in Hb concentration is desired and in patients on ESA therapy in whom an increase in Hb concentration or a decrease in ESA dose is required when transferrin saturation (TSAT) is 30% or lower and ferritin level is 500 ng/ml or lower[14] (see Table 83-3). Levels of ferritin above this threshold usually do not confer any clinical advantage and may exacerbate iron toxicity. The optimal transferrin saturation is above 20% to 30% to ensure a readily available supply of iron to the bone marrow. No upper limits of ferritin or TSAT were specified in the KDIGO anemia guidelines, largely because there is no robust evidence to determine a threshold beyond which harm or loss of efficacy supervenes. However, until more informative data become available, the treating nephrologist would be well advised to exercise caution in administering intravenous iron to patients with ferritin levels above 800 ng/ml or TSAT levels above 30%. Several studies support the maintenance of the percentage of hypochromic red cells at levels of less than 6% and the CHr at levels greater than 29 pg/cell. Other measures of iron status, such as serum transferrin receptor levels and erythrocyte zinc protoporphyrin levels, are mainly research tools and have not been established in routine clinical practice.

Markers of Iron Status in Chronic Kidney Disease Patients

Test	Recommended Range
Serum ferritin	100-500 µg/l (CKD) 200-500 µg/l (HD)
Transferrin saturation	20%-40%
Hypochromic red cells	<10%
Reticulocyte hemoglobin content (CHr)	>29 pg/cell
Serum transferrin receptor	Not established
Erythrocyte zinc protoporphyrin	Not established

Table 83-3 Markers of iron status and the recommended target ranges in CKD. *HD,* Hemodialysis.

Oral iron is poorly absorbed in uremic individuals, and there is a high incidence of gastrointestinal side effects. Intramuscular administration of iron is not recommended in CKD, given the enhanced bleeding tendency, the pain of the injection, and the potential for brownish discoloration of the skin. Thus, intravenous administration of iron has become the standard of care for many CKD patients, particularly those receiving hemodialysis.[37] There are several intravenous iron preparations available worldwide, including iron dextran, iron sucrose, iron gluconate, and the newer iron preparations ferric carboxymaltose, ferumoxytol, and iron isomaltoside 1000. The last three iron preparations allow higher doses of intravenous iron to be administered more rapidly, without the need for a test dose. All of the iron preparations contain elemental iron surrounded by a carbohydrate shell, which allows them to be injected intravenously. The lability of iron release from these preparations varies, with iron dextran being the most stable and iron gluconate being the least stable. Iron is released from these compounds to plasma transferrin and other iron-binding proteins and is eventually taken up by the reticuloendothelial system.

In hemodialysis patients, it is easy and practical to give low doses of intravenous iron (e.g., 10 to 20 mg every dialysis session) or, alternatively, 100 mg weekly. In peritoneal dialysis and nondialysis CKD patients, however, such low-dose regimens are impractical, and larger doses may be administered. The more stable the iron preparation, the larger the dose administration rate that can be used. For example, 1 g of iron dextran may be given by intravenous infusion,

whereas the maximum recommended dose of iron gluconate is 125 mg. The usual dose of ferumoxytol is 510 mg, whereas up to 1 g of ferric carboxymaltose or iron isomaltoside 1000 may be given as a single administration. All intravenous iron preparations carry a risk for immediate hypersensitivity reactions, which may be characterized by hypotension, dizziness, and nausea. These reactions are usually short-lived and caused by too large a dose given in too short a time. Iron dextran also carries the risk for acute anaphylactic reactions because of preformed dextran antibodies, and although this risk may be less with the lower-molecular-weight iron dextrans, the potential for anaphylaxis still remains. Other, longer-term concerns about intravenous administration of iron include the potential for increased susceptibility to infections and oxidative stress. Much of the scientific evidence for this has been generated from *in vitro* experiments, the clinical significance of which is unclear.

There is emerging evidence that intravenous iron may improve the anemia of CKD in up to 30% of patients not receiving ESA therapy who have a low ferritin level.[38] In such patients, a response to intravenous iron alone may occur within 2 to 3 weeks of iron administration. In those already receiving ESAs, there is considerable evidence that concomitant intravenous iron may enhance the response to the ESAs and result in lower dose requirements.[12,14,37]

CHAPTER 84

Other Blood and Immune Disorders in Chronic Kidney Disease

†Walter H. Hörl

PLATELET DYSFUNCTION AND COAGULATION DEFECTS

Normal hemostasis begins with platelet adhesion to vascular endothelium and requires a relatively vasoconstricted vessel wall, integrity of platelet glycoproteins (GPs), and a normal quantity of large-molecular-weight, multimeric von Willebrand factor (vWF) (Figs. 84-1 and 84-2). Main platelet GPs are GPIb, the platelet receptor for vWF, involved in platelet adhesion, and GPIIb/IIIa, the platelet receptor for fibrinogen, involved in platelet aggregation. Under static conditions, GPIb and vWF have no affinity for each other. However, these molecules develop a specific affinity for each other at high shear stress, resulting in arterial platelet adhesion. Aggregated fibrinogen-platelet mesh acts as a trap for binding and activation of other plasma clotting factors. The exposure of the preceding clotting factors to tissue factors, present on damaged endothelial cells, catalyzes the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin. Subsequent cross-linking of insoluble fibrin results in a stable hemostatic plug.

BLEEDING DIATHESIS IN UREMIA

Uremic bleeding caused by acquired platelet dysfunction is a major cause of morbidity and mortality in end-stage renal disease (ESRD) patients. The bleeding problems are characterized by abnormal prolongation of bleeding time and hemorrhagic symptoms, manifesting usually as ecchymoses or petechiae in the skin, epistaxis, gastrointestinal or gingival oozing, or prolonged hemorrhage from needle puncture or postoperative sites. The cutaneous bleeding time (normal values are 1 to 7 minutes) is the best laboratory hallmark of clinical bleeding caused by uremia; however, it is very difficult to standardize and thus not widely used. Other coagulation screen tests, such as activated partial thromboplastin time (APTT), prothrombin time, and thrombin time, are generally normal in patients with uremia.[1] Hemorrhagic complications in ESRD patients may also manifest as hemorrhagic pericarditis and/or hemorrhagic pleural effusion as well as intracranial, retroperitoneal, ocular, or uterine bleeding.

PLATELET DYSFUNCTION

The pathogenesis of platelet dysfunction in uremia is multifactorial and includes diminished adherence of platelets to vascular endothelium (Box 84-1). In uremic patients, total platelet GPIb content is reduced, whereas the total content of GPIIb and GPIIIa is normal. Platelet membrane GPIb levels and GPIIb/IIIa expression have been described as normal, decreased, or increased in uremic platelets. Plasma vWF level is normal or elevated in uremia. However, the observation that the administration of agents that increase plasma vWF or the factor VIII–vWF complex results in a shortening of prolonged bleeding time and a transient reversal of bleeding tendency in uremia suggests abnormalities in vWF metabolism, structure, and/or function.

A variety of circulating plasma proteases, such as plasmin, cleave the α chain of platelet GPIb. The resulting proteolytic degradation product glycocalicin contains binding sites for thrombin and vWF. Elevated plasma glycocalicin levels in uremic patients may contribute to diminished binding of uremic platelets to subendothelium because of the vWF binding site of glycocalicin. Furthermore, glycocalicin contains the thrombin binding site of GPIb which may also contribute to diminished platelet function in uremia.

Low GPIb expression on resting platelets obtained from patients with chronic kidney disease (CKD) correlates with the severity of impaired kidney function. However, GPIb expression in uremic platelets increases after stimulation. In contrast, GPIIb/IIIa expression on resting uremic platelets is normal but reduced after stimulation, indicating hyporesponsiveness of the uremic platelets.

The ability to bind both vWF and fibrinogen to GPs is reduced in uremia because of a conformational change in the GPIIb/IIIa receptor. Improvement of fibrinogen binding to GPIIb/IIIa by hemodialysis (HD) treatment suggests that uremic toxins such as methylguanidine, guanidinosuccinic acid, phenolic acid, and hydroxyphenylacetic acid also contribute to platelet dysfunction. HD and peritoneal dialysis (PD) correct platelet abnormalities partially because both procedures do not remove all uremic toxins effectively. PD is more effective than HD in improving impaired platelet function and prolonged bleeding time in uremia, possibly because of better clearance of uremic middle molecules. In addition, platelet contact with older cellulose-based HD membranes caused defects in platelet membrane receptors for vWF and fibrinogen, thus preventing normal platelet-vessel wall and platelet-platelet interactions. This can be demonstrated by a more prolonged bleeding time, a more decreased platelet responsiveness to thrombin, and a decreased platelet agglutination in response to ristocetin immediately after the HD procedure. Heparin administered during HD treatment contributes to the prolonged bleeding time immediately after dialysis although not for the platelet alterations described earlier. Platelet contact with the artificial surfaces may result in GPIb internalization, which may also occur during platelet activation.

Molecules such as prostacyclin and nitric oxide (NO) inhibit platelet function, modulate vascular tone, affect platelet–vessel wall as well as platelet-platelet interactions, and have an important role in preventing platelet activation under normal conditions. However, uremic platelets generate more NO than platelets obtained from healthy patients, which may contribute to the increased bleeding

†Deceased.

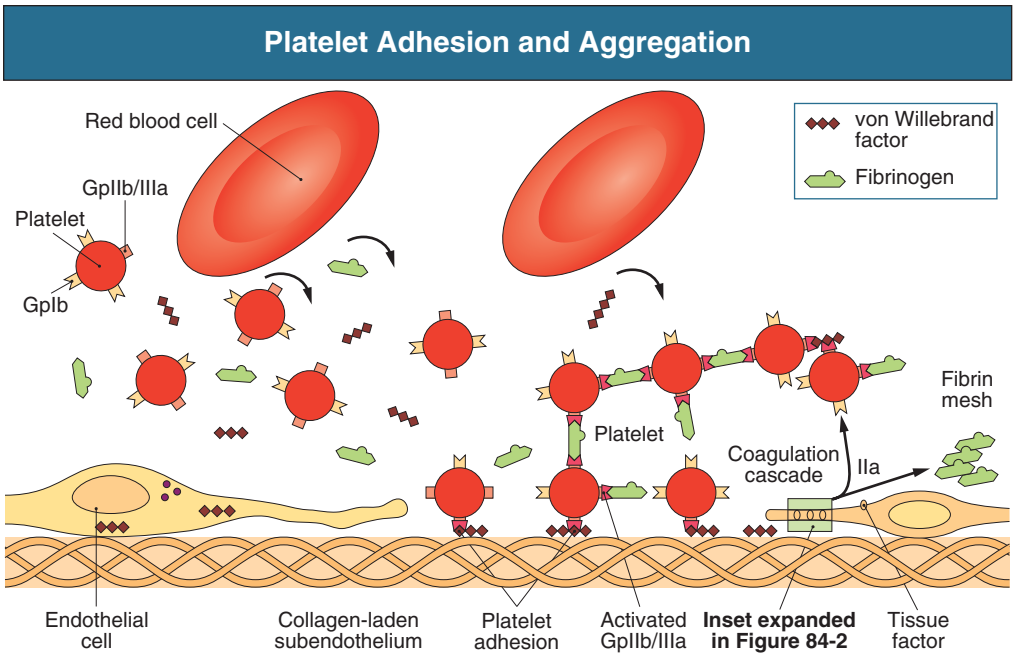

Figure 84-1 Platelet adhesion and aggregation. Platelets are pushed peripherally toward the vascular wall by red blood cells traversing centrally through the bloodstream. Damage to the vessel wall results in a disruption of the nonthrombogenic endothelial cell lining and exposure of subendothelial structures. Whereas collagen supports initial platelet adhesion (and subsequent aggregation), von Willebrand factor (vWF) deposition on the subendothelium serves as the main anchor for platelet adhesion through platelet GPIb receptor. Postadhesion conformational change in platelet GPIIb/IIIa receptor (fibrinogen or vWF receptor) results in interlinking platelet aggregation.

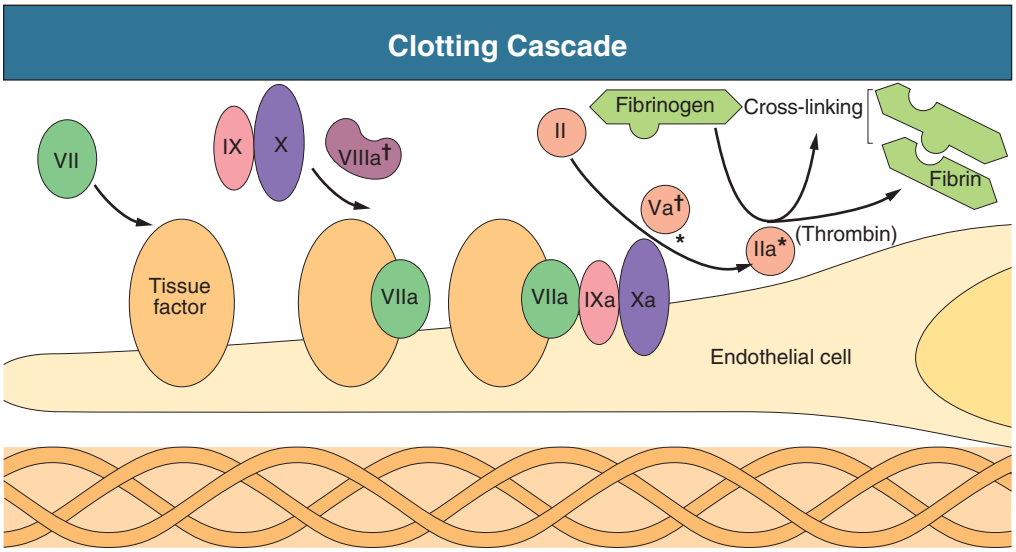

Figure 84-2 Clotting cascade. Expansion of the inset in Figure 84-1 shows the clotting cascade that takes place at the damaged vessel wall. Exposure of subendothelial tissue factor, present on pericytes and fibroblasts, allows eventual activation of prothrombin (factor II) to thrombin. Thrombin converts fibrinogen to fibrin, activates fibrin cross-linking, stimulates further platelet aggregation, and activates anticoagulant protein C. Naturally occurring anticoagulants antithrombin III, protein C, and protein S help maintain control and counterbalance on coagulation. *Site of anticoagulant effect for antithrombin III. †Site of anticoagulant effect for protein C–protein S complex. *(Courtesy James A. Sloand, MD, FACP, FASN, Baxter Healthcare Corporation, USA.)*

time in uremia. Uremic plasma induces NO synthesis in endothelial cells. Bleeding tendency in uremic patients is related to the increased platelet nitric oxide synthase (NOS) activity. The NOS substrate L-arginine inhibits platelet aggregation, whereas the NOS inhibitors NG-monomethyl-L-arginine (L-NMMA) and NG-nitro-L-arginine methylester (L-NAME) restore platelet adhesion and aggregation. Inhibition of NOS by L-NMMA restores the increased bleeding time in experimental uremia to normal. Elevated arginine transport in uremic platelets is mediated by the high-affinity amino acid transport system y^+L. Thus, increased L-arginine influx into uremic platelets is sustained and may contribute to platelet dysfunction even in the L-arginine–deprived uremic milieu.

Renal anemia is another determinant of the prolonged bleeding time in ESRD patients. Within the normal circulation red blood cells increase platelet–vessel wall contact by displacing platelets away from the axial flow and toward the vessel wall. Red blood cells also improve platelet function by releasing adenosine diphosphate (ADP) and inactivating prostacyclin. Vasodilating effects of prostacyclin and NO increase vessel luminal diameter and decrease peripheral dispersion of platelets and their contact with the vessel wall. Recombinant human erythropoietin (rHuEPO) improves platelet function mainly through increasing hematocrit, whereas an increase in blood viscosity may enhance the risk for thrombotic events. Platelet aggregation in uremia is ameliorated by rHuEPO therapy even at a dose that does not influence hemoglobin and hematocrit by the release of young platelets into the blood. Low-dose rHuEPO therapy in patients with uremia also improves impaired platelet aggregation stimulated by ADP and ristocetin.

PLATELET NUMBER IN UREMIA

Moderate thrombocytopenia (80 to 150×10^9/l) is a common finding in ESRD patients. The platelet number is reduced in 16% to 55% of uremic patients. However, the platelet count is rarely less than 80×10^9/L, a platelet number generally considered adequate for normal

Pathogenesis of Platelet Dysfunction in Uremia

- **Platelet abnormalities**
  - Alterations in membrane fluidity
  - Reduction in intracellular ADP and serotonin
  - Enhanced intracellular cAMP
  - Impaired release of β-thromboglobulin and ATP
  - Increased NO production
  - Increased intracellular Ca^{2+} (caused by secondary hyperparathyroidism)
  - Abnormal mobilization of platelet Ca^{2+}
  - Defective cyclooxygenase activity
  - Reduced thromboxane A_2 generation
  - Decreased platelet factor 3 availability
  - Reduced total GPIb content (with increased glycocalicin formation)
  - Reduced GPIIb/IIIa after stimulation
  - Diminished responsiveness to platelet agonists
  - Decreased clot retraction
  - Aggregation abnormalities (mostly hyperaggregation)
  - Abnormal platelet adherence
- **Uremic toxins**
- **Anemia**
- **vWF abnormalities**
- **Vessel abnormalities**
- **Drugs** (β-lactam antibiotics, nonsteroidal anti-inflammatory drugs, antiplatelet agents)

Box 84-1 Pathogenesis of platelet dysfunction in uremia. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *NO,* nitric oxide; *vWF,* von Willebrand factor.

hemostasis. In the past, the interaction of blood with cellulose-based dialyzer membranes (e.g., cuprophane) resulted in complement activation and transient thrombocytopenia during the dialysis procedure. In contrast, relevant platelet reduction does not occur with the use of newer non–complement-activating dialyzer membranes. Heparin may induce thrombocytopenia via the emergence of antibodies. The principle antigen is a complex of platelet factor 4 and heparin (PF-4/H). Frequencies of anti–PF-4/H antibodies range from 0% to 12% in HD patients continuously exposed to heparin. In patients with heparin-induced thrombocytopenia (HIT) type II, platelet counts range from 50 to 80 $\times$ 10^9/l (see later). Increased numbers of circulating reticulated platelets in uremia suggest shortened platelet survival under these conditions. Reduced platelet half-life and low-normal platelet number in uremia suggest increased platelet turnover. Normal controls have a mean of 2.8% $\pm$ 0.2% reticulated platelets (a marker of platelet turnover), whereas PD and HD patients have a significantly higher percentage of 6.9% $\pm$ 0.7% and 8.2% $\pm$ 0.4%, respectively, suggesting enhanced platelet turnover in uremia. Shortened platelet survival in uremia may be the result of increased exposure of negatively charged phosphatidylserine. This signal is recognized by macrophages and promotes phagocytosis of the platelets.

THERAPEUTIC STRATEGIES

The bleeding disorder of uremic patients has been classically defined as an acquired defect of primary hemostasis, characterized by prolongation of bleeding time. Therapeutic strategies include both prevention of bleeding in patients at high risk because of invasive procedures or surgery, and treatment of patients with active bleeding. Several options are available to prevent or treat uremic bleeding.

Mechanisms by Which Erythropoiesis-Stimulating Agent (ESA) Therapy Improves Uremic Bleeding Tendency

Displacement of platelets closer to the vascular endothelium with the increase in circulating red blood cells

Increase in reticulated (metabolically active) platelets

Increase in platelet aggregation

Improvement of platelet signaling (and thereby better response to stimuli)

Scavenging of nitric oxide by hemoglobin, resulting in increased platelet adhesion

Box 84-2 Mechanisms by which ESA therapy improves uremic bleeding tendency. *(Data from reference 2.)*

Dialysis

Adequate dialysis (Kt/V > 1.2 in HD and Kt/V > 1.7 in PD patients; see Chapter 94) by removal of uremic toxins improves platelet functional abnormalities. Hemorrhagic problems are fewer with PD than with HD. Deep-tissue biopsies or invasive surgical procedures that require improved hemostasis should ideally be scheduled 12 to 24 hours after dialysis in HD patients. The residual anticoagulant effect of unfractionated heparin (UFH) used during HD lasts as long as 2.5 hours or even longer with the use of low-molecular-weight heparin (LMWH). In case of clinical urgency or high risk of postoperative bleeding, heparin use should be minimized, stopped (using predilutional saline, 100 to 200 ml every 15 or 30 minutes, and a dialysis membrane with low thrombogenicity such as polysulfone), or replaced by regional anticoagulation with citrate during HD. Protamine sulfate administration (1 mg/100 U of heparin infused over 10 minutes) should be considered if there is marked, HD-induced prolongation of the partial thromboplastin time (PTT) and severe bleeding.

Correction of Anemia

The severity of anemia in uremic patients correlates with the prolongation of bleeding time. Beneficial effects of red cell transfusion on prolonged bleeding time are independent of changes in platelet function tests or in the level of vWF. Erythropoiesis-stimulating agent (ESA) therapy improves uremic bleeding tendency by several mechanisms (Box 84-2),[2] and this has diminished hemorrhagic problems in uremic patients. Increased intraoperative bleeding complications have been reported in ESRD patients with low preoperative hematocrit levels. Unfortunately, in ESRD patients, intraoperative transfusion of packed red blood cells may cause or aggravate hyperkalemia. If surgery is elective, ESA therapy (in combination with intravenous iron) may be administered preoperatively to raise hemoglobin and hematocrit to the upper acceptable values (see Chapter 83). In uremic patients on ESA therapy, a threshold hematocrit of 27% to 32% effectively normalized bleeding time.[1]

Cryoprecipitate

Cryoprecipitate is a blood product rich in factor VII, vWF, and fibrinogen. In uremic patients at high risk of bleeding or with active

bleeding, the effect of cryoprecipitate is apparent 1 hour after infusion, but maximal effects on the bleeding time are obtained 4 to 12 hours after the infusion. By 24 to 36 hours, the effect of cryoprecipitate is no longer detected. As many as 50% of patients fail to respond to cryoprecipitate.[1] Disadvantages include the risk of exposure to various blood-borne pathogens and allergic reaction.[2] It has therefore largely been replaced by other approaches.

Desmopressin

Desmopressin acetate (1-deamino-8-D-arginine-vasopressin, DDAVP) is a synthetic derivative of the antidiuretic hormone vasopressin. The compound has been shown to be useful in a variety of inherited and acquired hemorrhagic conditions, such as uremia, and in patients with hemostatic defects induced by therapeutic use of antithrombotic drugs, such as aspirin, dipyridamole, clopidogrel or ticlopidine. Moreover, DDAVP shortens bleeding time and APTT of patients receiving heparin. It is therefore helpful for the management of hemorrhagic complications during treatment with heparin. Desmopressin shortens the prolonged APTT and bleeding time by an increase in plasma levels of factor VIII and vWF. The increase in larger vWF–factor VIII multimers after infusion of DDAVP is associated with shortening of bleeding time. It also increases platelet GPIb expression.

Desmopressin is the most common agent used in uremic patients. The recommended doses range from 0.3 to 0.4 μg/kg administered intravenously in 50 ml normal saline over 20 to 30 minutes as a single infusion. Subcutaneous (0.3 μg/kg) or intranasal (2-3 μg/kg) routes of administration are also effective. One important advantage of DDAVP is its rapid onset of action in the setting of acute bleeding. Desmopressin decreases bleeding time within approximately 1 hour after administration. This advantage is important for CKD patients with prolonged bleeding time who require biopsies or major surgery. Disadvantages of DDAVP include tachyphylaxis caused by depletion of vWF from endothelial stores even after one single dose, headache, facial flushing, and rare thrombotic events. Because of the short duration of DDAVP activity (4 to 6 hours), bleeding time tends to return toward baseline within 24 hours, indicating patients are once again at risk of bleeding.[2] DDAVP can be given repetitively, but its effect may diminish in some patients as a result of tachyphylaxis if given at short time intervals.

Conjugated Estrogens

Conjugated estrogens can be given intravenously, orally, or transdermally. The intravenous route of administration at a cumulative dose of 3 mg/kg divided over 5 consecutive days produces a long-lasting reduction in the bleeding time of uremic patients. At least 0.6 mg/kg of a conjugated estrogen is needed to reduce bleeding time. A single oral dose of 25 mg normalizes the bleeding time for 3 to 10 days. Low-dose transdermal application of a conjugated estrogen (50 to 100 μg of estradiol per 24 hours) as a patch twice weekly also improves bleeding time and reduces bleeding complications. Conjugated estrogens are safe and well tolerated.[1] Side effects include flush, increase in blood pressure, and abnormal liver function tests.

Tranexamic Acid

Tranexamic acid (TXA) is an antifibrinolytic lysine analog that shortens bleeding time in uremic patients. TXA prevents the binding of plasminogen to fibrin and the activation of plasminogen to plasmin. Bleeding time improves or normalizes in uremic patients within 6 days of treatment with TXA (20 to 25 mg/kg/day) administered intravenously or orally. Improvement of bleeding time is already observed as soon as 24 to 48 hours after initiation of TXA therapy. TXA may be combined with DDAVP to prevent or treat bleeding in uremic patients, if other treatment options do not elicit the desired response.

PLATELET HYPERAGGREGABILITY IN UREMIA

Uremic patients also have a thrombophilic tendency and an increased incidence of thrombotic events because of platelet hyperaggregability and hypercoagulability. Binding of activated factor V to platelet surface exposed phosphatidylserine induces coagulation. In uremic patients who received muromonab-CD3 infusion for prophylaxis of graft rejection, platelet procoagulant activity increased by binding of anti–factor V/Va as a result of increased exposure of anionic phospholipids in platelets.

Platelet activation also results in shape change; activation of surface receptors for fibrinogen and other adhesion proteins; secretion of PF-4, β-thromboglobulin, thromboxane B_2, and serotonin; and induction of procoagulant activity. In HD patients, a relationship between recurrent vascular access failure and increase in CD62P-positive platelets and an increase in fibrinogen receptor (PAC-1 antigen)–positive platelets has been demonstrated.

Chronically activated circulating platelets seen in ESRD patients interact with leukocytes and erythrocytes, resulting in platelet-erythrocyte aggregates and platelet-leukocyte aggregates. Platelet-erythrocyte aggregates enhance platelet reactivity measurable by thromboxane B_2 formation and the release of β-thromboglobulin. Low levels of platelet-erythrocyte aggregates are found in healthy patients (1.2% ± 0.1%). This percentage increases approximately sixfold in ESRD patients but approximately 8-fold or 10-fold during HD. Platelet-leukocyte aggregates trigger neutrophil oxidative burst.

Platelets release small particles, so-called "platelet microparticles" (PMPs), after they are activated. PMPs express procoagulant proteins such as tissue factor and contain a membrane receptor for coagulation factor V. In addition, PMPs provide a highly catalytic surface for the prothrombinase reaction as a result of high amounts of negatively charged phospholipids at the outer membrane. PMP counts are significantly increased in predialysis patients as well as in patients undergoing regular PD or HD as compared with healthy patients.[3] The HD procedure does not affect PMP counts. However, rHuEPO therapy increases PMP release. Some studies suggest higher PMP counts in uremic patients with thrombotic events, but not all studies have confirmed these findings.

INDICATIONS FOR ANTIPLATELET AGENTS IN END-STAGE RENAL DISEASE

Despite the increased risk for bleeding in ESRD patients receiving antiplatelet agents, current evidence suggests that dialysis access thrombosis or loss of patency is reduced by antiplatelet agents, but only in native fistulas and not in grafts.[4] In contrast, access maturation or the need for intervention to attain patency or assist maturation tended to be improved or reduced, respectively, but this did not reach significance in a meta-analysis (see also Chapter 91).[4] There is no role for the routine use of warfarin, particularly in view of its adverse effects in HD patients (see later).

A recent Cochrane meta-analysis concluded that in CKD patients, myocardial infarction but not all-cause mortality was reduced by antiplatelet agents but that this came at the price of a 30% to 50%

increase in minor and major bleeding episodes.[4] The risk reduction of acute myocardial infarction was not major, and the number needed to treat to prevent one infarction was estimated as 77, which needs to be balanced against a number needed to harm of 115 to observe one major bleeding episode. The risks associated with antiplatelet therapy in the Cochrane analysis may, however, be an overestimate with respect to low-dose aspirin. Of importance, the Cochrane analysis yielded no evidence for increased mortality from antiplatelet agents, in particular aspirin, in CKD patients. For further discussion of this issue, refer to Chapter 82.

Because antiplatelet agents such as aspirin (low and full dose), dipyridamole, clopidogrel, or ticlopidine increase bleeding time, these drugs should not be given within 72 hours before biopsies and major surgery. Other drugs that may increase the risk of intraoperative bleeding in uremic patients include warfarin and coumadins, β-lactam antibiotics, nonsteroidal anti-inflammatory drugs, and diphenhydramine.

ANTICOAGULATION AND ASSOCIATED COMPLICATIONS IN UREMIA

Heparin-Induced Thrombocytopenia

Unfractionated heparin is the most commonly used anticoagulant in the United States. Risks of UFH use include bleeding, heparin-induced thrombocytopenia, hypertriglyceridemia, anaphylaxis, and possible bone mineral disease, hyperkalemia, and catheter-associated sepsis caused by the development of a biofilm.[5] HIT type II is a serious immune-mediated complication of heparin therapy. Severe thrombocytopenia (mean platelet number 60,000/mm^3) caused by platelet consumption usually occurs 4 to 14 days after the administration of heparin and is associated with arterial ("white clot syndrome") and, particularly, venous thromboembolism in 20% to 50% of the patients. HIT type II should be considered whenever the platelet count falls by 50% in a patient receiving heparin. HIT may develop when novel epitopes of PF-4 present on the platelet surface membrane are exposed because of cross-linking with heparin, resulting in autoantibody formation. These antibodies activate PF-4, resulting in peripheral thrombocytopenia. Patients with HIT antibodies without clinical complications need to be differentiated from those with HIT antibodies in whom active thrombosis (heparin-induced thrombotic thrombocytopenia syndrome [HITTS]) or hemorrhage exist. HITTS can be life-threatening. These patients not only require complete avoidance of all heparins but also need systemic anticoagulation. The direct thrombin inhibitors, such as argatroban, synthetic heparinoids, and danaparoid, are the current treatment options (Fig. 84-3). After heparin withdrawal, thrombocytopenia typically resolves within 5 to 7 days.[6,7] A negative HIT antibody test does not exclude the diagnosis of HIT type II syndrome. In HIT type II patients, warfarin should not be used until the platelet count has recovered.

In contrast, HIT type I presents with a nonimmune mild transient decrease in the platelet count (rarely <100,000/mm^3) 1 to 4 days after initiation of heparin therapy. It occurs in 10% to 20% of patients

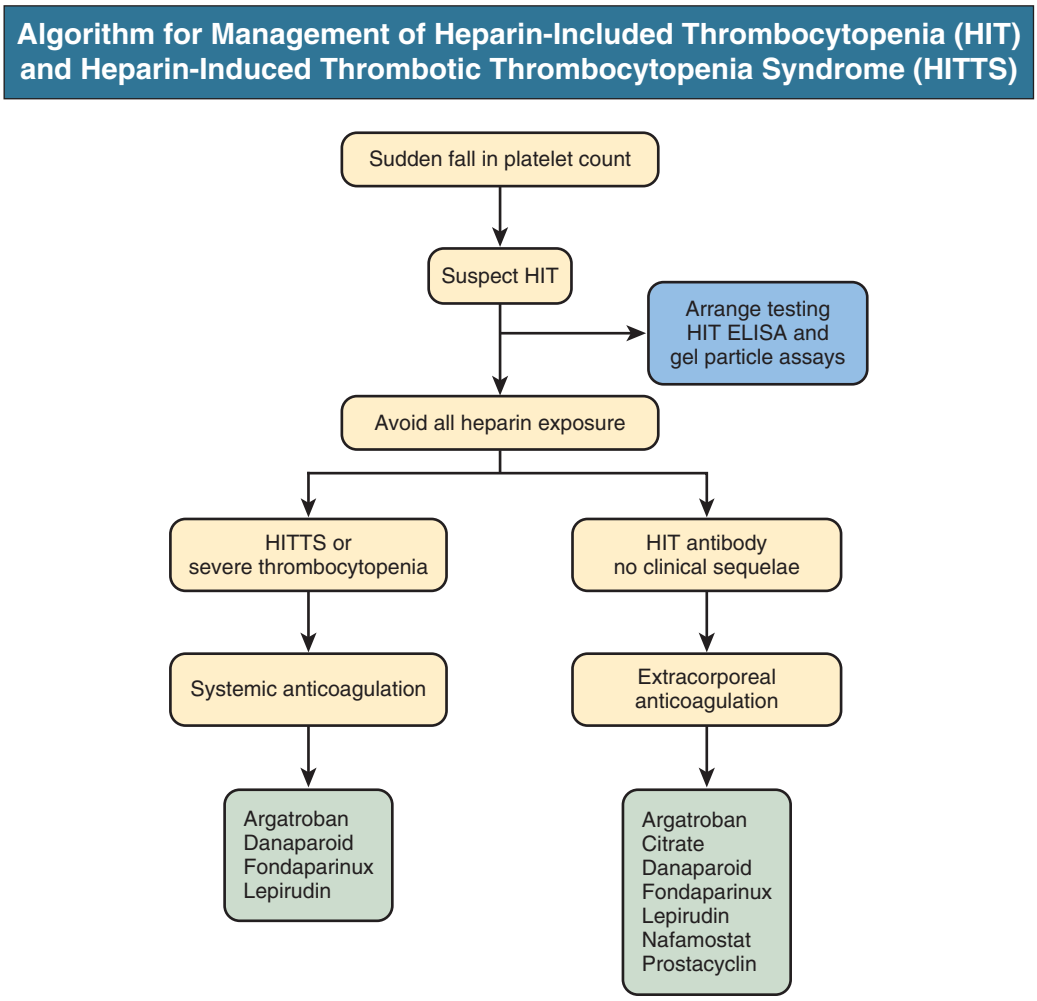

Figure 84-3 Algorithm for management of heparin-included thrombocytopenia (HIT) and heparin-induced thrombotic thrombocytopenia syndrome (HITTS). *ELISA,* Enzyme-linked immunosorbent assay. *(Modified from reference 6.)*

without appreciable clinical consequences and usually resolves spontaneously even though heparin therapy is continued.

In a summary of six trials performed in HD patients, 2.6% of patients had a positive test result for the HIT antibody, with a lower percentage in those using LMWH as compared with UFH.[8] Less than 1% of the HD patients were thrombocytopenic, and none had severe thrombotic complications. A recent survey reported a prevalence of 0.26 per 100 patients and an incidence of 0.32 per 100 patients of HIT II syndrome in the United Kingdom HD population. Only 17% of the patients have had complications of HIT II syndrome. Thirty-six percent of renal units used danaparoid as an alternative anticoagulation therapy in these patients.[9]

Danaparoid

Danaparoid is a mixture of glycosaminoglycans and acts by activating antithrombin. Danaparoid is a heparinoid with a molecular weight of 5.5 kDa and consists of heparin sulfate (83%), dermatan sulfate, and chondroitin sulfate. It is used as an alternative anticoagulant in HD patients with HIT type II in Canada and the European Community. Danaparoid reduces PF-4–containing immune complexes and therefore can prevent activation of platelets by HIT antibodies. It inhibits factor Xa more selectively than LMWH.[7] In 6.5% of patients with HIT, cross-reactivity against danaparoid may result in thrombocytopenia. For monitoring of danaparoid therapy, anti-Xa activity has to be measured. The half-life of the anti-Xa activity of danaparoid is 31 hours in patients with normal kidney function and is further prolonged in uremia. When treating patients with HITTS, systemic anticoagulation is required. It is recommended to start with a bolus of 2500 IU (1250 if <55 kg and 3750 IU if >90 kg), followed by an infusion of 200 IU/h, subsequently adjusted to maintain anti-Xa activity between 0.5 and 0.8 IU/ml.[6] An antidote is not available.[7]

Argatroban

Argatroban is a potent arginine-derived synthetic thrombin inhibitor. It is metabolized primarily by the liver. Its half-life is only moderately extended in patients with impaired kidney function. Argatroban does not cross-react with HIT antibodies. It reversibly binds to thrombin and thus requires continuous intravenous infusion. A loading dose of 250 μg/kg before HD and a maintenance dose of 1.7 to 3.3 μg/kg/min are recommended. Target APTT of argatroban-treated HD patients is 1.5 to 3.0 × mean of normal range.[7] Much lower doses are required for patients with liver disease. Over time, argatroban and the primary metabolite (with an anticoagulation effect) tend to accumulate, and excessive anticoagulation is a major risk. Because of protein binding, argatroban is not significantly cleared during HD. In patients with HIT antibodies without thrombosis, argatroban can be used for extracorporeal anticoagulation during HD, although the infusion should be stopped 20 to 30 minutes before the end of the dialysis session.[6] Currently, no antidote is available.

Lepirudin

Lepirudin is a recombinant hirudin preparation. It is mainly eliminated by the kidney. Thus, its half-life is markedly prolonged in patients with ESRD. After a single loading dose (0.1 mg/kg), therapeutic anticoagulation may persist for 1 week or even longer. Hirudin does not cross-react with HIT antibodies, but 44% to 74% of patients treated with hirudin for more than 5 days develop antihirudin antibodies. Antilepirudin antibodies are not necessarily associated with a decrease in efficacy. Only in 2% to 3% of patients with antilepirudin antibodies is an inhibitory effect seen, and dose adjustments are required. Target APTT is 1.5 to 2.5 times the normal value.

Fondaparinux

Fondaparinux is a fully synthetic pentasaccharide with high anti-Xa activity. Its half-life is prolonged in patients with impaired kidney function. Preliminary data suggest that administration of fondaparinux (2.0 to 3.5 mg for at least 5 days) is safe.[6] In patients with HITTS requiring systemic anticoagulation, 2.5 mg subcutaneously on nondialysis days and 2 mg intravenously predialysis provide systemic anticoagulation (anti-Xa 0.5 to 0.8 IU/ml). In patients not requiring systemic anticoagulation, 2.5 mg predialysis provides adequate extracorporeal anticoagulation. Fondaparinux is currently not approved in the United States.[6]

Regional Anticoagulation with Citrate

Citrate infused into the arterial line during HD inhibits the coagulation cascade in the extracorporeal circulation by the chelation of calcium and magnesium. The local deficit in ionized calcium is corrected by calcium substitution into the venous line before the blood is reinfused to the patient. In HD patients, regional citrate anticoagulation reduces bleeding complications and improves biocompatibility of dialysis membranes as compared with systemic anticoagulation with UFH or LMWH.

Careful reading of the information provided by the manufacturers and the dose recommendations is a prerequisite before alternative anticoagulation is initiated in patients with HIT type II.

THROMBOTIC EVENTS IN PATIENTS WITH END-STAGE RENAL DISEASE

Hemodialysis patients frequently experience thrombotic events at the site of vascular access, as well as in the coronary, cerebral, and retinal arteries. Pathogenetic mechanisms include enhanced platelet aggregability, diminished protein C anticoagulant activity, deficient release of tissue plasminogen activator (tPA), and elevated plasma levels of antiphospholipid (APL) antibodies, anti–protein C and anti–protein S antibodies, anticardiolipin antibodies, factor VIII, prothrombin fragments 1+2, fibrinogen, homocysteine, and lipoprotein(a). ESRD patients also develop thrombotic complications as the result of changes in secondary hemostasis and of impaired fibrinolytic system activity. APL antibodies can trigger activation of the coagulation cascade at the endothelial surface. These antibodies cross-react with protein C and S, rendering them functionally deficient. Reduced anti-thrombin III activity in uremia results in increased thrombin formation. Activated factor V (factor Va) serves as a cofactor for the conversion of prothrombin to thrombin. Its inactivation occurs by activated protein C. The factor V Leiden mutation alters factor C cleavage site by a single amino acid substitution, rendering it resistant to degradation by activated protein C. Heterozygosity for factor V Leiden mutation occurs in 2% to 5% of the Western population. Its prevalence is not increased in CKD patients, but factor V Leiden increases the risk of thrombotic complications.

Approximately 6% of ESRD patients at risk of thrombosis or thromboembolic events may be treated with oral anticoagulants, which increase the frequency of hemorrhages. Other potential adverse effects of long-term therapy with vitamin K antagonists, in particular in the dialysis population, are accelerated vascular and

valvular calcifications[10] (see Chapter 82), as well as a 10-fold increase in the risk of calcific uremic arteriolopathy (calciphylaxis) (see Chapter 88). Standard oral anticoagulation with an international normalized ratio (INR) of 2 to 3 is not sufficient to prevent clotting during HD. Additional low-dose LMWH or UFH is needed to facilitate adequate extracorporeal treatment.

The emergence of anticardiolipin antibodies in patients with systemic lupus erythematosus is a serious occurrence with regard to a high risk for thrombosis and thromboembolic complications. Immunoadsorption therapy may be an effective method to reduce anticardiolipin antibody levels rapidly and keep them at a low level in the long term.[11]

IMMUNE DYSFUNCTION IN UREMIA

End-stage renal disease is simultaneously associated with immune activation, marked by systemic inflammation, and immune deficiency, characterized by impaired response to vaccination, and increased incidence and severity of microbial infections. Uremia-associated immune deficiency is caused by a large number of alterations in leukocytes (Box 84-3).[12] ESRD-associated systemic inflammation and oxidative stress are commonly associated with atherosclerosis, cardiovascular disease (CVD), cachexia, and anemia, among other morbidities. Bacterial infections remain the most common cause of hospitalization and the second most common cause of death in patients with ESRD.

Vaccination against hepatitis B virus (HBV) decreased the incidence of chronic HBV carriers in ESRD patients. However, only 50% to 75% of dialysis patients develop protective antibodies (>10 IU/l) against HBV surface antigen as compared with greater than 90% in the healthy population. High failure rates have also been reported for vaccinations against the influenza virus, *Clostridium tetani,* and *Corynebacterium diphtheriae.* Because the antigens in all these vaccines are proteins, the antibody response is T lymphocyte dependent. In contrast, the response to polysaccharide antigens is normal in dialysis patients. Therefore antibody production after vaccination against pneumococci is normal in ESRD. Thus the disturbance of acquired immunity of uremic patients concerns mainly the T lymphocyte and not the B lymphocyte. This assumption is supported by the fact that serum IgG isotypes and both IgM and IgA production are normal in ESRD patients. Nevertheless, nonspecific B lymphocyte activation may be responsible for the enhanced autoantibody production observed in this population.[13]

Premature aging of the immune system in patients with ESRD might be related to a permanent skewing of the hematopoietic stem cell population toward myeloid-generating subsets, similar to that seen in healthy elderly individuals.[14] In uremia, a diminished immune defense contributes to the high prevalence of infections, whereas preactivation and priming of immune cells lead to inflammation and consequently to CVD (see also Chapter 82). Whereas the coordinated removal via apoptosis of activated immune cells is crucial for the resolution of inflammation, inappropriately high apoptotic rates lead to a diminished immune response. In uremia, the balance between proinflammatory and anti-inflammatory and between pro-apoptotic and antiapoptotic factors is disturbed. CVD and infections are directly or indirectly associated with a disturbed immune response and account for the high incidence of morbidity and mortality among patients with kidney dysfunction. Besides uremic toxins accumulating in CKD patients as a result of impaired glomerular filtration, deranged metabolic activities in ESRD interfere with the immune defense in uremia.[15] A variety of additional factors such as iron deficiency, iron overload, or vitamin D deficiency may also contribute to cardiovascular and infectious complications in patients with ESRD.

Causes of Uremia-Associated Immune Deficiency

Polymorphonuclear Leukocytes (PMNLs) and Monocyte-Macrophage Abnormalities

- Decreased granulocyte and monocyte-macrophage phagocytic function and microbial killing activity
- Reduced numbers and decreased antigen-presenting capacity of dendritic cells
- Upregulation of Toll-like receptors TLR-2 and TLR-4
- Upregulation of integrin expression
- Increased production of reactive oxygen radicals
- Marked degranulation
- Increased polymorphonuclear neutrophil apoptosis

B and T Cell Abnormalities

- Significant B lymphopenia
- Reduced antibody-producing capacity of B lymphocytes
- Diminished population of $CD5^+$ innate B cells and $CD27^+$ memory B cells as a result of enhanced apoptosis and impaired maturation induced by uremia
- Reduction and dysfunction of regulatory T cells
- Depletion of memory $CD4^+$ and $CD8^+$ T lymphocytes
- Reduced CD4/CD8 ratio, increased Th1/Th2 ratio and depletion of memory $CD4^+$ and $CD8^+$ T cells because of increased apoptosis

Box 84-3 Causes of uremia-associated immune deficiency. *(Data from reference 12.)*

VACCINATIONS IN UREMIA

Hepatitis B Vaccination

Patients receiving maintenance HD are at increased risk of acquiring HBV infection. Therefore, HBV vaccination is recommended for CKD patients negative for hepatitis B surface antigen (HBsAg) and antibody to hepatitis B core antigen (anti-HBcAg), with antibody to hepatitis B surface antigen (anti-HBsAg) below 10 IU/l. Because attenuated response in ESRD, patients usually receive a three- or four-dose vaccination schedule with a higher dose of a recombinant HBV vaccine (40 µg/dose) than immunocompetent adults (20 µg/dose) and intramuscularly into the deltoid muscle (Fig. 84-4). Seroconversion rates of ESRD patients after HBV vaccination are quite variable. Anti-HBsAg levels above 10 IU/l are usually accepted as an adequate response. Older age and diabetes mellitus but not hepatitis C virus (HCV) infection attenuate the immunologic response to the HBV vaccine in both predialysis and dialysis patients.[16,17] Because seroconversion rates correlate with the CKD stage, vaccination of patients with CKD should ideally be performed before they become dialysis dependent. Successful vaccinations in nonresponders have been achieved by simultaneous administration of HBV vaccine with one of tetanus, diphtheria, oral or inactive polio, pertussis, or *Haemophilus influenzae* type B vaccine. Similarly, immunization with combined hepatitis A and B virus vaccine results in better seroprotection against hepatitis B compared with HBV monovalent vaccine in HD patients.[18] Seroprotection persisted in 92% of strong responders but only in 44% of weak responders after 1 year of immunization against HBV.[19] Whereas the current recommendation is to

Hepatitis B Vaccination Scheme in End-Stage Renal Disease Patients

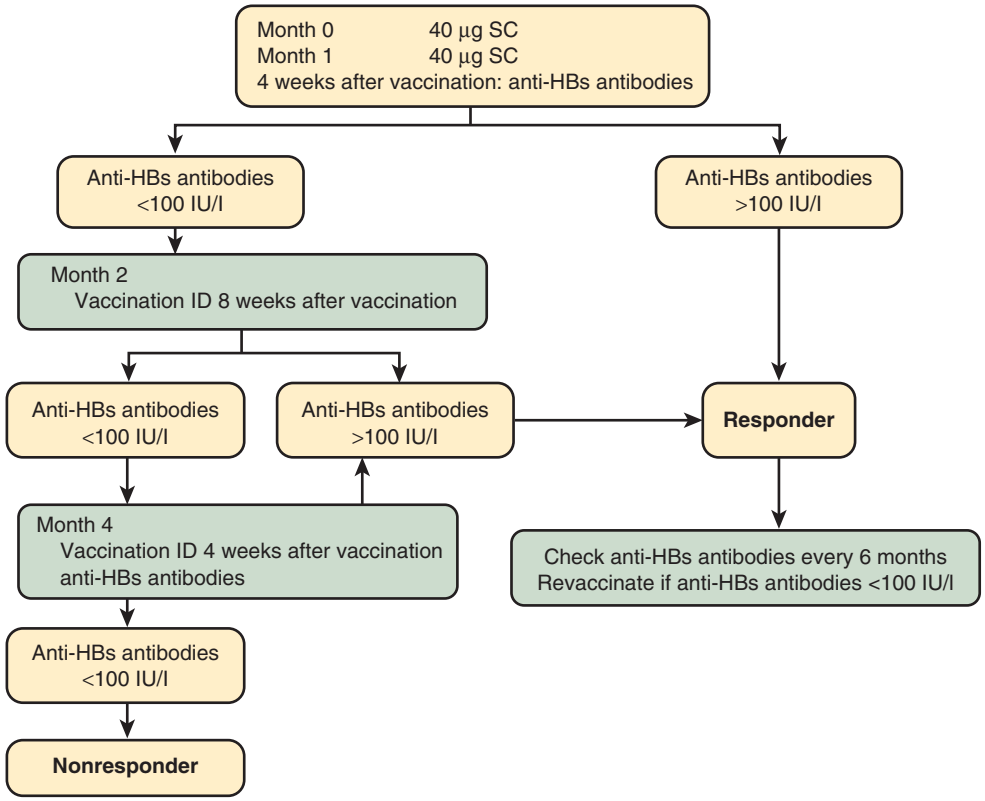

Figure 84-4 Hepatitis B vaccination scheme in patients with end-stage renal disease. *HBs,* Hepatitis B surface; *ID,* intradermal.

administer subsequent booster doses if protective antibody titers are below 10 IU/l, trials are needed to determine whether the threshold should be 100 IU/l or higher in immunocompromised individuals to maximize the duration of seroprotection.[20]

Hepatitis A Vaccination

The hepatitis A vaccine has been shown to be safe and effective in dialysis patients when given in standard doses. Seroconversion rates were also satisfactory in kidney transplant recipients when compared with healthy controls, but the majority of these patients will lose seroprotection after 2 years, probably because of immunosuppressive therapy.[20]

Vaccination Against Influenza and Pneumococcal Disease

Patients with ESRD are considered a high-risk population for hospitalization and death from seasonal influenza and pneumococcal disease. Dialysis patients who received influenza vaccination, vaccination against pneumococcal disease, or both had improved survival. The adjusted odds ratio of all-cause mortality for influenza vaccine alone was 0.79, and the adjusted odds ratio for coadministration of influenza and pneumococcal vaccine was 0.70 compared with no vaccination, suggesting that both influenza and pneumococcal vaccines prevent death and likely have a synergistic effect.[21]

Response rates of influenza vaccination have been reported to be similar to or lower than those in the general population. A single immunization using a higher than usual vaccine dose may be preferable in dialysis patients, because the effects of booster vaccinations were not uniform.[20]

Immunologic response to pneumococcal vaccine is lower in dialysis patients compared with the general population. The antibody levels are considerably lower than those of healthy vaccinated adults and decline rapidly (within 6 months to 5 years), whereas they usually remain sufficient in healthy patients after 5 years. Therefore vaccination every 2 years or an even more frequent regimen of annual vaccination in CKD patients is recommended.[20]

Tetanus and Diphtheria

The seroresponse to tetanus vaccination in HD patients is suboptimal because of impaired T cell–specific immunity. Protective antitetanus titers (≥0.1 IU/ml) develop at an about 20% lower frequency in HD patients compared with healthy individuals. Seroprotection against tetanus in HD patients has been shown to decline over time.[20]

Diphtheria immunization also results in lower protection rates and poor long-term immunity in ESRD patients as compared with healthy patients. In HD patients, long-term immunity against tetanus is better than against diphtheria. In ESRD patients, there is a need for regular monitoring of individual antibody levels and revaccination if required.[20]

Varicella Zoster Virus Vaccination

A relatively high prevalence of herpes zoster has been reported in the CKD and ESRD populations. The live attenuated vaccine has been shown to be highly effective in reducing the risk of zoster

among older adults or ESRD patients. A single dose of zoster vaccine has been recommended for persons aged 60 years or older with ESRD.

Vaccination against pneumococcal disease and varicella vaccination should not be performed at the same time because the combination has been shown to reduce the efficacy of the varicella vaccine.[20]

CHAPTER 85

Bone and Mineral Metabolism in Chronic Kidney Disease

Kevin J. Martin, Jürgen Floege, and Markus Ketteler

DEFINITION

Disturbances of mineral metabolism are common if not ubiquitous during the course of chronic kidney disease (CKD) and lead to serious and debilitating complications unless these abnormalities are addressed and treated. The spectrum of disorders includes abnormal concentrations of serum calcium, phosphate, and magnesium and disorders of parathyroid hormone (PTH), fibroblast growth factor 23 (FGF-23), and vitamin D metabolism. These abnormalities as well as other factors related to the uremic state affect the skeleton and result in the complex disorders of bone known as *renal osteodystrophy;* it is now recommended that this term be used exclusively to define the bone disease associated with CKD. The clinical, biochemical, and imaging abnormalities heretofore identified as correlates of renal osteodystrophy should be defined more broadly as a clinical entity or syndrome called *chronic kidney disease–mineral and bone disorder* (CKD-MBD).[1] The spectrum of skeletal abnormalities seen in renal osteodystrophy includes the following (Fig. 85-1):

- Osteitis fibrosa, a manifestation of hyperparathyroidism characterized by increased osteoclast and osteoblast activity, peritrabecular fibrosis, and increased bone turnover.
- Osteomalacia, a manifestation of defective mineralization of newly formed osteoid most often caused by aluminum deposition; bone turnover is decreased.
- Adynamic bone disease (ABD), a condition characterized by abnormally low bone turnover.
- Osteopenia or osteoporosis.
- Combinations of these abnormalities termed *mixed renal osteodystrophy.*
- Other abnormalities with skeletal manifestations (e.g., chronic acidosis, β_2-microglobulin amyloidosis).

EPIDEMIOLOGY

The prevalence of the various types of renal bone disease in patients with end-stage renal disease (ESRD) is illustrated in Figure 85-2.[2] In patients on hemodialysis, osteitis fibrosa and ABD now occur with almost equal frequency. In contrast, in patients on peritoneal dialysis, the adynamic bone lesion predominates. Osteomalacia represents only a small fraction of cases in either group but is more common in certain ethnic groups, particularly Indo-Asians. The abnormalities of the skeleton start relatively early in the course of CKD.

PATHOGENESIS

Several biochemical and hormonal abnormalities that are encountered during the course of CKD contribute to renal bone disease and can be affected by efforts at prevention and therapy. The major factors that are operative in early CKD may vary as CKD progresses (Fig. 85-3). Similarly, the predominance of one particular pathogenetic mechanism over another may contribute to the heterogeneity of bone disorders. We therefore discuss separately the two major entities, namely, high- and low-turnover osteodystrophy.

Osteitis Fibrosa: Hyperparathyroidism—High-Turnover Renal Bone Disease

Elevated levels of PTH in blood, hyperplasia of the parathyroid glands, and elevations in FGF-23 are seen early in CKD. Whereas the level of free (i.e., non–protein bound) calcium in blood is normally the principal determinant of PTH secretion, during the course of CKD, several metabolic disturbances also alter the regulation of the secretion of PTH.

Abnormalities of Calcium Metabolism

There are three main body pools of calcium: the bony skeleton (mineral component), the intracellular pool (mostly protein bound), and the extracellular pool (see Chapter 10). The calcium in the extracellular pool is in continuous exchange with that of bone and cells and is altered by diet and excretion. Calcium metabolism depends on the close interaction of two hormonal systems: PTH and vitamin D. Perturbations of both of these systems occur during the course of CKD, with adverse consequences on the skeleton. Total serum calcium tends to decrease during the course of CKD as a result of phosphate retention and decreased production of 1,25-dihydroxyvitamin D (calcitriol) from the kidney, decreased intestinal calcium absorption, and skeletal resistance to the calcemic action of PTH, but the levels of free calcium remain within the normal range in most patients[3] as a result of compensatory hyperparathyroidism. Because calcium is a major regulator of PTH secretion, persistent hypocalcemia is a powerful stimulus for the development of hyperparathyroidism and also contributes to parathyroid growth.

Abnormalities of Phosphate Metabolism

With progressive CKD, phosphate is retained, at least, transiently, by the failing kidney. However, hyperphosphatemia usually does not become evident before CKD stage 4. Until then, compensatory hyperparathyroidism and increases in circulating FGF-23 result in increased phosphaturia, maintaining serum phosphate levels in the normal range.[4]

One mechanism by which phosphate retention may lead to hyperparathyroidism is by a decrease in serum free calcium, which in turn stimulates the secretion of PTH (Fig. 85-4). Thus, a new steady state is achieved in which serum phosphate is restored to normal at the expense of a sustained high level of PTH. This cycle is

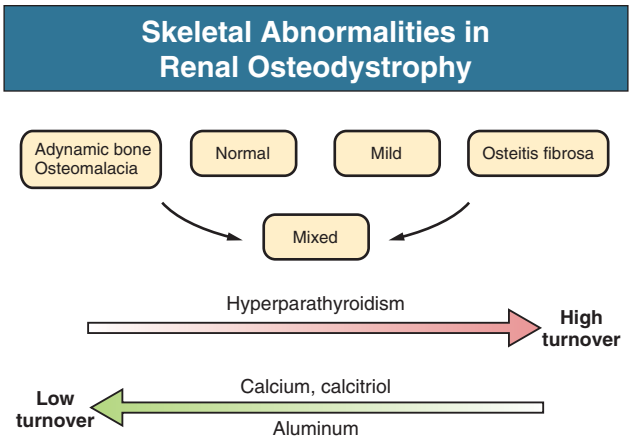

Figure 85-1 The spectrum of renal osteodystrophy. The range of skeletal abnormalities in renal bone disease encompasses syndromes with both high and low bone turnover.

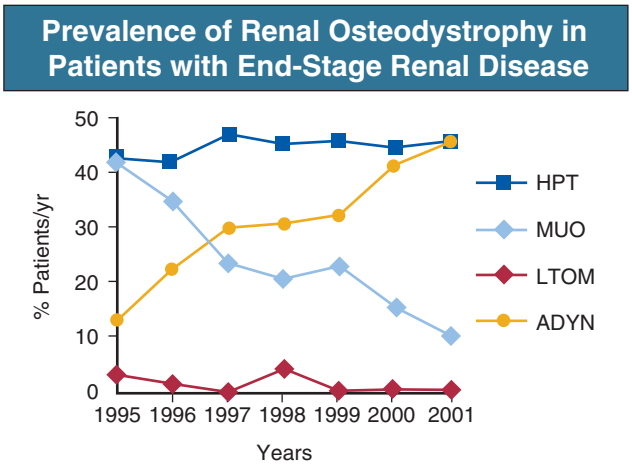

Figure 85-2 Prevalence of renal osteodystrophy in patients with end-stage renal disease. *ADYN,* Adynamic bone disease; *HPT,* high-turnover renal osteodystrophy; *LTOM,* low-turnover osteomalacia; *MUO,* mixed uremic osteodystrophy. *(From reference 40.)*

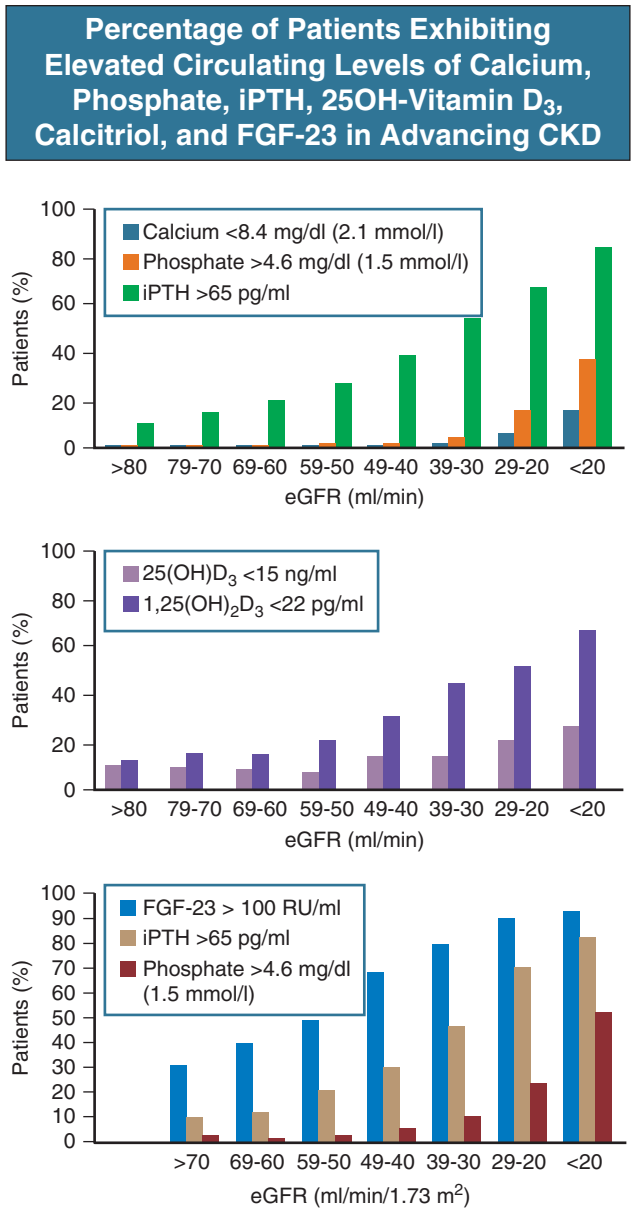

Figure 85-3 Percentage of patients exhibiting elevated circulating levels of calcium, phosphate, iPTH, 25OH-vitamin D_3, calcitriol, and FGF-23 in advancing CKD. In particular in early CKD stages there is wide variability at the individual level, and some patients, for example, may exhibit increased FGF-23 and normal iPTH, whereas others may have elevated iPTH levels with normal FGF-23 or elevations of both. *FGF-23,* Fibroblast growth factor 23; *iPTH,* intact PTH. *(Data from references 65 and 66.)*

repeated as renal function declines until sustained and severe hyperparathyroidism is present. Second, phosphate retention leads to decreased production of calcitriol by the kidney, either directly or by increasing the levels of FGF-23 (which decreases the activity of 1α-hydroxylase). The decrease in calcitriol allows increases in PTH gene transcription by direct action and also decreases intestinal calcium absorption, leading to hypocalcemia, which in turn stimulates PTH secretion. Third, hyperphosphatemia is associated with resistance to the actions of calcitriol in the parathyroid glands, which also favors the development of hyperparathyroidism and also induces resistance to the actions of PTH in bone. Finally, phosphate *per se* appears to affect PTH secretion independently of changes in serum calcium or serum calcitriol.[5,6] Phosphate may also have an effect on parathyroid growth independent of serum calcium.[7,8] Regardless of the mechanism by which phosphate retention causes hyperparathyroidism, restriction of dietary phosphate in proportion to the decrease in glomerular filtration rate (GFR), in experimental animals, can prevent the development of hyperparathyroidism. Current evidence suggests that FGF-23 also acts directly on the parathyroid gland and has inhibitory effects on PTH secretion and parathyroid growth.[9,10] This would suggest that the main effects of FGF-23 on the pathogenesis of hyperparathyroidism appear to be indirect as a result of the potent effect of FGF-23 to decrease calcitriol production. These various actions may explain the association of the levels of FGF-23 with patient outcome.[11]

Abnormalities of Vitamin D Metabolism

The conversion of 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D occurs mainly in the kidney by the enzyme 1α-hydroxylase. Extrarenal production of calcitriol also occurs and contributes to the circulating levels of calcitriol. Renal calcitriol production progressively declines during the course of CKD as a result of several mechanisms (Fig. 85-5).

Calcitriol production is compromised in the setting of CKD by a reduction in 25-hydroxyvitamin D levels[12] and the decrease in GFR,

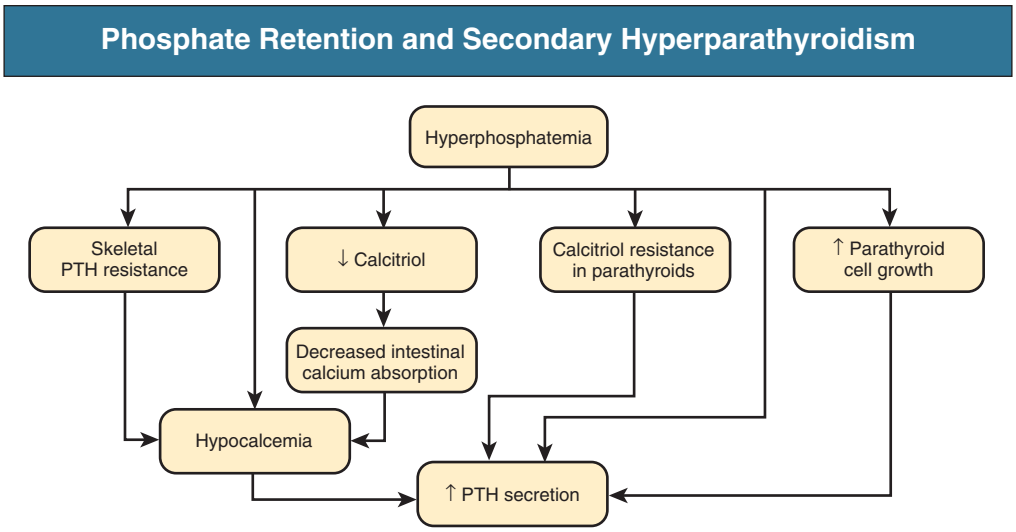

Figure 85-4 Role of phosphate retention in the pathogenesis of secondary hyperparathyroidism. Hyperphosphatemia stimulates parathyroid hormone *(PTH)* secretion indirectly by inducing hypocalcemia, skeletal resistance to PTH, low levels of calcitriol, and calcitriol resistance. Hyperphosphatemia also has direct effects on the parathyroid gland to increase PTH secretion and parathyroid cell growth.

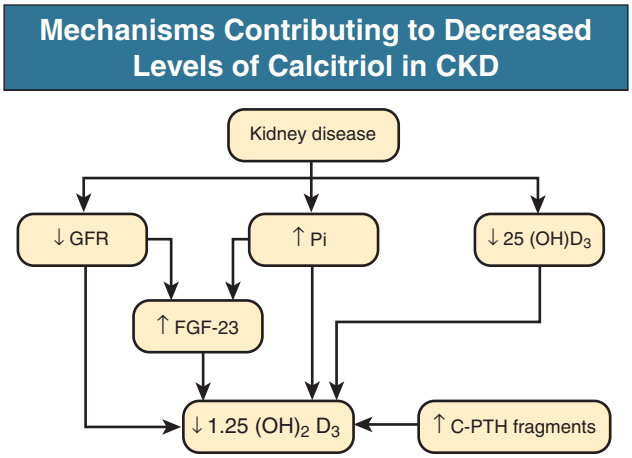

Figure 85-5 Mechanisms contributing to decreased levels of calcitriol in chronic kidney disease (CKD). *C-PTH,* Carboxyl-terminal parathyroid hormone; *FGF-23,* fibroblast growth factor 23; *GFR,* glomerular filtration rate; *Pi,* inorganic phosphate.

which further limits the delivery of 25-hydroxyvitamin D to the site of the 1α-hydroxylase in the proximal tubule. Phosphate retention either directly or by inducing an increase in FGF-23 also decreases the activity of 1α-hydroxylase. Finally, it appears that circulating PTH fragments may also directly decrease calcitriol production. The resultant decreased levels of calcitriol contribute to the pathogenesis of hyperparathyroidism by several direct and indirect mechanisms (Fig. 85-6). Low levels of calcitriol directly release the gene for PTH from suppression by the vitamin D receptor and allow increased PTH secretion. In many tissues, vitamin D regulates its own receptor by positive feedback; the vitamin D receptor content is decreased in parathyroid tissue in CKD. Administration of calcitriol has been shown to increase the vitamin D receptor content in the parathyroid glands coincident with the suppression of PTH secretion. Studies *in vitro* have shown that calcitriol is a negative growth regulator of parathyroid cells; therefore, calcitriol deficiency in patients with CKD may facilitate parathyroid cell proliferation. Other direct consequences of low levels of calcitriol that contribute to the pathogenesis of secondary hyperparathyroidism include an increase in the parathyroid set-point for calcium-regulated PTH secretion and possibly a decrease in the expression of calcium receptors.

Low levels of calcitriol may also promote the development of hyperparathyroidism indirectly. First, decreased calcitriol production as renal function decreases can lead to progressive reductions in intestinal absorption of calcium, leading to hypocalcemia and stimulation of PTH release. Second, low levels of calcitriol have been implicated in skeletal resistance to the calcemic actions of PTH, which may also contribute to the development of hyperparathyroidism.

Parathyroid Abnormalities in Chronic Kidney Disease

- Parathyroid gland hyperplasia: diffuse, nodular
- Decreased expression of vitamin D receptors
- Decreased expression of calcium receptors
- Increased set-point of calcium-regulated parathyroid hormone secretion

Box 85-1 Parathyroid abnormalities in chronic kidney disease.

Abnormalities of Parathyroid Gland Function

There are intrinsic abnormalities in parathyroid gland function in the course of CKD in addition to those caused by hypocalcemia, low levels of calcitriol, and skeletal resistance to the actions of PTH (Box 85-1).

Parathyroid hyperplasia is an early finding in CKD. In experimental models, hyperplasia begins within a few days after the induction of CKD and can be prevented by dietary phosphate restriction or by the use of calcimimetic agents.[7,13] Resected parathyroids from patients with severe hyperparathyroidism have nodular areas throughout the gland, which represent monoclonal expansions of parathyroid cells.[14] Within these nodules, there is decreased expression of vitamin D receptors as well as of calcium receptors.[15,16] The decreased expression of calcium receptors renders efforts to therapeutically affect these enlarged hyperplastic glands difficult.

The parathyroid calcium receptor is centrally involved in the regulation of PTH secretion by calcium.[17] Its expression and synthesis are decreased in parathyroid glands from hyperparathyroid patients,[16] leading to altered calcium-regulated PTH secretion. Increased concentrations of calcium are required *in vitro* to suppress PTH release from the parathyroid cells of uremic patients compared with those of normal controls. Thus, the set-point for the concentration of calcium required to decrease PTH release by 50% appears to be increased.

Abnormal Skeletal Response to Parathyroid Hormone

In patients with CKD, there is an impaired response of serum calcium to the administration of PTH and a delay in the recovery from induced hypocalcemia in the presence of larger increments in PTH levels. Thus, in CKD the skeleton is relatively resistant to the calcemic actions of PTH. The resultant decrease in serum calcium levels stimulates PTH secretion and contributes to the pathogenesis of secondary hyperparathyroidism. Factors involved in the skeletal resistance to PTH in CKD include decreased levels of calcitriol, downregulation of the PTH receptor, and phosphate retention. In addition, circulating fragments of PTH, truncated at the *N*-terminus, which still react in the older, second-generation two-site PTH assays, may serve to oppose the calcemic actions of PTH, probably acting at a receptor for the C-terminal region of PTH.[18,19]

CLINICAL MANIFESTATIONS OF HIGH-TURNOVER RENAL OSTEODYSTROPHY

Clinical manifestations of hyperparathyroidism are usually nonspecific and are often preceded by biochemical or imaging abnormalities. Aches and pains are common manifestations, often nonspecific in nature; occur in the lower back, hips, and legs; and are aggravated by weight bearing. Acute, localized bone pain can also manifest and may be suggestive of acute arthritis. Pain around joints may be caused by acute periarthritis, which is associated with periarticular deposition of calcium phosphate crystals, especially in patients with marked hyperphosphatemia. The symptoms may be confused clinically with gout or pseudogout and often respond to nonsteroidal anti-inflammatory drugs (NSAIDs). The gradual onset of muscle weakness is also common in patients with ESRD. Many factors are probably involved in its pathogenesis, including hyperparathyroidism and abnormalities of vitamin D. The arthropathy associated with β_2-microglobulin amyloidosis (see later discussion) should be considered in the differential diagnosis in very-long-term dialysis patients.

Bone deformities may occur in patients with severe hyperparathyroidism, particularly in children. In adults, deformities arise as a consequence of fractures, sometimes induced by brown tumors (see later discussion); the axial skeleton is most commonly affected. This can lead to kyphoscoliosis or chest wall deformities. Slipped epiphysis may occur in children, and frank rachitic features are occasionally evident. Growth retardation is also common in children, and although some improvement has been shown with calcitriol, this has not been the universal finding.

Extraskeletal calcifications are frequently encountered in patients with advanced CKD and are aggravated by persistent elevation of the calcium-phosphate product. Most commonly, vascular calcifications are seen, but calcifications may also occur in other sites, such as the lung, myocardium, and periarticular areas (see Fig. 85-7).

In the skin, hyperparathyroidism can manifest as pruritus (discussed in detail in Chapter 88). Rarely, it can also underlie the development of calciphylaxis, or calcific uremic arteriolopathy (discussed in detail in Chapter 88; see Figs. 88-6 and 88-7).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In addition to the clinical manifestations of renal osteodystrophy, a variety of biochemical and radiographic techniques are helpful to establish the specific diagnosis and to serve as a guide for the initiation and adjustment of therapeutic interventions. Although bone biopsy is not widely used in clinical practice, it remains the gold standard for the diagnosis of renal osteodystrophy.

Serum Biochemistry

The levels of free calcium and phosphate in serum are usually normal in patients with mild to moderate CKD. Usually in stage 4 CKD, the levels of serum calcium tend to fall and hyperphosphatemia manifests. Hypercalcemia may result from the administration of large doses of calcium-containing antacids or the administration of vitamin D metabolites. Patients with severe hyperparathyroid bone disease may develop hypercalcemia. It is important to differentiate among the different causes of hypercalcemia in the setting of CKD (see Chapter 10) because the management will vary greatly according to the cause. Also, the levels of serum calcium and phosphate, when used alone, are not useful in predicting the specific type of bone disease.

Parathyroid Hormone

Measurements of PTH are important for diagnostic purposes and for therapeutic guidance in the management of renal osteodystrophy. With renal impairment, there is accumulation of circulating PTH

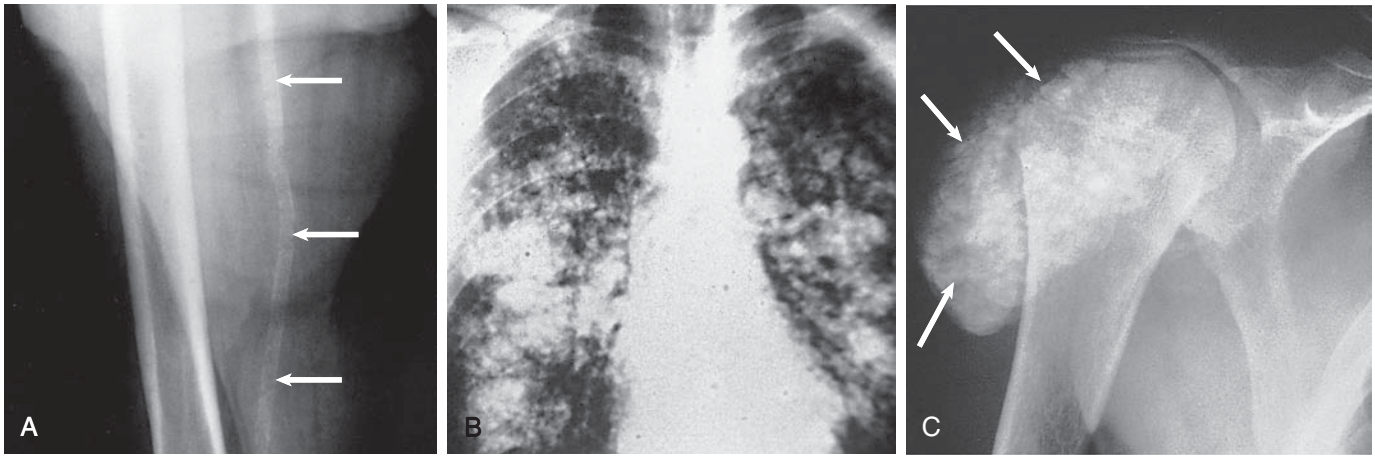

Figure 85-7 Extraskeletal calcification in chronic renal failure. A, Arterial calcification *(arrows).* **B,** Pulmonary calcification. **C,** Periarticular calcification *(arrows).*

fragments, which complicates the interpretation of PTH assays, including the two-site immunometric assays, which were thought to measure "intact" PTH (iPTH). Refinements in PTH assays have demonstrated that these iPTH assays also measure some large fragments of PTH, which are truncated at the *N*-terminus and may have important biologic activity. Although more specific assays for so-called "biointact" PTH (PTH 1-84) have been developed that exclude these fragments from measurement, work continues to define the clinical usefulness of such more specific assays.[20-22] Recent demonstration of the presence of oxidized PTH, which is biologically inactive, in patients with ESRD may further complicate PTH measurements.[23] It is hoped that continued efforts will lead to improved standardization among different PTH assays from various laboratories and various manufacturers of assay reagents. With existing iPTH assays (upper limit of the reference range, approximately 60 pg/ml), only values at the extremes are useful in the noninvasive diagnosis of renal osteodystrophy. In dialysis patients, iPTH levels above approximately 600 pg/ml are characteristic of patients with osteitis fibrosa. It is well accepted that there is an element of skeletal resistance to PTH in patients with CKD; therefore supranormal levels of PTH appear to be required to maintain normal bone turnover. Serial measurements of PTH are useful in the initial evaluation of patients with renal bone disease and are essential during the management of these disorders to assess response to therapy and to avoid overtreatment and undertreatment because either can have detrimental effects on bone histology. There are marked differences between commercial PTH assay results so that precise recommendations of desired ranges cannot reliably be provided.[24]

Vitamin D Metabolites

The levels of calcitriol in patients with CKD are not helpful in differentiating the histologic lesions of renal osteodystrophy. Measurements of calcitriol are not used routinely for diagnostic purposes unless extrarenal production of this metabolite is suspected, as in granulomatous disorders (see Chapter 10).

Vitamin D deficiency in CKD rarely results in osteomalacia in the United States and Europe but may contribute to hyperparathyroidism. In patients with CKD with proteinuria, there is loss of vitamin D–binding protein in the urine, which may result in decreased levels of 25-hydroxyvitamin D. Vitamin D deficiency may be encountered in patients with limited sun exposure, in those with intestinal malabsorption or malnutrition, and in susceptible racial groups, particularly Indo-Asians. Assessment of vitamin D nutrition is by measurement of serum 25-hydroxyvitamin D_3.

Markers of Bone Formation and Bone Resorption

Levels of circulating alkaline phosphatase offer an approximate index of osteoblast activity in patients with CKD. High levels are commonly present in hyperparathyroid bone disease. The discriminatory power of alkaline phosphatase measurements is enhanced by measurement of bone-specific alkaline phosphatase (BAP) isoenzyme and in particular in conjunction with PTH values. Serial measurements of alkaline phosphatase may be useful in assessing the progression of bone disease. Osteocalcin is another marker of osteoblastic activity, but it is not superior to alkaline phosphatase. Tartrate-resistant acid phosphatase and collagen degradation products are both markers of osteoclastic activity but are considered investigational at present.

Radiology of the Skeleton

Routine x-ray examination of the skeleton is relatively insensitive for the diagnosis of renal osteodystrophy, and radiographs can appear virtually normal in patients with severe histologic evidence of renal bone disease. However, subperiosteal erosions are often present in severe secondary hyperparathyroidism, detected in the hands (Fig. 85-8), clavicles, and pelvis. Skull radiographs may show focal radiolucencies and a ground-glass appearance, known as "pepper pot" skull. Osteosclerosis of the vertebrae is responsible for the "rugger-jersey" appearance of the spine (Fig. 85-9). Very rarely, brown tumors, focal collections of giant cells and typical of severe hyperparathyroidism, are seen as well-demarcated radiolucent zones in long bones, clavicles, and digits. They may be confused with osteolytic metastases. Looser zones or pseudofractures are characteristic of osteomalacia. Routine skeletal radiographs are not indicated unless there are symptoms.

Measurements of Bone Density

Dual-energy x-ray absorptiometry is widely used to assess bone density. However, there is no clear usefulness for this technique in the assessment of renal bone disease (see later discussion) because bone density measurements do not correlate with bone histology in

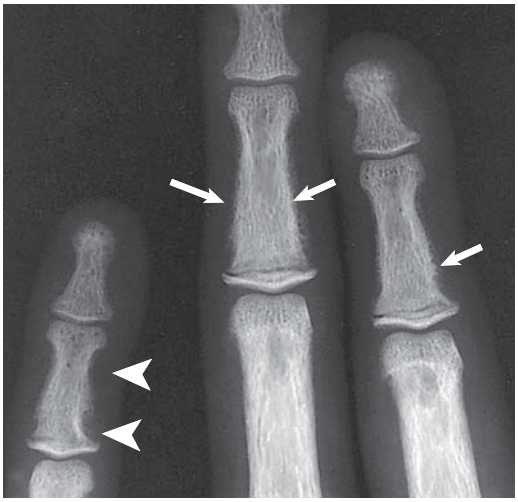

Figure 85-8 Subperiosteal erosions in hyperparathyroidism. Severe subperiosteal erosions as a manifestation of hyperparathyroidism *(arrows)*. The extensive scalloped appearance of the middle phalanx on the left *(arrowheads)* represents a small brown tumor.

Figure 85-9 "Rugger-jersey spine" in hyperparathyroidism. Vertebral bodies show the increased density of the ground plates and central radiolucency, which gives the striped appearance of a rugger jersey.

renal bone disease. Vascular and soft tissue calcifications may contribute to errors in bone density measurements.

Bone Biopsy

Biopsy of bone and the microscopic analysis of undercalcified sections after double tetracycline labeling provide definitive and quantitative diagnosis of renal bone disease.[25] To standardize reports on bone histology, the Kidney Disease: Improving Global Outcomes (KDIGO) CKD-MBD work group proposed the TMV classification, an assessment of turnover (T), mineralization (M), and bone volume (V).[1] Bone mineralization is assessed by the administration of two different tetracyclines spaced apart (e.g., tetracycline 500 mg three times daily for 2 days, followed by a 10-day interval, then demeclocycline 300 mg three times daily for 3 days) and biopsy 4 days later; the quantitation of bone mineralization rate is achieved by measuring the distance between the two fluorescent tetracycline bands.

Bone biopsy is not routinely performed in clinical practice because of the invasive nature of the procedure. Although noninvasive testing is useful to distinguish normal from high bone turnover, there is considerable overlap, and therefore biopsy might be required for definitive diagnosis when biochemistry is not conclusive (e.g., PTH in recommended range but bone alkaline phosphatase elevated, hypercalcemia with PTH only modestly elevated, or bone pain).

Osteitis fibrosa (hyperparathyroid bone disease) is characterized by increased bone turnover, increased number and activity of osteoblasts and osteoclasts, and variable amounts of peritrabecular fibrosis (Fig. 85-10, *A*). Osteoid may be increased but usually has a woven pattern distinct from the normal lamellar appearance. Osteomalacia is characterized by increased osteoid seam width, increase in the trabecular surface covered with osteoid, and decreased bone mineralization as assessed by tetracycline labeling (Fig. 85-10, *B*). The presence of aluminum can be detected on the mineralization front by specific staining (Fig. 85-10, *C*). Aluminum-related bone disease is defined by aluminum staining exceeding 15% of the trabecular surface and a bone formation rate of less than 220 mm^2/day. Features of osteitis fibrosa may occur together with features of osteomalacia; the combination is termed *mixed renal osteodystrophy.*

TREATMENT OF HIGH-TURNOVER BONE DISEASE

Prevention is the primary goal in the management of renal osteodystrophy. Therapy for hyperparathyroidism should ideally be initiated in CKD stage 3 so that parathyroid gland hyperplasia can be prevented. Because renal osteodystrophy is usually asymptomatic early in the course of CKD, attention is often not paid to secondary hyperparathyroidism. By the time CKD is advanced, patients may have already developed significant skeletal abnormalities or nodular parathyroid hyperplasia, and more aggressive therapy is required to prevent the long-term consequences of renal bone disease. The successful approach to the prevention and management of this disorder involves the integration of a variety of measures directed toward the suppression of PTH secretion and the prevention of parathyroid hyperplasia.

Prevention of Hypocalcemia

Hypocalcemia, if present, should be corrected because it is a potent stimulus for PTH secretion. In patients with hypoalbuminemia, free calcium should be measured. The initial approach to therapy for hypocalcemia in patients with mild to moderate CKD is the administration of calcium supplements such as calcium carbonate, taken between meals with increasing doses as required. Assessment of vitamin D status should be undertaken by measurement of 25-hydroxyvitamin D, and this should be corrected if it is below 30 ng/ml. The determination of 1,25-dihydroxyvitamin D levels is not helpful in this respect, given its 8-hour half-life. Assessment of efficacy of therapy is by follow-up determinations of serum calcium and PTH. Adjunctive therapy with active vitamin D sterols should be considered if hyperparathyroidism or hypocalcemia persists. In patients with ESRD, active vitamin D sterols are often required. In dialysis patients, the goal is to achieve levels of iPTH that are approximately two to nine times above the upper limit of the assay used.[26] Also, iPTH trends over time should be closely monitored. In CKD stages 3 to 5, progressive rises in iPTH above the normal range should be abrogated by correction of hypocalcemia, vitamin D deficiency, and hyperphosphatemia.

A, Osteitis fibrosa: Characteristic manifestations of severe hyperparathyroidism with increased osteoclast and osteoblast activity and peritrabecular fibrosis (stained blue; *arrow*). **B,** Adynamic bone disease: There is no cellular activity along the bone surface and no osteoid visible. **C,** *(arrowhead)* Mixed renal osteodystrophy: There is evidence of active osteoclasts on one bone surface *(arrowhead)* and evidence of thickened osteoid (stained red; *asterisk*). Indicating a mineralization defect on the other. **D,** Osteomalacia: Marked excess of unmineralized osteoid *(stained red)* surrounding the mineralized bone *(stained blue)*.

Control of Phosphate

Control of phosphate is the cornerstone of effective management of secondary hyperparathyroidism. In mild to moderate CKD, a normal serum phosphate concentration does not necessarily indicate normal parathyroid status, and except for the late stages of CKD, normophosphatemia may be maintained at the expense of elevated serum PTH and FGF23. Therefore, efforts to control phosphate, including dietary phosphate restriction and the use of phosphate binders, should not be delayed until frank hyperphosphatemia develops.

Dietary Phosphate Restriction

In experimental animals with mild CKD, dietary phosphate restriction can prevent excessive PTH synthesis and secretion, as well as parathyroid cell proliferation, independently of changes in serum calcium and calcitriol concentrations. Accordingly, restriction of dietary phosphate intake might be considered in patients with CKD stage 2 or 3. The input of a dietician is essential. Protein restriction and avoidance of dairy products but in particular processed foods containing high amounts of added phosphate are the mainstays of the regimen. In addition to reducing CKD progression, phosphate-protein restriction has been shown to increase the serum levels of calcitriol in patients with mild to moderate CKD. Restriction of phosphate by severe dietary protein restriction should be avoided because it may lead to protein-calorie malnutrition. Restriction of the daily dietary protein intake to 0.8 g/kg should be sufficient to provide phosphate restriction without the risk for malnutrition.

Phosphate Binders

Whereas dietary phosphate restriction is usually sufficient in early CKD, the control of phosphate becomes more difficult as renal function deteriorates. It then becomes necessary to also use agents that bind ingested phosphate in the intestinal lumen to limit its absorption. Compounds used for this purpose include calcium-containing antacids, magnesium salts, aluminum hydroxide, and, in recent years, non–calcium-containing, non–aluminum-containing phosphate binders (Fig. 85-11).

Aluminum-containing antacids are effective phosphate binders, but in patients with CKD, their use can no longer be recommended because of the risk for aluminum toxicity. There are certain circumstances that limit the use of calcium-containing phosphate binders, such as hypercalcemia, extensive vascular calcification, and calciphylaxis. In such patients, aluminum-containing antacids may be used for a short period, but the dose should be restricted to no more than 40 to 45 mg/kg/day, and frequent reassessments should be made to institute alternative therapy as soon as possible. Ingestion of aluminum-containing antacids together with foods containing citric acid (such as fruit juices and foods with sodium, calcium, or potassium citrate) may significantly increase aluminum absorption and therefore should be avoided.

Calcium carbonate or calcium acetate taken with meals effectively binds phosphates and limits their absorption. They are effective phosphate binders in 60% to 70% of patients on hemodialysis. The doses required to prevent hyperphosphatemia may vary according to the patient's compliance with dietary phosphate restriction as well as the CKD stage. Hypercalcemia and calcium loading are the major potentially serious side effects. Calcium citrate potentiates aluminum uptake and should be avoided in CKD. Current recommendations are to limit the ingestion of elementary calcium to 1500 mg/day. Consideration of overall calcium balance may be important with the use of calcium-containing phosphate binders.

Magnesium salts are also effective phosphate binders for patients who become hypercalcemic with calcium-containing phosphate binders, but they should be administered with caution in CKD patients not on dialysis because hypermagnesemia may have serious adverse effects. In patients on dialysis, magnesium carbonate (200 to 500 mg elemental magnesium per day) has been used successfully,

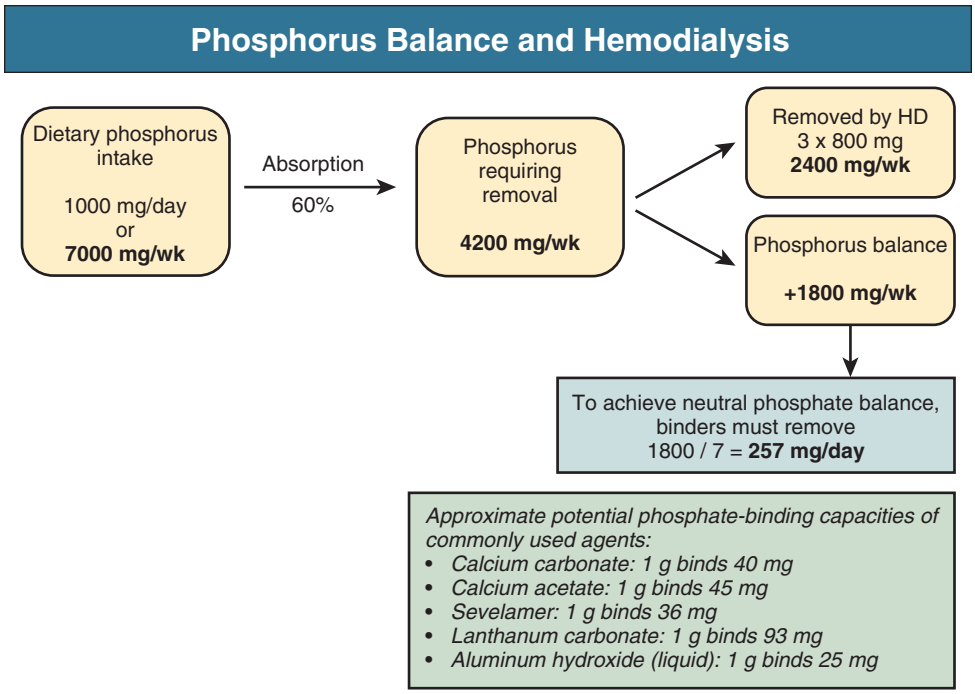

Figure 85-11 **Phosphate balance and phosphate binders used in hemodialysis patients.**

with prevention of hypermagnesemia through a reduction in dialysate magnesium concentration. The use of magnesium carbonate also allows reduction of the dose of calcium carbonate required by about half, but its use is frequently complicated by diarrhea.

The risks for hypercalcemia because of the high calcium load of calcium-containing phosphate binders can be prevented by the use of nonabsorbable polymers. Sevelamer hydrochloride in a dose range of 2.4 to 4.8 g daily provides effective phosphate control without hypercalcemia and also produces a significant reduction in total and low-density lipoprotein cholesterol. Agents such as sevelamer may offer great advantage over calcium-containing phosphate binders in terms of limiting the calcium load, although they are significantly more expensive. Studies have suggested that the use of sevelamer is associated with decreased progression of vascular calcification.[27,28] Sevelamer hydrochloride has largely been replaced by sevelamer carbonate, which has similar properties.[29] Sevelamer may be combined with both calcium- and magnesium-containing phosphate binders if necessary. Lanthanum carbonate also is an effective phosphate binder.[30] No significant toxicity has been observed, although some lanthanum appears to accumulate in bone and liver.[31] Finally, iron-containing phosphate binders have just entered the market.

Use of Vitamin D Metabolites

Calcitriol and other 1α-hydroxylated vitamin D sterols, such as 1α-hydroxyvitamin D_3 (alfacalcidol), 1α-hydroxyvitamin D_2 (doxercalciferol), and 19-nor-1α,25-dihydroxyvitamin D_2 (paricalcitol), are effective in the control of secondary hyperparathyroidism. Calcitriol lowers PTH levels and improves bone histology. In patients with very high levels of PTH and markedly enlarged glands with severe nodular hyperplasia, the effectiveness of vitamin D metabolites may be limited because the levels of vitamin D receptor are low in such tissue. Accordingly, it would appear rational to initiate treatment of secondary hyperparathyroidism with vitamin D metabolites early in CKD when the parathyroid glands are more sensitive to such therapy and thereby prevent the progression to a refractory stage. A beneficial effect of vitamin D metabolite therapy in the treatment of secondary hyperparathyroidism in patients with mild to moderate CKD has been shown, but the concern with initiation of vitamin D therapy at this stage of CKD is acceleration of the progression of renal disease should hypercalcemia occur. Because of the effect of calcitriol to increase intestinal phosphate absorption, hyperphosphatemia and elevations in calcium-phosphate product may predispose patients to the development of metastatic calcification; however, it appears that doses of 1α-hydroxyvitamin D_3 or calcitriol up to 0.5 μg/day are not commonly associated with hypercalcemia, hyperphosphatemia, or worsening renal impairment. Another concern with the use of vitamin D metabolites before dialysis is that oversuppression of hyperparathyroidism may increase the risk for adynamic bone. Accordingly, vitamin D therapy should be monitored carefully and should not be instituted without documentation of hyperparathyroidism, correction of 25-hydroxyvitamin D deficiency, and prior control of serum phosphate.

In patients with ESRD, indications for therapy with vitamin D metabolites are better defined; however, hypercalcemia and aggravation of hyperphosphatemia are frequent complications of therapy. Vitamin D metabolites are increasingly used as oral or intravenous pulses given intermittently (e.g., three times weekly) rather than as continuous oral therapy. In recent years, analogues of calcitriol that have less calcemic activity than the parent compound and yet retain the ability to suppress PTH release *in vivo* have been developed. Such analogues of vitamin D studied in patients with ESRD are 22-oxacalcitriol (OCT), 1α-hydroxyvitamin D_2, and 19-nor-1α,25-dihydroxyvitamin D2 (paricalcitol).[32-34] Direct comparisons between these compounds are not available. It is likely that a wider therapeutic window may be offered by these analogues. Several but not all studies have suggested that there may be a survival advantage associated with active vitamin D administration in patients with CKD as well as with ESRD.[35,36]

Role of Calcimimetics

An additional approach to the treatment of hyperparathyroidism in ESRD is the use of a calcimimetic agent, such as cinacalcet, which targets the calcium-sensing receptor and increases its sensitivity to calcium. In dialysis patients, cinacalcet results in a significant fall in PTH levels and when administered daily can facilitate the control of hyperparathyroidism. The addition of cinacalcet to standard therapy in patients with iPTH serum levels exceeding 300 pg/ml while receiving standard therapy allowed significantly more dialysis patients to achieve guideline targets for calcium, phosphate, and iPTH.[37] Cinacalcet is especially useful in patients with marginal or frank hypercalcemia or with hyperphosphatemia and can be used in conjunction with other therapies. Central side effects include hypocalcemia and nausea and vomiting; the latter can be somewhat improved by administering cinacalcet at night. Studies investigating the effect of cinacalcet on progression of vascular calcification demonstrate that progression of cardiovascular calcification may be attenuated.[38] A large randomized controlled trial—Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE)—to examine the effect of cinacalcet therapy on cardiovascular events and survival in hemodialysis patients with secondary hyperparathyroidism was nondefinitive because of, at least in part, significant migration from the control arm to commercial cinacalcet and an age difference between the two arms, whereby the cinacalcet patients were older on average and thus at higher cardiovascular risk.[39] In that trial, however, cinacalcet significantly reduced rates of parathyroidectomies and of calciphylaxis.[39] In CKD patients not on dialysis, the use of calcimimetics is accompanied by significant phosphate retention and is currently not recommended.

Role of Parathyroidectomy

Although the strategies discussed previously are effective for the control of hyperparathyroidism in many patients, there are occasions when these steps fail or are contraindicated, and surgical removal of the parathyroids should be considered (Box 85-2). Parathyroidectomy is indicated for patients with severe hyperparathyroidism that cannot be controlled medically (phosphate binders, vitamin D sterols, or calcimimetic). Severe hyperphosphatemia in these patients precludes the use of vitamin D metabolites because of the risk for metastatic calcification. Some control of iPTH levels may be obtained with calcimimetics, but even these compounds may fail in severe hyperparathyroidism because of downregulated calcium-sensing receptors in the parathyroid glands. Some patients with severe hyperparathyroidism may become hypercalcemic in the absence of calcitriol therapy; consequently, calcitriol and calcium-containing phosphate binders cannot be administered. In this circumstance, calcimimetic and non–calcium-containing phosphate binders should be administered. It is important to be certain that hypercalcemia represents severe hyperparathyroidism and is not caused by adynamic bone or other disease. For hypercalcemia to occur because of hyperparathyroidism in CKD, the levels of iPTH generally exceed 1000 pg/ml, and BAP is usually elevated. Surgical parathyroidectomy might also be considered in patients with very severe hyperparathyroidism who may receive a renal transplant in the near future, particularly if they are female and have significant osteopenia. Parathyroidectomy in these patients can help avoid posttransplantation hypercalcemia and hypophosphatemia (caused by PTH-induced phosphaturia) as well as osteopenia. By avoiding hypercalcemia, this may lead to improved graft function and possibly to less intragraft calcification. Parathyroidectomy might also be considered in patients with severe hyperparathyroidism who have evidence of metastatic calcification. The development of calciphylaxis is an urgent indication for parathyroidectomy if PTH levels are elevated (see Chapter 84). Before parathyroidectomy, consideration should also be given to the possibility of coexisting aluminum accumulation, with deferoxamine testing and bone biopsy performed if necessary, because this might predispose to osteomalacia after parathyroidectomy.

Indications for Parathyroidectomy

- Severe hyperparathyroidism
  - With persistent hyperphosphatemia
  - Unresponsive to calcitriol and calcium
  - With hypercalcemia
  - With intolerance or unresponsiveness to calcimimetics
  - In renal transplantation candidate
  - With evidence of metastatic calcification
- Calciphylaxis with evidence of hyperparathyroidism
- Severe pruritus, only if additional evidence of hyperparathyroidism

Box 85-2 Indications for parathyroidectomy.

The choice of surgical procedure for parathyroidectomy has been controversial. The most commonly used procedures are subtotal removal of the parathyroids and total removal of the parathyroids with reimplantation of parathyroid tissue in the forearm. Recurrence of hyperparathyroidism occurs in about 10% of patients. Total parathyroidectomy alone is less commonly performed; although this is an appropriate procedure for patients remaining on dialysis, there is concern that hypoparathyroidism after a renal transplantation may be a disadvantage of this approach if there is no residual parathyroid tissue. Unregulated tumor-like growth of parathyroid tissue implants has been described and may be related to the monoclonal nature of the nodular hyperplasia of severe hyperparathyroidism. Total parathyroidectomy with forearm implantation (our preference) or subtotal parathyroidectomy in the neck, marking remaining tissue with clips, may be performed.

Recurrence of hyperparathyroidism may respond to further medical therapy, but more surgery to remove the forearm implant or further neck exploration to search for additional glands is often necessary and may be guided by parathyroid imaging.

Synthesis of Therapeutic Strategies

The general recommendations for the prevention and therapy of renal osteodystrophy are summarized in Figure 85-12, in which therapeutic maneuvers are stratified according to the degree of CKD.

Therapy should be initiated if possible in stage 2 or 3 CKD (GFR, 30 to 90 ml/min), and dietary phosphate intake may be restricted once patients enter CKD stage 3. Levels of iPTH should be measured; if elevated above the normal range, the levels of 25-hydroxyvitamin D should be measured and corrected if less than 30 ng/ml. If hyperparathyroidism persists, calcium-based or other phosphate binders may be initiated. As CKD progresses within stage 3, dietary phosphate restriction should be continued or intensified, and the doses of calcium-containing phosphate binders should be adjusted on the basis of serial measurements of iPTH, with careful attention to avoid hypercalcemia or excessive calcium load. Acidosis, if present, should be treated with oral sodium bicarbonate because persistent acidosis has deleterious effects on the skeleton. The additional sodium load may require further salt restriction or increases in diuretics. Aluminum-based phosphate binders should be avoided. If hyperparathyroidism (iPTH > approximately 2-3 times above the upper normal range of the assay) persists despite these measures,

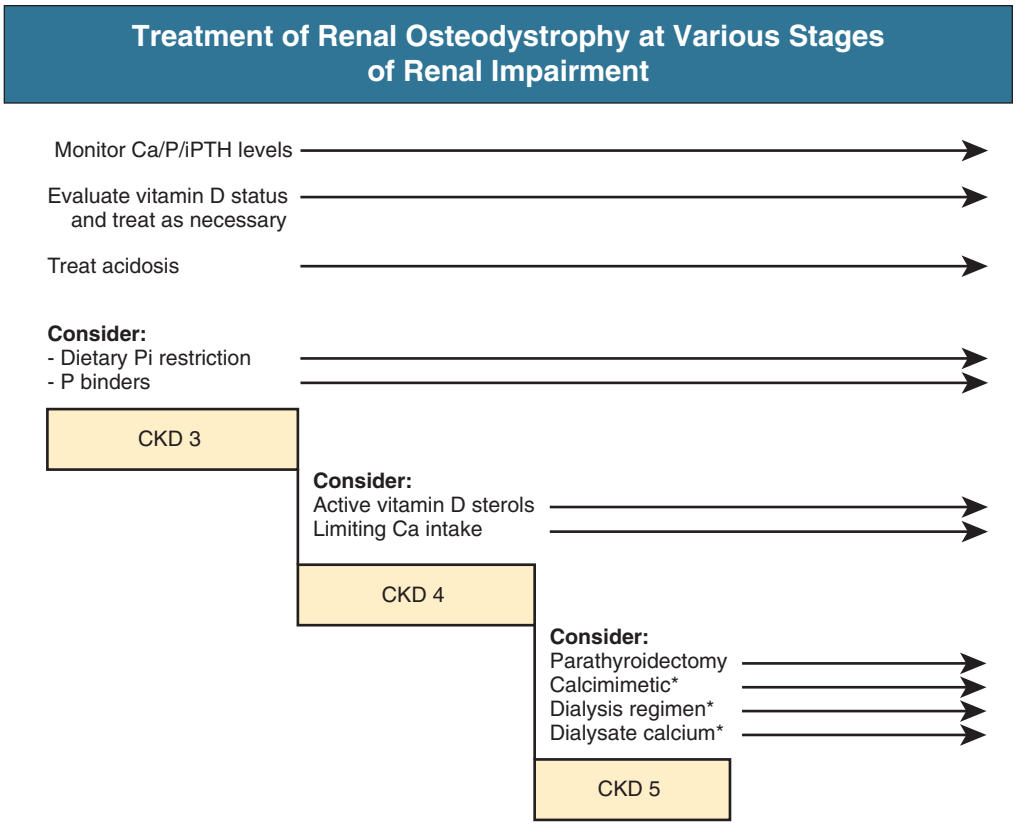

Figure 85-12 Treatment of renal osteodystrophy at various stages of renal impairment. *, Consider in CDK5D (i.e., dialysis dependent) only; *Ca,* calcium; *CKD,* chronic kidney disease; *iPTH,* intact parathyroid hormone; *P,* phosphate; *Pi,* inorganic phosphate. *(Modified from reference 67.)*

consideration should be given to the addition of calcitriol (0.25 to 0.5 µg/day), vitamin D analogues, or vitamin D prohormones to the regimen. Such therapy should be monitored carefully to avoid hypercalcemia and acceleration of progression of CKD.

In CKD stages 4 and 5, the preceding therapies may need to be intensified, and larger amounts of phosphate binders may be required to avoid hyperphosphatemia. The use of aluminum-containing phosphate binders is particularly undesirable at this stage in view of the increased risk for aluminum accumulation with worsening renal function. In patients on dialysis, calcitriol therapy can be intensified, with attention to the serum levels of calcium and phosphate and monitoring of iPTH levels. In CKD stage 5, iPTH levels should be maintained approximately two to nine times above the upper limit of the assay used to maintain normal bone turnover.[26] Calcitriol may be administered orally either daily or intermittently (pulse therapy) or administered intravenously to patients on hemodialysis. During therapy with calcitriol, it is imperative to ensure that serum phosphate remains controlled and that elevations of serum calcium do not occur to prevent metastatic calcification. Vitamin D analogues, which are less calcemic and phosphatemic than calcitriol and yet retain the ability to suppress the levels of PTH, may be useful. The calcimimetic cinacalcet provides additional effective control of hyperparathyroidism in patients with ESRD and may be used alone or in combination with the other strategies if iPTH levels do not fall into the target range. Parathyroidectomy needs to be considered in selected circumstances. Bone biopsy may be indicated in selected patients, particularly if aluminum overload is suspected. Aluminum overload may require chelation therapy with deferoxamine in selected circumstances, especially if it is symptomatic, but in most patients the prevention of further aluminum exposure is sufficient to allow a gradual reduction in the serum levels of aluminum. During therapy with potent vitamin D metabolites, attention should be given to the dialysate calcium concentrations because high concentrations may aggravate hypercalcemia. However, the increasingly frequent use of lower dialysate calcium levels, such as 1.25 mmol/l, requires careful monitoring of the patient to ensure compliance with calcium-containing phosphate binders and vitamin D metabolites to avoid progressive negative calcium balance. Dialysate calcium should not be taken outside the range of 1.25 to 1.75 mmol/l and, when possible, should be individually prescribed.

LOW-TURNOVER RENAL BONE DISEASE

Adynamic bone disease describes the morphologic consequences of low-turnover osteopathy in CKD. As CKD progresses, high-turnover renal osteodystrophy initially develops as an adaptive response to counteract the increasing skeletal PTH resistance and phosphate overload. ABD probably results from too rigorous suppression of this adaptive response. ABD is increasingly important in CKD-MBD because of the high percentage of affected individuals (>40% in CKD stage 5) and because of its association with cardiovascular calcification and mortality.[40,41] Furthermore, fracture incidence is estimated to be twice as high in individuals with low than in those with high bone turnover. ABD prevalence is markedly increasing in bone biopsy registries of dialysis patients, which may relate to the increasing prevalence of its central risk factors, namely, advanced age and diabetes mellitus. Peritoneal dialysis also represents a risk factor, possibly because of a continuous exposure of the patient to high dialysate calcium as opposed to hemodialysis, in which calcium exposure is cyclic.

Pathogenesis of Adynamic Bone Disease

As pointed out earlier, the bone develops a relative resistance of the PTH-1 receptor to its ligand PTH as CKD progresses. Therefore,

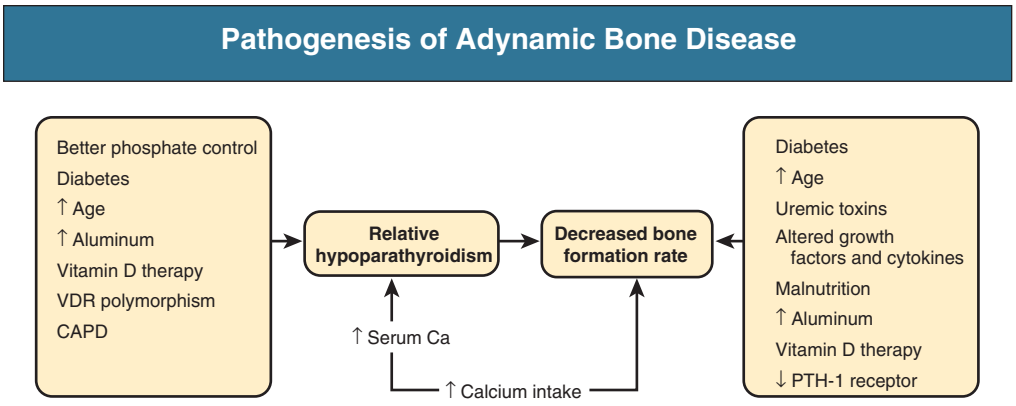

Figure 85-13 Pathogenesis of adynamic bone disease. *Ca,* Calcium; *CAPD,* continuous ambulatory peritoneal dialysis; *PTH,* parathyroid hormone; *VDR,* vitamin D receptor. *(Modified from reference 68.)*

PTH levels above the normal range are required to maintain adequate bone turnover. Unfortunately, there are no definite ranges of elevated PTH levels that can reliably differentiate an adaptive response (normal bone turnover) from a maladaptive response (increased bone turnover) because PTH resistance individually varies and because it depends on the stage of CKD. Accordingly, ABD is a consequence of inadequately low PTH levels, which cause suppression or cessation of both osteoblast and osteoclast activities, resulting in a reduced bone formation rate and low bone mass. Iatrogenic oversuppression of PTH in CKD mostly results from high-dose active vitamin D metabolite treatment, from calcium loading (high doses of calcium-containing phosphate binders, high dialysate calcium concentration), or after parathyroidectomy. The effects of intensified calcimimetic treatment on bone turnover have recently been prospectively evaluated in hemodialysis patients (Bone Histomorphometry Assessment for Incident Dialysis Patients with Secondary Hyperparathyroidism of End Stage Renal Disease [BONAFIDE]), but final results are not available yet, and patients in this cohort had significant high-turnover osteopathy at baseline (average iPTH >1200 pg/ml). Finally, diabetes, uremic toxins, malnutrition, and a disproportionate appearance of C-terminal PTH fragments may be additional factors favoring a state of low bone turnover (Fig. 85-13).

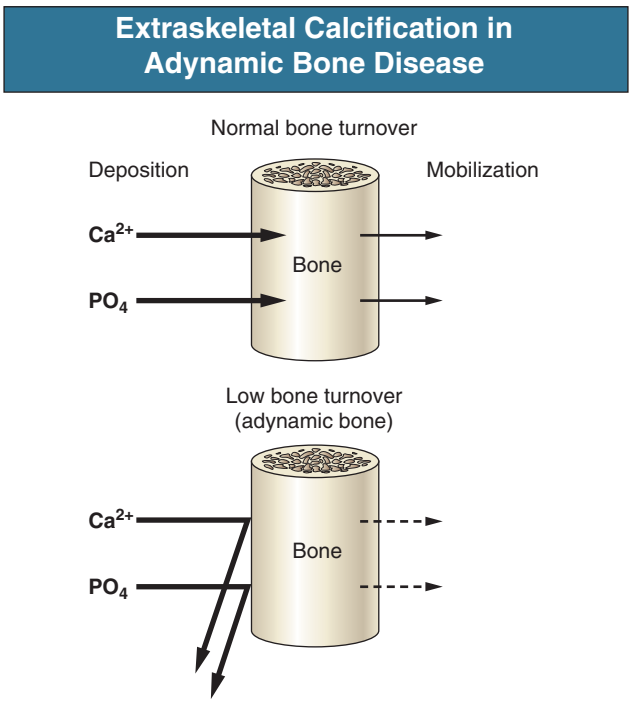

Figure 85-14 Bone turnover in adynamic bone disease. Reduced bone turnover leads to increased extraskeletal calcification. *Ca^{2+},* Calcium ion; *PO_4,* phosphate.

Diagnosis and Differential Diagnosis

Serum Biochemistry

Low iPTH levels (<100 pg/ml) are almost always indicative of low bone turnover in CKD stage 5D. However, histologically proven ABD may occur in many dialysis patients with iPTH levels of up to 300 pg/ml and, in exceptions, of up to 600 pg/ml.[42,43] Therefore, PTH levels alone are not a sensitive biomarker of ABD. Serum levels or activities of alkaline phosphatase or BAP are usually normal or low; downward trends may indicate the development of ABD. Serum calcium and phosphate can be normal or elevated, dependent on the choices of co-treatment (phosphate binders, vitamin D metabolites) and on the nutritional status. Particularly in instances of calcium and phosphate loading, hypercalcemia and hyperphosphatemia may be pronounced because adynamic bone is unable to buffer calcium and phosphate loads by osseous deposition (Fig. 85-14).

In CKD stages 3 and 4, there are uncertainties with regard to the diagnosis of ABD and its clinical consequences. It is unclear which PTH levels are required to maintain adequate bone turnover in these stages. It seems reasonable to correct vitamin D deficiency, hyperphosphatemia, and hypocalcemia when PTH levels start to rise, but beyond that, no firm recommendations can be given at this time.

Bone Biopsy

The gold standard for diagnosis of ABD is bone biopsy. According to the TMV classification (see earlier discussion),[1] ABD is characterized by low turnover, normal (or high secondary) mineralization, and low bone (osteoid) volume. The individual indication to perform bone biopsy should be considered in symptomatic patients on the basis of inconsistencies of biochemical parameters associated with unexplained fractures, bone pain, progressive extraosseous calcifications, or hypercalcemia. The KDIGO initiative recently investigated more than 600 bone biopsies (South America, Portugal, Turkey) and concomitant serum samples to identify biomarker patterns that may allow noninvasive testing of bone turnover status. These data are still unpublished, but preliminary reports suggested a predominance of ABD that was quite strongly associated with low-normal to low BAP levels. Aluminum toxicity is a relevant differential diagnosis versus ABD. Thus, if the patient's history suggests significant aluminum exposure, aluminum bone deposition should be excluded by specific staining.

Radiology and Measurements of Bone Density

There are no typical features of ABD in conventional bone radiographs or in dual-energy x-ray absorptiometry. In the latter, bone density may be low, normal, or high, depending on the primary or secondary mineralization state, but it never reflects the actual turnover and is therefore not a helpful diagnostic test (Fig. 85-15). A very high cardiovascular calcification burden on conventional radiographs may raise the suspicion of a low bone turnover state if accompanying biochemical parameters are compatible with this diagnosis. Biopsy-proven ABD is associated with the highest magnitude of vascular calcification in dialysis patients.[41]

Treatment of Adynamic Bone Disease

The key therapeutic approaches in the treatment of ABD are to avoid PTH overexpression and to restore adequate PTH levels, without triggering the progressive development of secondary hyperparathyroidism. Such a stepwise treatment approach may include reduction or withdrawal of active vitamin D metabolites, reduction or withdrawal of calcium-containing phosphate binders, and reduction of the dialysate calcium concentration (usually to 1.25 mmol/l). Any aluminum should be withdrawn. After these interventions, biochemical parameters (PTH, calcium, phosphate, perhaps alkaline phosphatase, and especially BAP) should be monitored more frequently than usual.

The best study data on this issue are available from studies comparing calcium-containing versus non–calcium-containing phosphate binders in dialysis patients.[42,44] In comparing baseline with follow-up bone biopsies in such cohorts, the administration of calcium-containing phosphate binders was associated with a higher percentage of individuals who developed ABD. This development was associated with a fall in serum PTH because of the higher calcium load. In an observational study, it was also shown that high-dose calcium-containing phosphate binder intake was associated with both low bone turnover and increased aortic calcification.[45] Other therapeutic approaches to ABD have not been systematically studied. They include optimized diabetes control, a change from peritoneal dialysis to hemodialysis to facilitate a more flexible dialysate calcium prescription, the administration of recombinant PTH (e.g., for patients after total parathyroidectomy), and calcilytics.[46] At present, many patients with ABD remain refractory to treatment.

OSTEOPOROSIS IN CHRONIC KIDNEY DISEASE

Whereas abnormal bone is common and fracture risk is increased in CKD patients, the relative contribution of classic osteoporosis (as defined by World Health Organization criteria) to the CKD-MBD complex is not well defined. Data from studies of antiosteoporosis agents are available only for patients in CKD stages 1 to 3. Nevertheless, postmenopausal women and elderly men nowadays are highly prevalent in late-stage CKD populations, and it is thus likely that classic osteoporosis also contributes to their bone disease.

Pathogenesis of Osteoporosis in Chronic Kidney Disease

Osteoporosis may be associated with low, normal, or high bone turnover and is characterized by thin and disconnected trabeculae and the loss of the platelike bone structure. Many patients with CKD have abnormal mineralization and increased osteoid, which is quite atypical for osteoporosis. Typical pathogenetic factors of osteoporosis, including hypoestrogenemia, immobilization, and corticosteroid use, are frequent in CKD patients, although some postmenopausal women with late-stage CKD may have relatively normal estrogen levels. However, the sum of CKD-MBD–related biochemical disturbances probably represents the decisive factors as to which bone phenotype predominates. Secondary hyperparathyroidism, relative hypoparathyroidism (as in ABD), and 25-hydroxyvitamin D as well as 1,25-dihydroxyvitamin D deficiencies may dominate and "overrule" the bone phenotype of osteoporosis even if classic risk factors are present.

Diagnosis and Differential Diagnosis

In patients with advanced CKD, bone turnover biomarkers and measurements of bone mineral density by dual-energy x-ray

absorptiometry are useless tools (see Fig. 85-15) in the differential diagnosis of classic osteoporosis versus other CKD-MBD–related bone disease. Assays for biomarkers, such as β-CrossLaps (C-terminal cross-linked, CTX; marker of bone collagen degradation), procollagen type I *N*-terminal propeptide (PINP; marker of bone collagen synthesis), and tartrate-resistant alkaline phosphatase 5b (TRAP5b; marker of osteoclast activity) are insufficiently validated in CKD patients, and low bone mineral density can be found in CKD-MBD–induced high-turnover bone disease, ABD, and osteomalacia (see Fig. 85-15). Furthermore, bone mineral density (as measured by dual energy x-ray absorptiometry [DXA]) does not predict fracture risk in CKD patients as it does in the general population, implying that abnormal bone quality rather than density is the major disturbance in such patients. Peripheral quantitative tomography (pQCT) of the radius may be a superior methodology for assessment of CKD patients in the future but awaits validation in sufficiently large patient cohorts.[47] The only reliable methodology to diagnose osteoporosis and to discriminate it from other bone manifestations in CKD patients is bone biopsy. In a large bone biopsy study, including 1429 samples from dialysis patients, osteoporosis was diagnosed in 52% of individuals, and 49% of them also had ABD.[48] These percentages may be quite different in patients in earlier CKD stages, but there are no systematic data available on such cohorts.

Treatment of Osteoporosis in Chronic Kidney Disease

Post hoc analyses of large prospective treatment studies using antiosteoporotic medications demonstrated that it seems safe and efficacious to treat postmenopausal women in stages CKD 1 to 3 if they have a high risk of fractures (according to World Health Organization criteria) and no features of CKD-MBD.[49-52] In such populations, bisphosphonates, raloxifene, and teriparatide appear to be feasible therapeutic options. A recent subanalysis from the Following Rehabilitation, Economics and Everyday-Dialysis Outcomes Measurements (FREEDOM) trial identified patients in CKD stages 2 to 4 and demonstrated a significantly reduced fracture risk with denosumab treatment versus placebo, independent of the stage of CKD.[53] In contrast, for patients in CKD stages 3 to 5 with features of CKD-MBD, there are no data available on the safety and efficacy of any of these antiosteoporotic medications. In CKD patients with ABD, bisphosphonates may aggravate osteoclast paralysis. In CKD patients with secondary hyperparathyroidism, bisphosphonates may upregulate PTH secretion. None of these antiosteoporotic compounds can thus be recommended in patients with CKD-MBD to date, unless bone biopsy proves the exclusive presence of osteoporosis.

β_2-MICROGLOBULIN–DERIVED AMYLOID

β_2-Microglobulin–derived ($A\beta_2M$) amyloidosis, also termed *dialysis-associated amyloidosis,* exclusively affects patients with stage 5 CKD. It is a systemic amyloidosis. Clinical manifestations are largely confined to the musculoskeletal system. In recent years the disease has become notably infrequent. $A\beta_2M$ amyloidosis in CKD stage 5 should not be confused with a rare hereditary systemic amyloidosis derived from the Asp76Asn variant of β_2-microglobulin, which manifests in the absence of CKD.

Pathogenesis

Fibrils of $A\beta_2M$ amyloid are derived from the circulating precursor protein β_2-microglobulin, the nonvariable light chain of the human leukocyte antigen (HLA) class I complex. The pathogenesis appears to involve three events:

1. Pronounced renal retention of β_2-microglobulin (11.8 kd), leading to plasma levels that can be elevated up to 60-fold in dialysis patients[54]; however, even massive overproduction of β_2-microglobulin in mice was not sufficient to induce amyloid deposits, and thus further steps must be important.[55]
2. Modifications of the β_2-microglobulin molecule that render it more amyloidogenic, such as limited proteolysis or the formation of different sugar-protein cross-links.[56]
3. Local factors that contribute to and determine the particular spatial localization of the amyloidosis.

Epidemiology

Histologic studies from the 1990s observed amyloid deposits in 100% of dialysis patients treated for more than 13 years.[57] Most amyloid deposits never cause clinical problems. Main risk factors for $A\beta_2M$ amyloid deposition are age at onset of renal replacement therapy and the duration of (nontransplant) renal replacement therapy.[54,56] $A\beta_2M$ amyloid–related symptoms presently are largely confined to patients who have been dialyzed for more than 15 years.

Clinical Manifestations and Diagnosis

$A\beta_2M$ amyloidosis mainly manifests at osteoarticular sites, particularly synovial membranes; visceral manifestations are rare.[54,56] Carpal tunnel syndrome typically worsens at night and during hemodialysis. It is often bilateral and usually requires surgery. Osteoarthropathy of peripheral joints, resulting from amyloid deposition in periarticular bone and the synovial capsule (Fig. 85-16), is characterized by recurrent or persistent arthralgias, stiffness of large and medium-sized joints, and swelling of capsules and adjacent tendons. Recurrent joint effusions and synovitis, often in the shoulders and knees, may occur. The clinical presentation may vary from frank, acute arthritis to slow, progressive destruction of the affected joints. Destructive spondyloarthropathy (Fig. 85-17) resulting from $A\beta_2M$ amyloidosis can manifest as asymptomatic deposits, radiculopathy, stiffness, "mechanical ache," and, finally, medullary compression with resulting paraplegia or cauda equina syndrome.[54,55] Other manifestations include camptodactyly (a flexion deformity resulting in bent fingers that cannot completely extend or straighten) resulting

from amyloid deposits along the flexor tendons of the hands (Fig. 85-18). Patients undergoing dialysis can also have subcutaneous tumorous deposits of $A\beta_2M$ amyloid; however, diffuse infiltration of the subcutaneous fat or skin has not been observed.

Case reports of clinically relevant organ manifestations are usually in patients treated with hemodialysis for more than 15 years and have described heart failure, odynophagia, intestinal perforation of both small and large bowel, gastrointestinal bleeding and pseudo-obstruction, gastric dilation, paralytic ileus, persistent diarrhea, macroglossia or functional tongue disturbances (abnormal taste, mobility, articulation), ureteral stenosis, and renal calculi.[54,56]

Diagnosis

Plasma levels of β_2M do not distinguish between patients with the amyloidosis and those without. Ultrasound can detect synovial $A\beta_2M$ amyloidosis as thickening of the joint capsules of the hip and knee, biceps tendons, and rotator cuffs as well as the presence of echogenic structures between muscle groups and joint effusions.[54,56] On radiologic examination, affected joints may present with single or multiple juxta-articular, "cystic" (i.e., amyloid-filled) bone radiolucencies (Fig. 85-19; see also Fig. 85-16). Such bone defects are prone to pathologic fractures. Diagnostic criteria for $A\beta_2M$ amyloid–induced cystic bone radiolucencies have been published.[58] They include (1) diameter of lesions more than 5 mm in wrists and more than 10 mm in shoulders and hips, (2) normal joint space adjacent to the bone defect, (3) exclusion of small subchondral cysts in the immediate weight-bearing area of the joint and of defects of the "synovial inclusion" type, (4) increase of defect diameter of more than 30% per year, and (5) presence of defects in at least two joints. Scintigraphy, using either radiolabeled serum amyloid P component or β_2-microglobulin,[59] offers more specific detection of amyloid deposits but is not widely available. The definitive diagnosis of $A\beta_2M$ amyloidosis relies on histology. Fat aspiration and rectal biopsy are not helpful in $A\beta_2M$ amyloidosis, but diagnostic material can be obtained from synovial membranes, synovial fluid, or bone lesions.[54]

Treatment and Prevention

Therapy for established $A\beta_2M$ amyloidosis is symptomatic. NSAIDs and physical and surgical measures, such as carpal tunnel decompression, endoscopic coracoacromial ligament release, and bone stabilization in areas of cystic destruction, are all used.[54] Although some dialysis modalities allow significant removal of β_2-microglobulin, there is at present no convincing evidence that this is of therapeutic value in an established $A\beta_2M$ amyloidosis. Renal transplantation is the preferred treatment because it leads to rapid symptomatic improvement and halts further progress of the disease, but whether this can actually lead to regression of established $A\beta_2M$ amyloid deposits is a subject of controversy.

A number of strategies exist for prevention of the clinical manifestations of $A\beta_2M$ amyloidosis.[54] The risk of carpal tunnel syndrome is reduced by 40% to 50% in patients treated with high-flux hemo(dia)filtration[60] and minimal in patients receiving online hemodiafiltration.[61] A dramatic reduction in the prevalence of carpal tunnel syndrome occurred in patients dialyzed with ultrapure dialysate.[62] In another study, an 80% reduction of amyloid signs in a chronic hemodialysis population appeared to relate to dialysate factors such as microbiologic purity and the use of bicarbonate buffer.[63] Finally, in uncontrolled studies a β_2-microglobulin adsorption column was reported to decrease $A\beta_2M$ amyloid–associated symptoms, but the effect on bone lesions was not significant.[64]

CHAPTER 86

Neurologic Complications of Chronic Kidney Disease

Julian L. Seifter and Martin A. Samuels

Disorders of the nervous system are associated with renal disease in patients with systemic disorders (e.g., hypertensive encephalopathy, thrombotic microangiopathies, atheroembolic and atherosclerotic disease, vasculitides), and fluid and electrolyte abnormalities. Neurologic complications accompany acute kidney injury in the intensive care setting and in outpatients with chronic kidney disease (CKD). Furthermore, patients with CKD are at increased risk of toxin- and pharmacologic agent–induced neurotoxicity. This chapter focuses on the direct neurologic consequences of CKD.

UREMIC ENCEPHALOPATHY

The syndrome of uremic encephalopathy (UE) involves a spectrum of brain abnormalities that may clinically range from nearly imperceptible changes to coma.

Pathogenesis

The brain in CKD has decreased metabolic activity and oxygen consumption.[1,2] As long as the underlying renal disease has not affected cerebral hemodynamics and responsiveness to carbon dioxide, these functions appear intact, but subtle disturbances have been detected after dialysis.

Many theories support the role of uremic toxins that accumulate in CKD. The balance of excitatory and inhibitory neurotransmitters may be disrupted by organic substances,[3] in particular guanidino compounds, which are increased in the cerebrospinal fluid.[4,5] These compounds antagonize γ-aminobutyric acid $GABA_A$ receptors and at the same time have agonistic effects on *N*-methyl-D-aspartate glutamate receptors, leading to enhanced cortical excitability. Asymmetric dimethylarginine,[6] which is increased in CKD, inhibits endothelial nitric oxide synthase, and levels correlate with cerebrovascular complications in uremia. Disturbances in monoamine metabolism include a depletion of norepinephrine and suppression of central dopamine, which has been linked to the impairment of motor activity in uremic rats. Myo-inositol, carnitine, indoxyl sulfate, polyamine content as well as disrupted solute transport and permeability, have been implicated in the neuronal dysfunction of uremia. Metabolites of drugs, including cimetidine and acyclovir, increased in uremia because of inhibition of organic anion transporter 3 (OAT3) and may result in neurotoxic syndromes.[7] Levels of opiates and in particular metabolites of meperidine increase in plasma because of decreased excretion through renal cation secretory transport, with subsequent neurotoxicity.

Secondary hyperparathyroidism may also play a role in UE[8,9] because brain calcium is increased in CKD and calcium transporters within neurons are parathyroid hormone sensitive. Increased cellular calcium may play a role in neuroexcitation.

Appetite regulation is abnormal in uremia (see Chapter 87). A high rate of tryptophan entry across the blood-brain barrier may increase the synthesis of serotonin, a major appetite inhibitor.[10] High levels of cholecystokinin, a powerful anorectic, and low levels of neuropeptide Y, an appetite stimulant, have been observed. Cachexia may result from anorexia, acidosis, and inflammation. Inflammatory cytokines such as leptin, tumor necrosis factor α, and interleukin-1 may signal anorexigenic neuropeptides such as pro-opiomelanocortin and α-melanocyte–stimulating hormone in the arcuate nucleus of the hypothalamus.

Clinical Manifestations

Whereas 20% of patients with acute kidney injury in an intensive care unit setting developed neurologic impairment,[11] the syndrome in CKD is more subtle, not correlating closely to the level of azotemia.[12] Cross-sectional studies in hemodialysis (HD) patients found cognitive impairment in 30%, with about 10% exhibiting severe impairment. Neurocognitive deficits may have special implications for CKD in early childhood, adversely affecting development of the brain.[13]

Uremic encephalopathy can manifest as complex mental changes or motor disturbances (Table 86-1). The full-blown syndrome is a risk factor for morbidity and mortality.[1,2] Mental findings include emotional changes, depression, disturbing and disabling cognitive and memory deficits, and, in the most severe form, a generalized disorder characterized by delirium, psychosis, seizures, coma, and ultimately death. Such advanced UE is more likely to occur in patients in whom a decision has been made not to initiate renal replacement therapy (see also Chapter 90). Severe motor symptoms or signs are rare. Depression, anxiety, and even suicide are important underdiagnosed and undertreated aspects of uremia and may be related to metabolic or poor nutritional state and fear of dialysis or death. Other known causes of depression should always be sought.

Stable UE manifests with fine action tremor, asterixis, and hyperreflexia. Asterixis is characterized by intermittent loss of muscle tone in antigravity muscles. It is distinguished from tremor by the fact that it is not an oscillation but rather an intermittent loss of tone. Myoclonus is also seen in patients with UE. It is similar in timing to asterixis (10 to 100 milliseconds) but is caused by activation of antigravity muscles. For this reason, some consider asterixis to be a form of negative myoclonus. The distinction between asterixis and myoclonus is less important than once thought because both or either may be present in many metabolic encephalopathies and some structural brain diseases as well. Asterixis and myoclonus may be elicited with the hands outstretched but may be more sensitively assessed by looking at the protruded tongue or the index finger raised with the hand resting on a firm surface. Asterixis and myoclonus may be seen in patients with renal impairment who have received various drugs

Clinical Manifestations of Uremic Encephalopathy	
Early Encephalopathy	**Late Encephalopathy**
Mental Changes	
Mood swings Impaired concentration, loss of recent memory Insomnia, fatigue, apathy	Altered cognition and perception Illusions, visual hallucinations, agitation, delirium Stupor, coma
Motor Changes	
Hyperreflexia Tremor, asterixis Dysarthria, altered gait, clumsiness, unsteadiness	Myoclonus, tetany Hemiparesis Convulsions

Table 86-1 Clinical manifestations of uremic encephalopathy.

(e.g., metoclopramide, phenothiazines, antiepileptic drugs including gabapentin, and opioids, especially meperidine). Metabolic acidosis may also produce an indistinguishable encephalopathy, as can aluminum toxicity. Therefore, before UE is considered a clinical feature of advanced uremia requiring renal replacement therapy, a careful search for other causes should be initiated.

Advanced UE is usually characterized by a reduced level of consciousness, anorexia, asterixis, myoclonus, and upper motor neuron signs that result in disturbances of gait and speech.

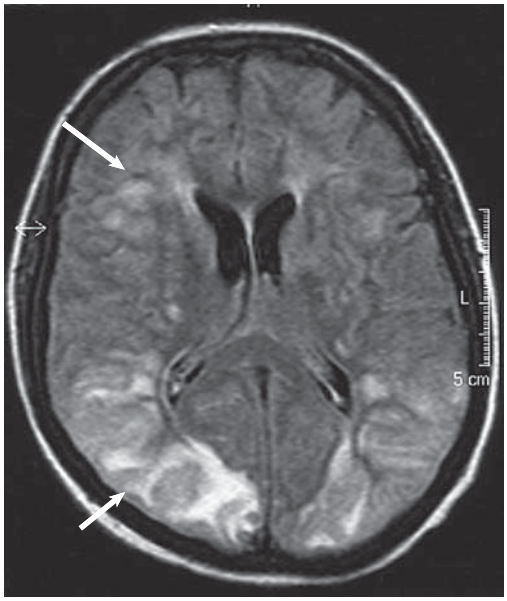

Figure 86-1 Magnetic resonance imaging (MRI) findings in uremic encephalopathy. Axial T2-weighted MRI (fluid-attenuated inversion recovery) scan from a 40-year-old woman. The extensive hyperintense lesion involves the cortical and subcortical areas of both occipital lobes and, in a more focal distribution, the basal ganglia and the frontal white matter *(arrows)*. The volume of the affected brain parenchyma is increased. Reversibility of the MRI changes was noted 2 weeks later after the initiation of regular dialysis. *(Courtesy A. Thron, Aachen, Germany.)*

Diagnosis and Differential Diagnosis

The diagnosis of UE is based on clinical findings and their improvement after adequate therapy (see next section). Lumbar puncture, electroencephalography, and imaging procedures largely serve to exclude other causes in patients in whom the clinical diagnosis is doubtful. In UE the cerebrospinal fluid is often abnormal, sometimes demonstrating a modest pleocytosis (usually <25 cells/mm^3) and increased protein (usually <100 mg/dl). The electroencephalogram is usually abnormal but nonspecific. Generalized slowing with an excess of delta and theta waves is found.[14] Brain imaging usually shows cerebral atrophy and enlargement of the ventricles (Fig. 86-1).

The differential diagnosis of UE is shown in Table 86-2. Seizure activity may be secondary to UE, hypertensive encephalopathy, cerebral embolism, cerebral venous thrombosis, or electrolyte and acid-base abnormalities. Tetany can develop when treatment involves alkalinization of an acidemic patient with renal disease and hypocalcemia.

Treatment

Most nephrologists consider advanced cognitive or memory impairment an indication for initiation of renal replacement therapy. Most of the manifestations of central nervous system involvement are reversible with dialysis within days or weeks, but mild signs of UE may persist. In dialyzed patients with persistent or recurrent symptoms, increasing the delivered dialysis dose may improve clinical findings. Successful renal transplantation usually results in resolution of the UE syndrome within days.

Correction of anemia with recombinant erythropoietin in the dialysis patient to a target hemoglobin level (see Chapter 83) may be associated with improved cognitive function and decreased slowing on the electroencephalogram.[15] Too rapid overcorrection of anemia may be associated with seizures. Similarly, parathyroid hormone suppression with vitamin D analogues and a calcimimetic is important, given the potential role of parathyroid hormone as a neurotoxin (see Chapter 85). Treatment of psychosis in kidney disease must take into account the pharmacokinetics of the specific agent. For example, risperidone may be useful, but dose reduction is necessary because of a prolonged half-life with CKD.

PERIPHERAL NEUROPATHY

Patients with CKD are susceptible to both polyneuropathies and mononeuropathies. The pathophysiologic process of polyneuropathy involves axonal degeneration in a length-dependent fashion. Primary demyelinating neuropathies are rare in the context of CKD except when the renal disease is the result of an illness that also causes demyelination (e.g., multiple myeloma). Mononeuropathies in CKD may be caused by nerve entrapment with compression of metabolically weakened nerves, particularly in wheelchair-bound or bed-bound patients. Mononeuritis multiplex should raise the question of vasculitic neuropathy, especially when systemic vasculitis (e.g., antineutrophil cytoplasmic antibody [ANCA]–positive small-vessel vasculitis or polyarteritis nodosa) is causing the CKD. Functional sparing of small-diameter axons in uremia is suggested by relatively intact thermal thresholds (hot and cold thermal threshold testing is a surrogate for pain threshold). The modestly slowed nerve conduction velocities in the polyneuropathies of uremia may be related to the reversible inhibition of the sodium-potassium adenosine triphosphatase by a uremic toxin. According to the middle molecule hypothesis, accumulated toxins in the range of 300 to 12,000 d, including peptide hormones and polyamines, may lead to progression of neuropathy in HD patients.[4,8,9] Lower limb motor axons in uremic patients are depolarized before but not after dialysis, consistent with a role of hyperkalemia in the development of altered nerve excitability.[16] Elevated magnesium levels will also slow nerve

Differential Diagnosis of Uremic Encephalopathy

Differential Diagnosis	Comment
Hypertensive encephalopathy	
Systemic inflammatory response syndrome (SIRS)	Observed in septic patients
Systemic vasculitis	Vasculitis or lupus with cerebral involvement
Drug-induced neurotoxicity	
Analgesics	Meperidine, codeine, morphine, gabapentin
Antibiotics	High-dose penicillins (may cause seizures), acyclovir, ethambutol (optic nerve damage), erythromycin and aminoglycosides (may cause ototoxicity), nitrofurantoin and isoniazid (peripheral neuropathy)
Psychotropics	Lithium, haloperidol, clonazepam, diazepam, chlorpromazine
Immunosuppressants	Cyclosporine, tacrolimus
Chemotherapeutics	Cisplatinum, ifosfamide
Others	High doses of loop diuretics (ototoxic), ephedrine, methyldopa, aluminum metoclopramide (myoclonus, dystonia)
Cerebral atheroembolic disease	Follows recent aortic or cardiac angiography; associated with peripheral manifestations, including lower extremity cyanosis, livedo reticularis, and eosinophilia
Subdural hematoma	
Posterior leukoencephalopathy	Observed particularly following renal transplantation as a result of reversible, abnormal permeability of the blood-brain barrier Often manifests with headache followed by mental depression, visual loss, and seizures in the context of volume expansion, acute hypertension, and often treatment with corticosteroids or calcineurin inhibitors Lesions in the parietal, temporal, and occipital lobes may be seen on imaging studies

Table 86-2 Differential diagnosis of uremic encephalopathy.

conduction velocity. *In vitro,* extracellular acidosis contributes to decreased sodium conductance in large sensory neurons. Very slow nerve conduction velocities (i.e., less than half normal) suggest a demyelinating neuropathy, a finding that should lead the physician to seek a specific cause (e.g., a paraprotein).

Polyneuropathies occur in about two thirds of uremic patients and may progress rapidly in advanced CKD.[1,16,17] Characteristic symptoms and signs are sensory loss, pain, paresthesias, and insensitivity to temperature, particularly cold. These findings can advance to include motor findings, such as footdrop. Phrenic neuropathy may cause dyspnea because of oor diaphragmatic movement, whereas hiccups are more likely a result of the central nervous system effects of uremia. The distal lower extremities are usually affected first because axonal polyneuropathies are length dependent. Decrease in vibratory sensation and position sense and Romberg sign (i.e., greater instability of stance with eyes closed than with eyes open) are common signs. Muscle stretch reflexes are reduced or absent. In the diabetic dialysis patient who has progressive neuropathy, it is important to establish adequacy of the dialysis as well as glucose control. Uremic polyneuropathy is aggravated by malnutrition, inadequately controlled hypertension, and a number of comorbid conditions, including diabetes mellitus, alcohol abuse, atherosclerotic vascular disease, and medications (e.g., nitrofurantoin, isoniazid, hydralazine).

The diagnosis of uremic polyneuropathy can usually be made from clinical findings. Nerve conduction velocity is modestly reduced, and needle electromyography shows evidence of chronic denervation and sometimes reinnervation. If electromyography and nerve conduction tests are performed, they should not be done in an extremity bearing an arteriovenous fistula because the surgery may cause local nerve injury, which can complicate the interpretation of the clinical neurophysiologic studies.[16]

Lead polyneuropathy should be considered, particularly when there is a known exposure history. Lead accumulates in the dialysis patient but could also be the cause of CKD. A lower motor neuron syndrome caused by lead toxicity may be mistaken for amyotrophic lateral sclerosis. A bone lead scan using K-line x-ray fluorescence spectroscopy of the tibia is a promising new noninvasive test that may become useful. Serum lead values and red cell protoporphyrin levels may be normal if exposure is remote. There may be associated depression, the so-called "saturnine temperament," so named because the ancients believed that Saturn was made of lead and was associated with a melancholy disposition. Gout, hypertension, renal glycosuria, and microcytic anemia also may be caused by lead toxicity.

Other conditions in the differential diagnosis of mixed polyneuropathy include other heavy metals (such as arsenic and mercury), nutritional deficiencies (such as pyridoxine, thiamine, and niacin), human immunodeficiency virus–related neuropathy, amyloid, vasculitis, sarcoid, lupus, and a paraneoplastic syndrome.

Progressive polyneuropathy may be an indication for initiation of dialysis or for renal transplantation. Symptoms usually will not deteriorate further or may even show a slow improvement thereafter. If polyneuropathic symptoms worsen in a dialysis patient, the dialysis dose should be increased. Physical therapy is an important component of the management. Patients experiencing neuropathic pain may be treated with tricyclic antidepressants (e.g., amitriptyline, 10 to 25 mg, increasing to 75 to 150 mg at bedtime) or antiepileptic drugs (e.g., carbamazepine, 200 to 400 mg initially, increasing to 1200 mg maximally; phenytoin, 100 to 200 mg initially, maximally 600 mg).[1,2] Gabapentin is an antiepileptic drug that is sometimes used to treat neuropathy but may result in oversedation and myoclonus in CKD because of marked prolongation of the drugs half-life. When it is used, it should be monitored closely at reduced doses. Deficiencies of cobalamin (vitamin B_{12}), folate, and pyridoxine may be reflected in an elevated serum homocysteine level. Thiamine deficiency, often associated with malnutrition, can also aggravate neuropathy, but whether replacement of any of these vitamins is effective in preventing or curing polyneuropathy in uremic patients is not well established. Thiamine deficiency is the cause of Wernicke encephalopathy in dialysis or malnourished patients. This syndrome is suspected when the triad of mental change (often amnesia), ataxia, and oculomotor disturbances (most often abducens palsies with gaze-evoked nystagmus) is seen in any patient whose diet is deficient in B vitamins. When amnesia is combined with a polyneuropathy, the term *Korsakoff psychosis* applies. In malnourished patients, the cause of Korsakoff psychosis is usually multiple subclinical attacks of Wernicke encephalopathy, hence the term *Wernicke-Korsakoff disease.*

Specific mononeuropathic syndromes include ulnar nerve entrapment, associated with uremic tumoral calcinosis and subsequent ischemia, and carpal tunnel syndrome, for example, caused by

β_2-microglobulin–derived amyloidosis (see Chapter 85) or by an arteriovenous fistula.[1,17] These syndromes may be treated with anti-inflammatory agents, anticonvulsants, and surgical decompression. It is important to ensure adequacy of dialytic treatment.

Pruritus in the uremic patient may be severe and is not primarily a skin disorder (see also Chapter 88). Rather, it may represent a form of sensory neuropathy. This symptom usually improves with renal replacement therapies. Antihistamines, with their sedating effect, are not always effective. Gabapentin and carbamazepine block the afferent pathway in uremic neuropathic itch. Gabapentin and pregabalin inhibit calcitonin gene–related peptide from primary afferent neurons by inhibiting GABA and opioid receptor antagonists (naloxone and naltrexone) and may antagonize transmission of itch. Antidepressants have also been successful, possibly by interfering with reuptake of serotonin and norepinephrine to reduce pruritus perception.[18]

AUTONOMIC NEUROPATHY

Autonomic neuropathy is also very common in patients with advanced CKD, probably because diabetes is a common cause of CKD. Hyperglycemia may be more difficult to control in CKD because glucose filtration is decreased. Amyloidosis, a less common cause of CKD, also is associated with autonomic neuropathy. A typical manifestation is orthostatic hypotension, which is most severe in patients with diabetes mellitus or amyloidosis as a cause of CKD. Some patients have evidence of peripheral neuropathy and may manifest hyporeninemic hypoaldosteronism with hyperkalemia and renal tubular acidosis. The low blood pressure may preclude antiproteinuric treatment with angiotensin antagonists in the predialysis patient and may complicate fluid removal during dialysis. Patients on peritoneal dialysis may be particularly affected. CKD patients were thought to have decreased baroreceptor function, but normal baroreceptor responses to graded decrements in mean arterial blood pressure have been described.[19] Instead, CKD patients have sympathetic hyperactivity, which contributes to hypertension, more rapid progression to renal failure in the predialysis patient, and greater cardiovascular risk. Accordingly, α- and β-adrenergic blockade has been advocated in CKD.[19] Autonomic neuropathy is caused by axonal disease and thus is length dependent. For that reason, the longest autonomic nerve, the vagus, is usually the first affected, resulting in the loss of the normal sinus arrhythmia, significant reductions of day-night blood pressure variation, and possibly sudden cardiac death related to the loss of the balance between the sympathetic and parasympathetic limbs of the autonomic nervous system. Gastrointestinal complaints include gastroparesis, particularly problematic for the diabetic patient. In the predialysis patient, nausea and early satiety associated with gastroparesis may be confused with uremia. Several medical regimens have been used for the uremic patient with gastroparesis; they include erythromycin, which can activate the gastric motilin receptor. Levodopa-carbidopa, as a dopamine agonist, may be effective, as may metoclopramide, 10 mg before sleep, or domperidone 10 to 20 mg. Nocturnal diarrhea is another consequence of vagal neuropathy. Erectile dysfunction and incontinence (urinary more commonly than fecal) may also be related to autonomic neuropathy.

CRANIAL NEUROPATHIES

Cranial nerve involvement is most often vestibulocochlear. Hearing loss needs to be distinguished from drug-induced ototoxicity or the neurosensory deafness of hereditary nephropathy.[1,2] Bilateral vestibular failure leads to inability to stand or to walk normally without vertigo or nystagmus. It is often related to the use of aminoglycoside antibiotics in the patient with CKD, unless the dose is properly adjusted. *N*-acetylcysteine given with aminoglycosides may reduce the risk of cochlear toxicity. Sulfa-based loop diuretics, often used at high doses in patients with CKD, may cause vestibular or cochlear damage. Decreased olfactory function, especially a reduced ability to discriminate among and to identify odors, and dysgeusia are commonly seen in patients with CKD.

SLEEP DISORDERS

Many HD and peritoneal dialysis patients exhibit obstructive sleep apnea that is independent of obesity.[20] The associated sleep deprivation contributes to fatigue and cognitive impairment and increases the risk of cardiovascular complications.[20] Both obstructive and central sleep apnea are seen in patients with CKD. Obstructive sleep apnea is a condition in which blockage of the upper airway can interfere with nocturnal breathing. Nighttime oxygen and continuous positive airway pressure (CPAP) may help. Treatment of obstructive sleep apnea, with use of CPAP in a fashion similar to the treatment of nonuremic individuals, is effective. Nocturnal HD has been reported to significantly reduce the occurrence of sleep apnea.[20] Central sleep apnea, often accompanied by heart failure, causes prolonged apneic episodes and also may respond to oxygen. Initiation of dialysis may be helpful.

Daytime sleepiness is common and underdiagnosed in patients with CKD and contributes not only to worsened hypertension and increased cardiovascular risk but also to social dysfunction. Whether obstructive sleep apnea and its associated excessive daytime sleepiness is an independent risk factor for the progression of renal failure is not yet settled. It is assessed by a multiple sleep latency test, that is, the duration of time from "lights out" to the onset of sleep. If it is less than 5 minutes, it is consistent with sleep deprivation. There was also a reduced proportion of rapid eye movement sleep. An increased arousal frequency is related to periodic limb movements during sleep and the presence of sleep apnea.

Sleep-wake complaints are common in patients on dialysis, with an incidence of up to 80%. Contributors include peripheral neuropathy, pain, and pruritus.

RESTLESS LEGS SYNDROME (EKBOM SYNDROME)

Restless legs syndrome (RLS), described by K. A. Ekbom in 1944,[21] is frequent in CKD, particularly in women. It may result from a decrease in dopaminergic modulation of intracortical excitability, with reduced supraspinal inhibition and increased spinal cord excitability. RLS is characterized by unpleasant "creeping" sensations in the extremities and a compulsive need to move the limbs, usually the legs.[22-24] The movement is worsened by periods of rest or inactivity and is relieved by walking or stretching. Symptoms are worse at night and may lead to insomnia and consequent daytime sleepiness and reduced quality of life. Nocturnal muscle cramps are also common in CKD and should be distinguished from RLS. The Ekbom syndrome consists of restless legs plus other obsessive-compulsive–like disorders including various pica behaviors, such as pagophagia (ice eating), geophagia (clay eating), and amylophagia (starch eating).

Periodic limb movement disorder is characterized by episodes of involuntary repetitive extension of the big toe and dorsiflexion of the

ankle as well as flexion of the knee and hip.[23,24] This disorder is more likely to occur in those with RLS.

Iron deficiency or iron transport into the central nervous system plays a central role in RLS. Iron is a cofactor for the enzyme tyrosine hydroxylase, the rate-limiting step in the biosynthesis of dopamine, possibly explaining the link between iron deficiency and dopamine deficiency in RLS. Overt iron deficiency is easily diagnosed and should be treated.[23,24] In patients with normal red blood cell indices and serum iron and total iron-binding capacity, serum ferritin should be tested. Transferrin saturation ratio may be an even more sensitive indicator of iron deficiency. If these are both normal, a spinal fluid ferritin analysis may reveal a subtle central nervous system iron deficiency syndrome. RLS often persists after initiation of dialysis but may improve after transplantation and has been linked to abnormalities in calcium and phosphorus metabolism as well as to anemia. Iron replacement should be initiated if there is any indication of iron deficiency. Oral replacement is the safest method. Intravenous iron may be required (see Chapter 83). Dopaminergic treatment is often helpful, usually starting with the dopamine receptor agonists pramipexole and ropinirole. Levodopa combined with decarboxylase inhibitors (e.g., carbidopa-levodopa) may be used as well as gabapentin, opioids, and benzodiazepines.[22-24] Care should be taken with gabapentin because of toxicity with accumulation, the symptoms of which are sedation, cognitive slowing, and various movement disorders including tremor, ataxia, and asterixis (see previous discussion). Older dopamine receptor agonists, such as bromocriptine and pergolide, are rarely used now for RLS.

NEUROLOGIC SYNDROMES ASSOCIATED WITH RENAL REPLACEMENT THERAPY

Renal replacement therapy is associated with an increased incidence of subdural hematoma and intracranial hemorrhage, presumably connected to hypertension and anticoagulation with HD as well as Wernicke encephalopathy (see earlier discussion).[1,2] A syndrome of muscle weakness has been attributed to L-carnitine depletion from dialysis, leading to decreased mitochondrial fatty acid usage.

Dialysis disequilibrium syndrome is a rare complication of rapid metabolic changes occurring with HD, usually affecting patients in whom HD is being initiated (see also Chapter 95).[25] It is most common in patients with severe uremia of long duration and with severe hypertension. Characterized by acute onset of headache, nausea, vomiting, disorientation, a confusional state, and seizures, it is a diagnosis of exclusion. It usually results from acute changes in osmolality during HD, in which the rapid decrease in urea in the extracellular fluid favors water movement into brain cells, resulting in cerebral edema. Alternatively, other intracellular osmolytes within brain cells may draw water from the extracellular fluid. The syndrome normally reverses spontaneously after a period of regular HD. If no improvement is seen after a month of HD, one should investigate for other possible causes of the clinical syndrome by imaging the brain, obtaining an electroencephalogram, and examining the spinal fluid. Dialysis disequilibrium syndrome may be prevented by decreasing HD length to 2 to 3 hours, dialyzing daily, and reducing HD efficacy during the first sessions.

Dialysis encephalopathy (formerly called *dialysis dementia*) is probably a multifactorial syndrome occurring in sporadic-endemic and epidemic types. In particular, in the epidemic type, aluminum-based phosphate binders and exposure to a dialysate containing more than 20 μg of aluminum per liter are considered to be major causes.[26,27] Aluminum transferred to the nervous system by transferrin results in a characteristic clinical condition with prominent stuttering that usually worsens toward the end of a dialysis session and encephalopathy, initially responding well to intravenous benzodiazepines but then becoming unresponsive, leading to a severe encephalopathy and death. With the almost universal preparation of dialysate water by reverse osmosis and the marked reduction in aluminum-containing phosphate binder use, aluminum-induced encephalopathy has virtually disappeared. If it is present, aluminum toxicity is treated with deferoxamine (see Chapter 85). Renal transplantation is an effective treatment for dialysis dementia.

CHAPTER 87

Gastroenterology and Nutrition in Chronic Kidney Disease

Gemma Bircher and Graham Woodrow

GASTROINTESTINAL PROBLEMS IN CHRONIC KIDNEY DISEASE

Gastrointestinal (GI) symptoms and disease are common in patients with chronic kidney disease (CKD), including those receiving renal replacement therapy (Table 87-1). Anorexia, nausea, and vomiting can arise from uremic toxicity. They may indicate the need to start dialysis or may be a manifestation of inadequate dialysis clearances. GI disturbances contribute to the development of malnutrition and wasting. These common complications of advanced CKD carry an adverse prognosis for survival. Some GI conditions are a result of uremia or the effects of renal replacement therapy. Other GI symptoms are manifestations of conditions also responsible for the renal disease. Medications may result in a range of GI complications in patients with CKD.

GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Oral Disease in Chronic Kidney Disease

Glossitis can result from deficiency of iron, vitamin B_{12}, other B vitamins, or folic acid. Halitosis is a feature of uremia, and reduced taste sensation or abnormal or unpleasant taste can impair dietary intake. Dental disease may prevent adequate nutrition. Gingival hyperplasia is a frequent complication of treatment with calcium channel blockers or cyclosporine. Oral candidiasis occurs in patients receiving immunosuppressive drugs including corticosteroids, in those undergoing antibiotic therapy, in patients with diabetes, and in older malnourished individuals. If extensive, particularly with esophageal involvement, it may lead to dysphagia (Fig. 87-1).

Gastroesophageal Reflux Disease and Esophagitis

Gastroesophageal reflux disease is a common complaint that is defined by symptoms of heartburn or mucosal changes arising from reflux of caustic gastric contents into the esophagus. It occurs more frequently in patients with CKD because of GI dysmotility or delayed gastric emptying and may be more prevalent with peritoneal dialysis (PD) because of increased intra-abdominal pressure.[1] It is more common in patients with scleroderma because of reduced esophageal peristalsis. Esophagitis also results from the irritant effects of drugs, including slow-release potassium preparations, tetracyclines, iron preparations, aspirin, nonsteroidal anti-inflammatory drugs, and bisphosphonates. The diagnosis is made from the patient's symptoms. Typical features appear on endoscopy but may be absent in symptomatic patients. Other investigations include 24-hour ambulatory esophageal pH monitoring and demonstration of reflux on barium swallow examination. It is important to consider ischemic cardiac disease in CKD as an alternative cause of atypical symptoms. Management includes weight loss in obese patients; avoidance of bedtime snacks, fatty foods, cigarettes, and alcohol; and raising the head of the patient's bed. Proton pump inhibitors are the most effective medical treatment, and maintenance therapy may be required. Other drugs include histamine H_2 receptor antagonists and antacid preparations. Sucralfate should be avoided in patients with CKD because of the risk of aluminum accumulation.

Peptic Ulcer Disease, Gastritis, and Duodenitis

In the early days of dialysis, peptic ulceration and GI hemorrhage were major complications of renal failure. However, with effective drug therapies and improvement in dialysis therapy, peptic ulcer disease is not more common in CKD than in the general population, although it remains an important cause of GI hemorrhage. Peptic ulcers in patients with CKD are more often multiple than in the general population and situated in a postbulbar position.[2] Hemorrhage occurs more often, but pain is less frequent.[2]

Gastritis and duodenitis are common in patients with CKD and abdominal symptoms. Hypergastrinemia occurs with CKD but is not important in causation of gastritis, duodenitis, or peptic ulcers. Despite high urea concentrations in patients with CKD, incidence of *Helicobacter pylori* infection is not increased.[3] Increased susceptibility of gastric and duodenal mucosa to damage in CKD may be an underlying mechanism. The presence of *H. pylori* infection in PD has been suggested as a possible cause of anorexia, inflammation, and malnutrition.[4]

Dyspepsia without other warning features (weight loss, vomiting, hemorrhage) may be managed by testing for *H. pylori* with a breath test or stool antigen test (which are valid in CKD) and an empirical course of acid-suppressing therapy. Persistent symptoms of new onset in patients older than 55 years warrant upper GI endoscopy to exclude malignant disease. The frequent coexistence of other symptoms in CKD, such as nausea, vomiting, and weight loss, may lead to a lower threshold for performance of endoscopy. Management includes use of proton pump inhibitors and histamine H_2 receptor antagonists. There is a risk of excess calcium and magnesium absorption with some antacids in CKD, and aluminum- or bismuth-containing preparations should be avoided.

Delayed Gastric Emptying and Gastroparesis

Gastric emptying is impaired in uremia (possibly to a greater degree in PD)[5,6] and is affected by some conditions leading to renal disease, particularly diabetes and amyloidosis. This results in reduced

Important Causes of Common Gastrointestinal Symptoms in Patients with Chronic Kidney Disease

Clinical Feature	Important Causes in CKD
Anorexia	Uremic toxicity Inadequate dialysis clearances Delayed gastric emptying
Nausea and vomiting	Uremic toxicity Delayed gastric emptying Gastritis, duodenitis Peptic ulcer disease Drugs
Constipation	Drugs, including opioid analgesia GI pseudo-obstruction Diverticular disease
Diarrhea	Diabetic enteropathy Dialysis-related amyloidosis Diverticular disease *Clostridium difficile* infection
GI hemorrhage	Gastritis, duodenitis Esophagitis Peptic ulcer disease Angiodysplasia Intestinal ischemia Dialysis-related amyloidosis Vasculitis
Acute abdominal pain	Gastritis, duodenitis Complications of peptic ulcer disease Acute pancreatitis Intestinal ischemia Diverticulitis GI pseudo-obstruction Colonic perforation from fecal impaction Complications of peritoneal dialysis (peritonitis, dialysis catheter malposition, dialysate infusion pain) Complications of autosomal dominant polycystic kidney disease Retroperitoneal hemorrhage

Table 87-1 Important causes of common gastrointestinal (GI) symptoms in patients with chronic kidney disease (CKD).

appetite, early satiety, nausea, vomiting, and malnutrition. Mechanisms in uremia may include autonomic neuropathy and retained GI peptides. The diagnosis is confirmed by scintigraphic measurement of gastric emptying. It may be suspected when endoscopy demonstrates residual gastric contents despite fasting. Endoscopy is important to exclude gastric outlet obstruction. Reversible causes should be addressed, including optimization of diabetic control, correction of electrolyte abnormalities, and discontinuation of drugs that impair gastric emptying (e.g., those with anticholinergic and opioid effects). Dietary measures, with frequent smaller low-fat meals and avoidance of nondigestible solids, are often disappointing. Antiemetic agents are also often ineffective. The mainstay of treatment is prokinetic drug therapy, including metoclopramide, domperidone, and erythromycin. Prokinetic drugs improve nutritional state in patients with delayed gastric emptying.[7] Nutritional support through feeding nasoenteric or jejunostomy tubes may be required.

Large Bowel Disorders

Diverticular disease has an incidence in CKD similar to that in the general population, except in patients with autosomal dominant polycystic kidney disease (ADPKD), in whom it is increased.[8] It presents as acute diverticulitis or colonic perforation and is associated with PD peritonitis caused by enteric organisms. There is a greater risk of bleeding in CKD (because of uremic bleeding tendency) and perforation with high-dose corticosteroids (e.g., after renal transplantation).

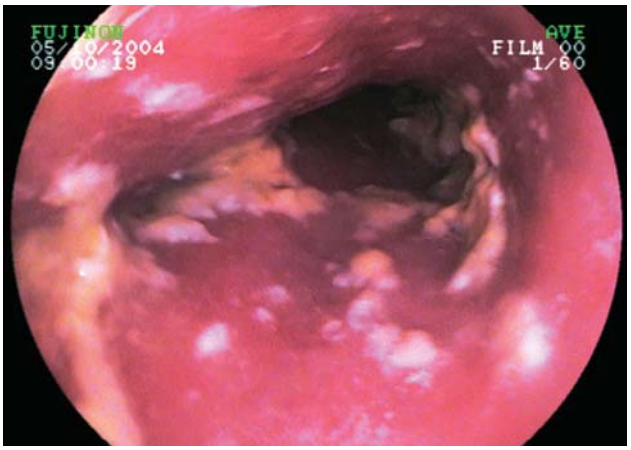

Figure 87-1 Endoscopic appearance of esophageal candidiasis. *(Courtesy Dr. B. Rembacken, Leeds, United Kingdom.)*

Constipation is common in CKD. Predisposing factors include drugs, dietary restrictions, low oral fluid intake, and electrolyte abnormalities, including hypercalcemia. In PD, constipation results in impaired dialysate drainage and catheter malposition. Severe constipation is a risk factor for large bowel perforation. Management includes stool-softening agents, stimulant laxatives, and fiber preparations. Drugs predisposing to constipation include calcium-based phosphate binders, sevelamer, oral iron, opioid analgesics, and calcium resonium.

Colonic perforation may occur in CKD from a number of causes. These include diverticulitis, fecal impaction, and dialysis-related amyloidosis. This condition has a higher mortality in CKD patients.

Gastrointestinal Pseudo-obstruction

Pseudo-obstruction presents with acute or more chronic clinical features of abdominal pain, vomiting, constipation, or diarrhea. It arises from disordered gut motility and is more common in dysmotility states, such as diabetes, amyloidosis, and scleroderma. Drugs that reduce bowel motility and electrolyte disturbance such as hypokalemia predispose to pseudo-obstruction, and it may be acutely precipitated by surgery, constipation, and retroperitoneal hemorrhage. Investigations include plain abdominal radiography, computed tomographic scanning, and bowel contrast studies. Management includes nutritional support (which may require parenteral feeding) and prokinetic agents. Nasogastric tube insertion and aspiration may be required for symptomatic control. Complications include intestinal perforation[9] and bacterial overgrowth.

Vascular Disease of the Gastrointestinal Tract

Intestinal ischemia is an important cause of an acute abdomen in older CKD patients. A proportion of cases result from nonocclusive mesenteric ischemia, in which there is no critical vascular occlusion.[10] It may be precipitated by excess fluid removal by hemodialysis (HD). Predisposing factors include hypotension, cardiac failure, hypoxia, increased plasma viscosity, and constipation (which increases intraluminal pressure, impairing vascular perfusion).

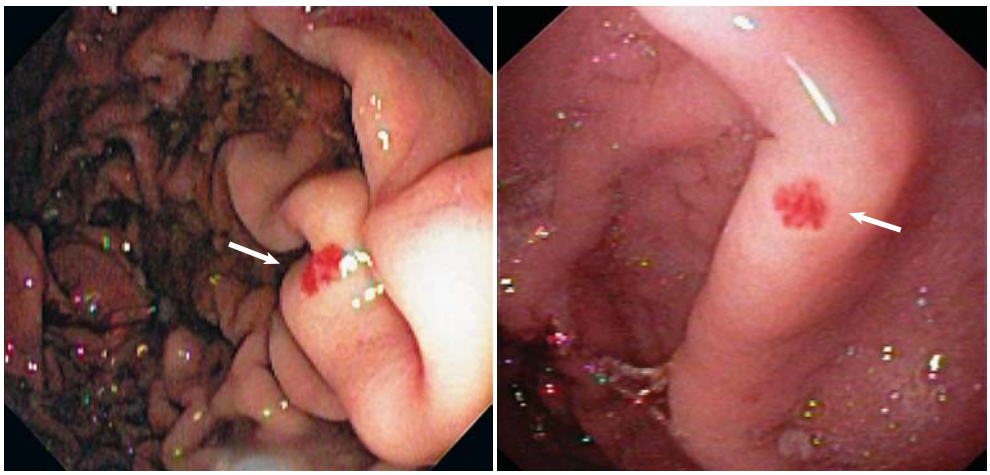

Figure 87-2 Two examples of gastric angiodysplasia *(arrows)* in a dialysis patient. *(Courtesy Drs. R. Winograd and C. Trautwein, Aachen, Germany.)*

Presentation is with abdominal pain, diarrhea, or lower GI bleeding. Abdominal signs such as peritonism can be misleadingly modest at presentation, but there is often peripheral neutrophil leukocytosis and progressive lactic acidosis. Milder cases may settle with hemodynamic resuscitation. Patients with more severe cases with features of peritonism and intestinal infarction require laparotomy and have a high mortality.

GASTROINTESTINAL HEMORRHAGE

Gastrointestinal hemorrhage is an important complication of CKD, with increased incidence compared with the general population. Causes include a greater incidence of lesions such as gastritis and duodenitis,[11] angiodysplasia, and, more rarely, dialysis-related amyloidosis and systemic vasculitis (Fig. 87-2). Uremic hemostatic defects and anticoagulation during HD are also important. Upper GI endoscopy is the major diagnostic investigation in upper GI bleeding and also allows therapeutic procedures to stop bleeding. Flexible sigmoidoscopy and colonoscopy are performed for lower GI bleeding. Investigations in which the cause remains unclear include angiography, small bowel enteroscopy or capsule study, and radiolabeled red cell scanning.

Resuscitation requires careful monitoring in patients with CKD. Adequate fluid replacement to maintain renal perfusion in patients not on dialysis or with residual renal function in patients on dialysis, but avoiding fluid overload, is crucial. Monitoring of serum potassium with avoidance of hyperkalemia complicating blood transfusion is also important. Correction of coagulation defects in patients with CKD includes optimization of dialysis clearance, correction of anemia, and use of DDAVP or cryoprecipitate. Drugs that increase bleeding risk should be discontinued when possible. HD, when it is required, should be performed without heparin for anticoagulation. Specific treatment is directed at the cause of hemorrhage. Bleeding from angiodysplasia in HD may improve on transfer to PD.[12] The presence of CKD increases the risk of mortality in GI hemorrhage.[10]

Clostridium difficile Infection

Clostridium difficile is a major cause of nosocomial diarrheal illness. Clinical manifestations vary from mild diarrheal illness to severe pseudomembranous colitis (Fig. 87-3). Patients with CKD are at risk of more frequent or severe infection and have a higher resulting mortality.[13] Reasons include the older age of CKD patients, frequent use of acid-suppressing drugs, and antibiotics. Diagnosis is made by identifying *C. difficile* toxin in diarrheal stools. In severe cases, there are radiologic appearances of acute colitis with mucosal edema, but these are not specific for *C. difficile.* A pseudomembrane may be visualized on sigmoidoscopy, but diarrhea can occur in its absence. The precipitating antibiotic should be stopped if possible. Oral metronidazole is first-line antibiotic therapy; oral vancomycin is used if there is intolerance of or failure to respond to metronidazole. Fidaxomicin is a newer, expensive agent that may be used for recurrent infection, and intravenous immunoglobulin has been used for refractory cases.[14] Fluid and electrolyte replacement are important, and drugs that reduce diarrhea or impair gut motility must be avoided because they may precipitate toxic megacolon. Colectomy may be required in life-threatening disease. *C. difficile* infection is a major problem in the hospital setting, including renal units. Preventive measures, including hand washing, cleanliness of physical

Gastrointestinal-Renal Syndromes: Conditions Typically Resulting in Both Renal and Gastrointestinal Disease		
Disorder	**Renal Involvement**	**GI Involvement**
Diabetes	Proteinuria, CKD	Gastroparesis, diabetic enteropathy, constipation
Systemic vasculitis	Proliferative glomerulonephritis, CKD	Intestinal ischemia, GI hemorrhage, bowel perforation, hepatobiliary involvement, acute pancreatitis
Systemic amyloidosis	Nephrotic syndrome, CKD	Diarrhea, malabsorption, splenic rupture
Autosomal dominant polycystic kidney disease	CKD, cyst hemorrhage, and infection	Abdominal pain (from renal or hepatic cysts), diverticular disease, hernia
Inflammatory bowel disease	AA amyloidosis, drug-induced interstitial nephritis, IgA nephropathy, oxalate renal calculi (with terminal ileal Crohn disease)	Abdominal pain, diarrhea, GI hemorrhage, malabsorption
Scleroderma	CKD, acute scleroderma renal crisis	Dysphagia, constipation, malabsorption, and bacterial overgrowth
Fabry disease	Hematuria, proteinuria CKD	Abdominal pain, episodes of diarrhea, or constipation
Celiac disease	IgA nephropathy	Malabsorption, iron-deficiency anemia
IgG4-related tubulointerstitial nephritis	Tubulointerstitial nephritis	Autoimmune pancreatitis

Table 87-2 Gastrointestinal (GI)-renal syndromes: conditions typically resulting in both renal and GI disease. *CKD,* Chronic kidney disease.

environment, and isolation of affected inpatients with barrier nursing, are essential. Antibiotic policies should minimize use of broad-spectrum antibiotics, which induce *C. difficile* infection.

Acute Pancreatitis

There is some evidence suggesting that acute pancreatitis is more common in CKD, and the incidence may be greater in PD than in other CKD patients.[15] Most cases are secondary to biliary tract disease or alcohol use or are idiopathic. Rarer causes, in CKD patients, are hypercalcemia, vasculitis, and drugs including corticosteroids, azathioprine, angiotensin-converting enzyme (ACE) inhibitors, and diuretics. Serum amylase is the usual diagnostic measure, although concentrations are normally elevated up to threefold in renal failure and are lowered in PD patients receiving icodextrin dialysate (because of competitive inhibition of icodextrin and metabolites with the amylase assay). Serum lipase is an alternative diagnostic marker (although it is also elevated in uremia). Amylase and lipase concentrations may be measured in dialysate in PD patients with suspected pancreatitis. Radiology, including ultrasound, computed tomography, and magnetic resonance imaging, is useful to confirm the diagnosis and to detect underlying biliary disease and complications such as pancreatic necrosis and pseudocyst formation. In PD patients with acute pancreatitis, dialysate may become cloudy with increased leukocytes, hemorrhagic, or dark brown (cola colored).

Acute Abdomen

Some causes of acute abdominal pain occur more commonly in or are specific to CKD patients. A high index of suspicion for ischemic bowel is important because of the frequency of vascular disease in CKD. Pain may result from complications of autosomal polycystic kidney disease. Retroperitoneal hemorrhage can arise from anticoagulation, including during HD. In PD, abdominal pain arises from peritonitis, acidity of the fluid (causing dialysate infusion pain), catheter malposition, constipation, and encapsulating peritoneal sclerosis. Other surgical conditions need to be distinguished from dialysis-specific causes. Although air uncommonly enters the peritoneal cavity during PD, in the setting of acute abdominal symptoms the finding of free gas on radiologic imaging of the abdomen suggests visceral perforation.

GASTROINTESTINAL-RENAL SYNDROMES

A number of conditions result in both renal and GI manifestations (Table 87-2).

Diabetes

Diabetes is commonly complicated by disordered gut motility. Gastroparesis needs to be distinguished from uremic upper GI symptoms. Diarrhea caused by diabetic enteropathy is also common, classically is nocturnal, and usually is neurogenic in origin. Treatment is usually by antimotility agents. Bacterial overgrowth is uncommon and is diagnosed by the hydrogen breath test. GI symptoms may be exacerbated by drug treatments for diabetes, including metformin and α-glucosidase inhibitors. Gastroparesis results in difficulties with glycemic control, fluid and electrolyte imbalance, drug malabsorption, and malnutrition. The speed of colonic transport is decreased in diabetes, which may result in constipation.

Systemic Vasculitis

Gastrointestinal manifestations of vasculitis include intestinal ischemia or infarction, hemorrhage, and perforation with peritonitis. Abnormal liver function test results arise from hepatitis, and cholecystitis and pancreatitis have been described. Serositis with abdominal pain is a feature of systemic lupus erythematosus. Abdominal pain, vomiting, and GI hemorrhage are typical of Henoch-Schönlein purpura.

Systemic Amyloidosis

Primary AL amyloidosis may result in both renal and GI involvement. Conversely, inflammatory bowel disease is an important cause of secondary AA amyloidosis, which may result in renal

involvement. Thus, in a patient with renal amyloidosis who has GI symptoms, it is important to characterize the type of amyloid and the underlying cause of GI disturbance.

Autosomal Dominant Polycystic Kidney Disease

Abdominal hernias are more common in ADPKD[16] and are a particular problem in PD patients. Colonic diverticular disease occurs more frequently. The enlarged kidneys can result in abdominal pain, hemorrhage, abdominal fullness, and anorexia. Hepatic cysts and occasionally massive hepatomegaly may cause chronic abdominal pain and fullness. Common bile duct dilation, of uncertain significance, occurs more frequently in ADPKD.

Inflammatory Bowel Disease

Inflammatory bowel disease may be complicated by AA amyloidosis and IgA nephropathy. Drug therapy, such as aminosalicylates, can lead to renal disease, including chronic interstitial nephritis. Terminal ileal disease in Crohn disease can lead to hyperoxaluria and oxalate calculi.

Celiac Disease

Celiac disease is a relatively common condition and occurs with increased frequency in association with other autoimmune conditions, such as diabetes mellitus. There is also a reported association with IgA nephropathy.[17]

DRUGS AND GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Drugs commonly used in CKD can lead to GI problems (Table 87-3). Phosphate-binding drugs commonly result in abdominal symptoms. Nausea and vomiting are important complications of cinacalcet. Other drugs important in CKD that may cause GI problems include statins, ACE inhibitors, iron supplements, sodium bicarbonate, bisphosphonates, and metformin. Acid-suppressing drugs including proton pump inhibitors and H_2 receptor blockers are commonly prescribed in CKD. They are often inappropriately continued for long periods[18] and have their own associated side effects. They increase the risk of *C. difficile* infection. Proton pump inhibitors can result in symptoms including nausea, vomiting, abdominal pain, diarrhea, and constipation. By reducing gastric acidity they may also reduce the effectiveness of calcium carbonate prescribed as a phosphate binder (because it is only soluble in an acid environment).

SPECIFIC GASTROINTESTINAL COMPLICATIONS OF RENAL REPLACEMENT THERAPY

Idiopathic Dialysis-Related Ascites

Idiopathic ascites occurs in HD patients and may be caused by suboptimal dialysis clearances. Diagnosis is by exclusion of other causes of ascites. Aspirated fluid usually has an elevated protein content. Management includes fluid and sodium intake restriction and ultrafiltration by dialysis. Small-solute clearance must be optimized, and paracentesis may be required for symptom control. The condition may resolve after renal transplantation, and switching to PD can be tried.

Gastrointestinal Side Effects of Drugs Commonly Used in Patients with Chronic Kidney Disease

Drug	GI Side Effects
Calcium-based phosphate binders	Constipation, abdominal discomfort
Sevelamer	Constipation, dyspepsia, bowel obstruction (very rare)
Lanthanum carbonate	Dyspepsia, nausea, diarrhea
Cinacalcet	Anorexia, nausea, vomiting
Statins	Abdominal discomfort, diarrhea, constipation
ACE inhibitors	Nausea, constipation, diarrhea, acute pancreatitis
Iron supplements	Nausea, epigastric pain, constipation, diarrhea
Bisphosphonates	Esophagitis, esophageal ulcers and strictures
Polystyrene sulfonate (calcium resonium, Kayexalate)	Severe constipation, colonic necrosis
Calcium channel blockers	Constipation, intestinal pseudo-obstruction
Metformin	Anorexia, nausea, vomiting, diarrhea
Proton pump inhibitors	Nausea, vomiting, abdominal pain, constipation, diarrhea
Mycophenolate mofetil	Diarrhea, abdominal pain, vomiting
Azathioprine	Dyspepsia, acute pancreatitis, hepatitis

Table 87-3 Gastrointestinal (GI) side effects of drugs commonly used in patients with chronic kidney disease (CKD). *ACE,* Angiotensin-converting enzyme.

Peritoneal Dialysis–Related Gastrointestinal Conditions

A number of complications relating to PD may affect the abdomen, including infectious peritonitis, pain on dialysate infusion and drainage, and encapsulating peritoneal sclerosis (see Chapter 97). Hemoperitoneum in PD is typically related to the menstrual cycle, occurring during menstruation or ovulation, or may be self-limited, probably resulting from minor peritoneal membrane trauma from the PD catheter (Fig. 87-4). Rarely, underlying pathologic causes are present, including encapsulating peritoneal sclerosis, malignant disease, pancreatitis, hepatobiliary disease, and hemorrhage from polycystic kidneys.

Dialysis-Related Amyloidosis

Amyloidosis caused by deposition of β_2-microglobulin in very rare patients on very long-term dialysis can result in GI manifestations. These include GI hemorrhage, diarrhea, pseudo-obstruction, ischemia, and perforation (see Chapter 85).

Transplantation and Gastrointestinal Disturbance

A variety of GI problems occur after renal transplantation (see Chapters 104 and 105). Gastritis or duodenitis results from corticosteroid therapy, and peptic ulcers occur most commonly in the initial year after transplantation.[19] Mycophenolate mofetil commonly leads to

Figure 87-4 Hemoperitoneum. Blood-stained peritoneal dialysate from a peritoneal dialysis patient who has developed acute pancreatitis.

diarrhea, abdominal pain, or vomiting. Infectious complications of the GI tract include oral and esophageal candidiasis, cytomegalovirus disease, and diarrhea from *C. difficile* infection. Post-transplantation lymphoproliferative disease may also involve the GI tract.

NUTRITION IN CHRONIC KIDNEY DISEASE

Nutrition plays an important role in the management of hypertension, obesity, hyperlipidemia, and diabetes, all of which affect CKD progression. As the glomerular filtration rate (GFR) deteriorates, retention of nitrogenous metabolites, decreased ability to regulate levels of electrolytes and water, and certain vitamin deficiencies can be affected by dietary changes. In addition, protein-energy depletion predicts a poor outcome.

Malnutrition: Protein-Energy Wasting

In kidney disease there are often conditions that lead to wasting that are not related to reduced intake alone. Many terms exist to indicate wasting in CKD, including *uremic malnutrition, protein-energy malnutrition,* and *malnutrition–inflammation complex syndrome.* Because *malnutrition* refers to an intake that is inadequate for the needs of the individual, it can be misleading to use this blanket term when reduced intake is not necessarily the sole cause of wasting. Nutrition intervention alone in these cases may not successfully reverse the loss of skeletal muscle and fat mass. Accepted definitions are useful to help clinicians recognize problems and develop appropriate treatment strategies as well as to focus research; in 2008 the International Society of Renal Nutrition and Metabolism recommended that the term *protein-energy wasting* be used for loss of body protein and fuel reserves.[20]

The prevalence of protein-energy wasting in dialysis patients ranges from 10% to 70%, depending on the choice of nutritional marker and the population studied.[21,22] There is also diminished nutritional status before initiation of dialysis, which strongly predicts mortality on dialysis. Paradoxically, several investigators have found a significant inverse relationship between mortality risk and body size in HD populations, a phenomenon termed *reverse epidemiology* (see Chapter 82).

Several factors related to the uremic state may contribute to the high incidence of protein-energy wasting:

Assessment of Nutritional Status

Area	Assessments
Physical examination	
Assessment of dietary intake	Diet history, food diaries, appetite assessment questionnaires
Anthropometric measurements	Body weight, height, body mass index Percentage weight change Skinfold thickness Midarm muscle circumference
Body composition	Neutron activation Near-infrared reactance Bioelectrical impedance Dual-energy x-ray absorptiometry (DXA) Total body potassium
Biochemical determinations	Serum electrolytes Serum proteins PNA, PCR Serum cholesterol Creatinine index
Nutritional scoring systems	Subjective global assessment
Immunologic assays	Blood lymphocytes Delayed cutaneous hypersensitivity tests
Functional tests	Grip strength

Table 87-4 Assessment of nutritional status. Methods used to assess nutritional status are shown. *PCR,* Protein catabolic rate (mathematically identical to PNA); *PNA,* protein equivalent of total nitrogen appearance. The creatinine index is measured as the sum of creatinine removed from the body (measured from the creatinine removed in dialysate, ultrafiltrate, and/or urine), any increase in the body creatinine pool, and the creatinine degradation rate. See also http://www.kidney.org/professionals/kdoqi/pdf/KDOQI2000NutritionGL.pdf.

- Inadequate protein and calorie intake. Nutrient intake parallels the decrease in GFR and is largely driven by CKD-associated anorexia.[23] This anorexia is caused by impaired taste acuity and diminished olfactory function, medications, autonomic gastroparesis, psychological and socioeconomic factors, and inadequate dialysis. Elevated serum leptin, a long-term regulator of appetite, has also been linked to the anorexia seen in CKD.[24]
- Nutritional losses occur during treatment. Eight to 12 g of amino acids is lost per HD treatment, and 5 to 10 g of protein is lost daily during PD, depending on the peritoneal membrane transport type. This may be significantly higher during episodes of PD peritonitis.
- Metabolic acidosis and periods of acute or chronic illnesses may induce protein catabolism. This is mediated in large part through the ubiquitin-proteasome pathway of protein degradation.[25]
- Protein catabolic effects that can further compromise patients early after transplantation include large doses of corticosteroids, the stress response to surgery, and delayed graft function.
- Inflammatory state of uremia (see also Chapter 82).[26]
- Endocrine disorders, such as insulin resistance, increased parathyroid hormone concentrations (which may promote amino acid catabolism and gluconeogenesis), and vitamin D deficiency (which can contribute to proximal myopathy), may have an adverse effect on nutritional status.

Assessment of Nutritional Status

The measurement of nutritional status does not lend itself to one simple test, and a panel of measures is required for optimal screening of nutritional status. Table 87-4 summarizes some of the methods used for assessment of nutritional status.

Estimation of Intake

Diet history, recall, and food diaries are the mainstays for estimation of dietary intake. In addition, a gradual decrease in blood urea nitrogen and reduced phosphate and potassium levels may indicate a decrease in protein intake in dialysis-dependent patients, and low serum cholesterol level may indicate a poor calorie intake.

The excretion of the protein end product urea is easily measured and is often used to estimate adequacy of dialysis. The protein equivalent of total nitrogen appearance (PNA) can be estimated on HD from interdialytic changes in urea nitrogen concentration in serum and the urea nitrogen content of urine and dialysate. nPNA is the term for PNA related to body weight. On the basis of the assumption that nitrogen excretion equals nitrogen intake in steady state, nPNA has been used to approximate dietary protein intake in the short term. Results, however, need to be interpreted with caution (urea kinetic modeling and adequacy of dialysis are further discussed in Chapters 94 and 96. Equations for estimation of nPNA have been recommended by the Kidney Disease Outcomes Quality Initiative (KDOQI).[27]

Body Composition

A range of techniques are available that can distinguish body compartments on the basis of physical characteristics, which can provide information about nutritional state (body lean tissue and fat content) and hydration.

Skinfold thickness can be used to assess body fat, and muscle mass can be assessed by measurement of mid–upper arm muscle circumference (MAMC; Fig. 87-5). The midpoint of the upper dominant arm is used, as this is the arm less likely to have an arteriovenous fistula.

$$\text{MAMC (cm)} = \text{Midarm circumference (cm)} - \left[3.14 \times \text{Triceps skinfold (cm)}\right]$$

Figure 87-5 Routine measurement of skinfold thickness. The dominant arm, which does not have an arteriovenous fistula or graft, is used in patients with renal failure.

The measurement is taken after dialysis for patients on HD. Although these anthropometric measurements are inexpensive and relatively easy to learn and quick to carry out, they are limited by intervariability and intravariability. Nevertheless, serial measures over time can be useful to track changes in the same patient when they are used in conjunction with other nutritional indices.

Subjective global assessment (SGA) is a reliable nutritional assessment tool for patients on dialysis.[28] A series of questions about recent changes in nutrient intake is used with simple observations of the patient's body weight and muscle mass to determine subjectively the nutritional status of the individual; patients are classified as well nourished; mildly malnourished or with suspected malnutrition; or severely malnourished. Figures 87-6 and 87-7 show muscle wasting in a patient on HD classified by SGA as severely malnourished. SGA is by definition subjective and has been criticized for being insufficiently sensitive to define the degree of malnutrition. Other scoring

Figure 87-6 A severely malnourished hemodialysis patient. There is marked wasting of the quadriceps and calf muscles. In addition, note skin lesions from scratching due to uremic pruritus.

Figure 87-7 A severely malnourished hemodialysis patient. Muscle wasting around clavicle and shoulder.

systems that use components of the conventional SGA are presently being evaluated.

Visceral Protein

Fluid status, impaired liver function, age, and acute inflammatory conditions can all affect albumin levels. However, despite its relatively long half-life (20 days), albumin still remains an important measure of nutritional status and health of the patient. Clinically, it may be possible to observe the growth of white nails when there has been a transient period of hypoalbuminemia (Fig. 87-8). Other serum protein markers of nutritional status are also difficult to interpret because of the influence of factors other than nutrition. Serum transferrin is linked to body iron stores and may be altered with changes in iron status. Prealbumin levels can be increased by CKD because of impaired metabolism in the kidney. Levels of prealbumin also decline rapidly during episodes of acute inflammation.

With the low specificity and sensitivity of many of the anthropometric and biochemical markers, it becomes clear that integration of a range of measurements along with evaluation of the subjective well-being of the patient is needed to assess nutritional status (Table 87-5).

Figure 87-8 White nails in hypoalbuminemia. The white band grew during a transient period of hypoalbuminemia caused by nephrotic syndrome.

Nutritional Guidelines

Guidelines are useful, but it is important that dietary restrictions not be unnecessarily imposed and that advice be tailored to the individual and altered as circumstances dictate. Table 87-6 summarizes the nutritional recommendations for CKD.

Hyperlipidemia

Although disturbances in lipid metabolism are commonly seen in CKD, there is a paucity of data on the effect of diet therapy in this group. A diet low in fat, particularly saturated fat, with an increased intake of soluble fiber may be helpful in reducing cholesterol level,

Some Indices of Malnutrition

Assessment	Indices
Biochemical parameters	Serum albumin below the normal range Serum prealbumin <300 mg/l (30 mg/dl) (for maintenance dialysis patients only, because levels may vary according to GFR level for CKD 2-5) Low serum creatinine, phosphate, potassium, urea in patients on dialysis Serum cholesterol <150 mg/dl (3.8 mmol/l) Low creatinine index Low PNA, PCR
Anthropometric parameters	Continuous decline in weight, skinfold thickness, midarm muscle circumference Body mass index <20 kg/m^2 Body weight <90% of ideal Abnormal muscle strength

Table 87-5 Some indices of malnutrition. *GFR,* Glomerular filtration rate; *PCR,* protein catabolic rate; *PNA,* protein equivalent of total nitrogen appearance.

Nutritional Recommendations in Chronic Kidney Disease

Daily Intake	Predialysis CKD	Hemodialysis	Peritoneal Dialysis
Protein (g/kg ideal BW) (see KDOQI[27] for estimation of adjusted edema-free body weight)	0.6-1.0 Level depends on the view of the nephrologist 1.0 for nephrotic syndrome.	1.1-1.2[27,31] This is a broad recommendation; protein intake would be individualized according to the patient's nutritional status, serum phosphate levels, and dialysis adequacy.	1.0-1.3[27,38]
Energy (kcal/kg BW)	35[27] (younger than 60 yr) 30-35[27] (older than 60 yr)	35[27] (younger than 60 yr) 30-35[27] (older than 60 yr)	35[27] including dialysate calories (younger than 60 yr) 30-35[27] including dialysate calories (older than 60 yr)
Sodium (mmol)	<100 (more if salt wasting)	<100	<100
Potassium	Reduce if hyperkalemic	Reduce if hyperkalemic	Reduce if hyperkalemic; potassium restriction is generally not required.
	If hyperkalemic, advice will take the form of decreasing certain foods (e.g., some fruits and vegetables) and giving information about cooking methods.		
Phosphorous	Reduce; level dependent on protein intake Advice will take the form of reducing certain foods (e.g., dairy, offal, some shellfish), processed foods with high content of added phosphates, and giving information about the timing of binders with high phosphorus meals and snacks.		
Calcium	In CKD stages 3-5, total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day.	Total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day.	Total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day.

Table 87-6 Nutritional recommendations in chronic kidney disease (CKD). Recommendations are for typical patients but should always be individualized on the basis of clinical, biochemical, and anthropometric indices. *BW,* Body weight; *KDOQI,* Kidney Disease Outcomes Quality Initiative.

although the role of cholesterol lowering in CKD patients is controversial (see Chapter 82). Losing weight if overweight and consuming a diet lower in sugar may improve hypertriglyceridemia, but a balance needs to be struck between healthy eating concepts and nutritional adequacy. Additional fiber, within the confines of the diet, has the benefit of helping to regulate bowel function, particularly important in PD patients.

Hypertension

The role of diet in the prevention and treatment of hypertension is discussed fully in Chapter 35.

Vitamins, Minerals, and Trace Elements

Vitamin, mineral, and trace element abnormalities in CKD relate to dietary restriction, dialysate losses, and the necessity of intact kidney function for normal metabolism of certain vitamins. However, the dietary requirements for patients with CKD are not clear-cut.

Protein and potassium restrictions can lead to inadequate intakes of pyridoxine, vitamin B_{12}, folic acid, vitamin C, iron, and zinc. The use of recombinant human erythropoietin may increase the requirement for iron and folic acid (see Chapter 83).

Increased serum homocysteine is a known risk factor for cardiovascular morbidity in CKD (see Chapter 82). However, lowering of serum homocysteine concentration with folic acid, vitamin B_{12}, and pyridoxine supplements has been shown to have no effect on mortality or risk of cardiovascular events in patients with end-stage renal disease (ESRD).[29] A recent systematic review and meta-analysis also showed that the effects of folic acid–based homocysteine lowering did not reduce cardiovascular events in people with kidney disease.[30]

A variety of multivitamin preparations are available that contain a recommended vitamin profile for dialysis patients. The preparations vary slightly, but the following is one example: vitamin C, 60 mg; biotin, 300 µg; calcium pantothenate, 10 mg; cyanocobalamin, 6 µg; folic acid, 800 µg; niacinamide, 20 mg; pyridoxine, 10 mg; riboflavin, 1.7 mg; and thiamine, 1.5 mg. In the absence of firm guidance, it is prudent to have a low threshold for commencing such a vitamin preparation. The European Best Practice Guidelines (EBPGs) on nutrition give opinion-based recommendations for intakes of vitamins, minerals, and some trace elements in patients on HD.[31]

Although there is evidence for vitamin C having a role in improving anemia management in ESRD, high-dose vitamin C supplements, popular in the general population, should not be taken, because there is a risk that this may lead to tissue oxalate deposition in response to increased serum oxalates not being cleared by the failing kidneys.

A review summarizing the current literature on fat-soluble vitamins in advanced CKD has recently been published.[32] There is universal agreement that supplementation with vitamin A is generally not recommended (unless a patient is receiving total parenteral nutrition) because deficiencies are rare, dialysis losses are minimal, and accumulation leading to toxicity can occur. Vitamin E is known to have antioxidant properties. Deficiency and toxicity are reportedly rare, and status in dialysis patients is inconsistent. More guidance is needed around potential benefits of vitamin E supplementation in CKD, although the EBPGs do recommend that vitamin E can be supplemented in HD patients for secondary prevention of cardiovascular events (based on results from the Secondary Prevention with Antioxidants of Cardiovascular Disease in Endstage Renal Disease [SPACE] study) and prevention of recurrent muscle cramps.[31]

Vitamin K functions as a cofactor for the enzyme gamma-glutamyl carboxylase and may have a role in inhibiting vascular calcification (see Chapter 85). There is evidence to suggest that most dialysis-dependent patients have subclinical vitamin K deficiency, and there is no known toxicity. However, research is ongoing in this area to determine if supplementation of vitamin K, and at what level, may have a beneficial role in preventing vascular calcification and reducing mortality in patients with advanced CKD.

Guidelines for vitamin D type and dose as well as phosphorus and calcium intake in CKD have been provided by KDOQI and recently updated by the KDIGO (Kidney Disease: Improving Global Outcomes) organization (see also Chapter 85).

Recommendations for mineral intakes are shown in Table 87-6.

Monitoring and Treatment

Monitoring of patients with CKD involves a combination of nutritional assessment, noting relevant biochemistry (potassium, phosphate, lipids), and observation of fluid status. The challenge comes in giving advice that carefully balances control of electrolytes while not compromising nutritional status. When anorexia is present, strategies to treat this should be considered, and nutrient intake maximized by use of one or more of the methods discussed in the following sections.

Enteral Supplementation

If food fortification advice is insufficient, supplements, in the form of high-protein, high-calorie drinks, powders, and puddings, should be administered. Enteral tube feeding is also an option if nutrient intake cannot be increased sufficiently by use of oral supplements. Renal-specific tube feeds and supplements are available that have lower fluid and electrolyte contents. A systematic review suggested that enteral multinutrient support increases serum albumin concentration and improves total dietary intake in patients receiving maintenance dialysis.[33] In addition, maintenance hemodialysis patients with albumin levels of 3.5 g/dl or lower received intradialytic oral nutritional supplements in a recent large retrospective matched-cohort study. Despite limitations, the results indicated a significantly better survival in the supplemented group versus similarly matched patient controls.[34]

Supplementation of Dialysate Fluids

Intradialytic parenteral nutrition (IDPN) has been used to provide intensive parenteral nutrient therapy with use of concentrated hypertonic solutions three times weekly during HD treatments without the need for establishing a central venous line. The nutrients, usually a mixture of amino acids, glucose, and lipid, are infused into the venous blood line, and only about 10% of infused amino acids are lost into the dialysate. In 2010 a systematic review of the evidence for use of this treatment was published and concluded that the evidence from clinical studies is insufficient to demonstrate either a net benefit or a net harm associated with providing IDPN to malnourished HD patients. The authors recommended that further clinical research is needed in this area.[35]

Intraperitoneal amino acids (IPAAs) can be used in PD. A 1.1% amino acid solution is substituted for glucose in PD fluid, and about 80% of the amino acids are absorbed in a 4-hour period.[36] The long-term effects of IPAAs on nutritional status and clinical outcomes are not known, and the solution is often used primarily to reduce glucose exposure.

Kidney Disease Outcomes Quality Initiative has suggested that IPAAs (for PD) or IDPN (for HD) should be considered for patients who have evidence of protein or energy malnutrition and inadequate protein or energy intake and who are unable to tolerate adequate oral supplements or tube feeding.[27] However, the American Society for Parenteral and Enteral Nutrition (ASPEN) presently recommends that IDPN not be used as a nutritional supplement in malnourished

hemodialysis patients, because studies so far do not offer strong support for IDPN.[37] Clearly, larger randomized controlled trials in malnourished patients are needed to determine the clinical benefit of this treatment.

Appetite Stimulants

Megestrol acetate, a progesterone derivative, moderately improved appetite in HD patients in small studies. However, as megestrol acetate is not without its side effects, larger trials are required before recommendations can be made for CKD patients. More studies are also required for ghrelin, an orexigenic hormone, and melanocortin-receptor antagonists.

Metabolic Acidosis

Although some trials have shown no detrimental effect of mild metabolic acidosis, many others have reported that normalization of the predialysis serum bicarbonate concentration is beneficial for protein nutritional status and bone metabolism. Medical management of metabolic acidosis is discussed further in Chapter 12. Current guidelines recommend the correction of acidosis in dialysis-dependent patients.[31,38]

Exercise

There is a large body of research in the area of exercise training for adults with chronic kidney disease showing significantly beneficial effects on physical fitness, cardiovascular parameters, well-being, and nutritional markers.[39] The future is likely to hold more guidance in this area for clinical practice.

CHAPTER 88

Dermatologic Manifestations of Chronic Kidney Disease

Pieter Evenepoel and Dirk R. Kuypers

Cutaneous disorders are common in patients with end-stage renal disease (ESRD), with the most prevalent disorder being hyperpigmentation. Many of these cutaneous disorders are caused by the underlying renal disease, whereas others relate to the severity and duration of uremia.

Skin lesions associated with cutaneous aging have a high incidence in ESRD patients, including wrinkling, senile purpura, actinic keratoses, and diffuse hair loss. The prevalence of skin cancers does not appear to be increased unless the patient has received or is receiving immunosuppression.

Improved treatments in dialysis patients have resulted in changes in the frequency and types of skin disorders observed in conjunction with ESRD. Dermatologic conditions such as uremic frost, erythema papulatum uremicum, uremic roseola, and uremic erysipeloid now rarely occur. Pigmentary alterations, xerosis, ichthyosis, half-and-half nails, acquired perforating dermatosis, bullous dermatoses, pruritus, and calcific uremic arteriolopathy (CUA) are prevalent (Fig. 88-1), whereas nephrogenic systemic fibrosis is a rare and waning entity, now that the causative agent has been identified.[1,2] The last four skin disorders are the focus of this chapter because they are associated with significant morbidity or mortality and represent an ongoing diagnostic or therapeutic challenge.

UREMIC PRURITUS

Clinical Manifestations

Uremic pruritus (UP) is a frequent symptom of ESRD with a reported prevalence ranging from 22% to 48%. Although its incidence in adult dialysis patients has declined as a result of improved dialysis efficacy and the introduction of so-called "biocompatible dialysis membranes," pruritus remains a frustrating problem for patients, causing serious discomfort and skin damage, often in association with disturbance of day and night rhythm, sleeping disorders, depression, anxiety, and diminished quality of life.[3,4] The intensity and spatial distribution of UP vary significantly among patients and over time throughout the course of renal disease. Excoriations, induced by uncontrollable scratching with or without superimposed infection, are frequently encountered in severely affected patients and rarely lead to prurigo nodularis, that is, a treatment-resistant lichenified or excoriated papulonodular chronic skin eruption (Fig. 88-2). The most frequently involved body areas are the back, limbs, chest, and face; 20% to 50% of patients report generalized pruritus.[5]

Pathogenesis

Many uremic factors are thought to contribute to UP. Parathyroid hormone (PTH) and divalent ions (calcium, phosphate, and magnesium) have been implicated because itching is a frequent symptom accompanying severe secondary hyperparathyroidism and elevated calcium-phosphate product. However, the lack of consistent correlations between serum and skin levels of PTH, calcium, phosphorus, and magnesium with the severity of UP indicates that other factors contribute to its development. Histamine released by mast cells has been implicated in UP. The number of dermal mast cells is increased in uremic patients, and higher tryptase and histamine plasma concentrations are reported in severe cases. Histamine release is triggered by substance P, a neurotransmitter involved in itch sensation. The role of elevated serotonin (5-hydroxytryptamine [5-HT_3]) levels in dialysis patients with UP is debated; clinical trials using a selective inhibitor of 5-HT_3 have yielded conflicting results (see later discussion). Xerosis is a common skin problem in dialysis patients (60% to 90%) that predisposes to UP. Skin dryness is caused by primary dermal changes associated with uremia, such as atrophy of sweat glands with impaired sweat secretion, disturbed stratum corneum hydration, sebaceous gland atrophy, and abnormal arborization of free cutaneous nerve fiber endings.

There are two major hypotheses of the mechanisms of UP. The opioid hypothesis proposes that UP is caused by overexpression of opioid μ receptors in dermal cells and lymphocytes. Consistent with this hypothesis, activation of the κ opioid system using a κ-receptor agonist was efficient in reducing pruritus in a mouse model. In contrast, the immune hypothesis considers UP an inflammatory systemic disease rather than a local skin disorder. Studies examining the beneficial effects of ultraviolet B (UVB) exposure on pruritus showed that UVB attenuates the development of Th1-type lymphocytes in favor of the Th2 type. Indeed, the number of CXCR3-expressing and interferon-γ–secreting $CD4^+$ cells (indicating Th1 differentiation) is significantly increased in the circulation of dialysis patients with pruritus compared with those without. Levels of serum markers of inflammation, such as C-reactive protein, interleukin-2, and interleukin-6, are also higher in patients with UP.

Treatment

Common causes of UP in chronic kidney disease (CKD) and dialysis patients, such as primary skin disorders (e.g., urticaria, psoriasis, atopic and contact dermatitis), liver disease (e.g., hepatitis), and endocrine diseases (e.g., hypothyroidism, diabetes mellitus) should be ruled out and adequately treated. The treatment approach to UP is shown in Figure 88-3.

Optimizing Dialysis and Mineral Metabolism Therapy

Optimizing dialysis biocompatibility and efficacy and improving the nutritional status may result in a reduced prevalence and severity of UP. Adequate control of calcium and phosphorus serum concentrations by short-term use of dialysate with low calcium and magnesium concentrations ameliorated pruritus symptoms in only a few small studies and may lead to worsening of renal osteodystrophy in

Figure 88-1 Cutaneous disorders in patients with end-stage renal disease. A, A spectrum of pigmentary alterations occurs in dialysis patients, brownish hyperpigmentation in sun-exposed areas being the most prevalent. **B,** Xerosis, a dry or roughened skin texture, is seen in up to 75% of dialysis patients. **C,** Half-and-half nails (also termed red and white nails) occur in as many as 40% of patients on dialysis. The nails exhibit a whitish or normal proximal portion and an abnormal brown distal portion. **D,** Acquired perforating dermatosis affects approximately 10% of the dialysis population. The lesion is usually asymptomatic and consists of grouped dome-shaped papules and nodules, 1 to 10 mm in diameter. The trunk and the extremities are most commonly involved.

cases of prolonged use. Parathyroidectomy is not advocated for relief of UP because no consistent beneficial effects have been demonstrated.

Skin Emollients

Emollients continue to be the primary treatment given by nephrologists, although the literature is mixed on the overall efficacy of this approach. The use of simple emollients without perfumes or other additives is preferred. Continuous bath oil therapy containing polidocanol, a mixture of monoether compounds of lauryl alcohol and macrogol, seems to be of value for some patients. Sericin, a biopolymer protein from the silkworm *(Bombyx mori)* contains 32% serine, the main amino acid of the natural moisture factor in human skin, and suppresses the release of proinflammatory cytokines. Sericin was shown to effectively reduce UP score in a randomized, double-blind, placebo-controlled 6-week study in 50 dialysis patients.[6]

Antihistaminic Drugs

Classic antihistamines have limited efficacy and do not differ in efficacy compared with emollients; newer, second-generation

antihistamines (e.g., desloratadine) might have some effect in UP. Ketotifen (2 to 4 mg/day), a putative mast cell stabilizer, was beneficial in one small study.

Phototherapy

Ultraviolet light, especially UVB (wavelength, 280 to 315 nm), is effective for treatment of UP and is well tolerated except for occasional sunburn. The duration of the antipruritic effect of thrice-weekly total body UVB therapy (total, 8 to 10 sessions) is variable, but it may last for several months. Potential carcinogenic effects of UV radiation require serious consideration, and its prolonged use is contraindicated in patients with a fair complexion (skin phototypes I and II).

5-Hydroxytryptamine Antagonist

Ondansetron, a selective 5-HT_3 antagonist, was used successfully in a small study in peritoneal dialysis patients. However, a subsequent larger randomized, placebo-controlled study failed to show superiority over placebo in HD patients.

Figure 88-2 Prurigo nodularis. *(Courtesy I. Macdougall, London, United Kingdom.)*

Opioid Receptor Agonists

A κ-opiate receptor agonist, nalfurafine, given intravenously after HD, was tested in two randomized, double-blind, placebo-controlled trials comprising 144 patients. Itching intensity, excoriations, and sleep disturbances were significantly reduced in patients receiving the active compound without an excess of drug-related side effects compared with placebo.[7] Oral daily doses of 2.5 to 5 mg nalfurafine were equally effective in reducing UP scores compared with placebo during a 2-week treatment period in 337 dialysis patients.[8] A subsequent 1-year study (n = 211) confirmed the sustained beneficial effect of 5 mg nalfurafine on UP, with the most frequently reported adverse events being insomnia (19%), constipation (7%), and increased blood prolactin concentrations.[9]

Gabapentin

Gabapentin, an anticonvulsant drug, administered after dialysis (300 mg) was effective in reducing pruritus. A reduced dose is required if it is given chronically to patients with ESRD, because it has a narrow therapeutic window, and it can accumulate and cause neurotoxic side effects.[10] UP score was significantly reduced in two controlled studies after 4 weeks of gabapentin therapy at a dose of 100 to 300 mg administered thrice weekly after dialysis. Gabapentin was well tolerated; no patients stopped therapy because of side effects, which were limited to dizziness, somnolence, fatigue, and nausea. Similar effects were demonstrated in a smaller study using pregabalin.

Immunomodulators and Immunosuppressive Agents

A 7-day course of thalidomide reduced the intensity of UP by up to 80% in a placebo-controlled crossover study of 29 HD patients. Because of its strong teratogenic properties, thalidomide should probably be reserved for therapy-resistant severe UP in individuals

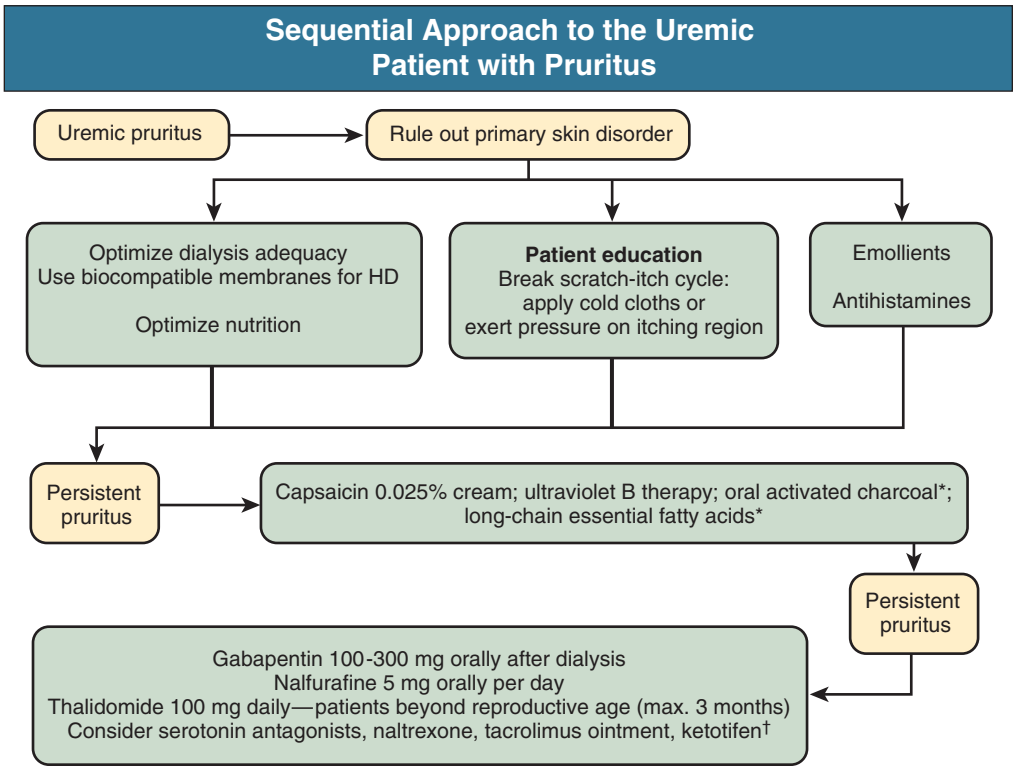

Figure 88-3 Sequential approach to the uremic patient with pruritus. *See text for details. †Therapeutic benefit in studies has been described variably; see text for details. *HD,* Hemodialysis.

outside the reproductive-age category. Adverse effects of thalidomide, such as peripheral neuropathy and cardiovascular side effects, limit its continuous longer use. A prospective, single-center study of 25 chronic dialysis patients with UP demonstrated that 6 weeks of treatment with tacrolimus ointment (0.1%) significantly reduced the severity of UP. Tacrolimus was well tolerated in this trial and caused no detectable systemic exposure or side effects.[11] However, a subsequent, smaller vehicle-controlled trial showed equal relief of UP with vehicle and tacrolimus. The risks of long-term topical use of these agents are currently unknown, and their prolonged use is not recommended until more data are available.

Long-Chain Essential Fatty Acids

Oral administration of γ-linoleic acid (GLA)–rich primrose oil resulted in significant improvement of UP in chronic dialysis patients. Supplementation of GLA-rich primrose oil is thought to augment synthesis of anti-inflammatory eicosanoids. Similar effects could be obtained through use of fish oil, olive oil, and safflower oil.

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a natural alkaloid found in the pepper plant that depletes the cutaneous type C sensory nerve endings of substance P. Two clinical studies showed that application of a 0.025% capsaicin cream significantly alleviated UP in dialysis patients, who exhibited no side effects.

Oral Activated Charcoal

Pruritus symptoms completely disappeared or were significantly reduced in chronic dialysis patients treated with activated charcoal (6 g/day) for 8 weeks. In two different clinical studies, comparable results were obtained with this inexpensive and well tolerated compound, rendering it a valuable alternative for patients with UP.

Miscellaneous

Various other types of therapies have been examined in the treatment of pruritus but are, despite the effectiveness of some, not considered first choice in chronic HD patients because of undesirable side effects, cumbersome use, or incompatibility with renal replacement therapy (sauna, cholestyramine, nicergoline). Other therapies that have not reduced UP in a controlled setting and are therefore not advocated include acupuncture, low-protein diet, intravenous lidocaine, sertraline, and mexiletine.

BULLOUS DERMATOSES

Bullous dermatoses are reported in up to 16% of patients on maintenance dialysis. This skin disease entity mainly comprises pseudoporphyrias (e.g., secondary to nonporphyrinogenic drugs and chemicals) and other photodermatoses, whereas true porphyrias (e.g., porphyria cutanea tarda [PCT], variegate porphyria) remain a rare entity.[9] Pseudoporphyrias, true porphyrias and photodermatoses are clinically and histologically similar and are characterized by a blistering photosensitive skin rash. The dorsal hands and the face are the most affected areas (Fig. 88-4).

Porphyria cutanea tarda is caused by abnormalities in the porphyrin-heme biosynthetic pathway leading to an accumulation of highly carboxylated uroporphyrins in the plasma and skin. Phenotypic expression of the disease also requires one or more of a number of external contributory factors, including alcohol, estrogens, iron overload, and infection with hepatitis B and C. It is important to distinguish PCT from other porphyrias in which patients are at risk for development of potentially fatal neurologic attacks if they are exposed to porphyrinogenic drugs and other precipitants. Therapeutic options include avoidance of environmental triggers, HD with high-flux membranes, repeated small-volume phlebotomies, and iron chelators.

Figure 88-4 Porphyria cutanea tarda. Tense bullae, erosions, and crusts of the dorsal hands. *(From reference 12.)*

The term *pseudoporphyria* was originally used for patients with normal plasma porphyrins who exhibited PCT-like skin lesions secondary to drugs and chemicals. However, some dialysis patients also develop similar skin lesions that spontaneously heal and leave a hypopigmented area; this entity is known as *dialysis porphyria;* a proportion of these patients have raised plasma porphyrins but without the disturbances in porphyrin metabolism classically found in the porphyrias. In rare patients, an offending medication can be identified. However, in most dialysis patients, protection from sun exposure appears to be the only preventive measure.

CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Definition

Calcific uremic arteriolopathy, or calciphylaxis, is a devastating and life-threatening ischemic vasculopathy confined primarily to patients with CKD. There are also reports of this disease in nonuremic patients. The ischemia may be so severe that frank infarction of downstream tissue develops. The most common and most noticeable damage is in the skin and subcutaneous tissues.[12,13] CUA should be distinguished from benign nodular calcification (calcinosis cutis), which can develop in patients with very high serum calcium-phosphate product (Fig. 88-5).

Pathogenesis

The pathogenesis of CUA involves abnormalities in mineral metabolism in uremia that predispose to vascular and soft tissue calcification,[14] but no single abnormality is sufficient to predict the development of this disorder. Elevated levels of PTH and therapy with vitamin D analogues have been associated with an increased risk of CUA, although the evidence is not always striking. A perturbation of the calcium and phosphate homeostasis most probably underlies the positive association. However, in acute CUA serum calcium and phosphate levels can be low. Insufficient activation or expression of inhibitors of calcification should also be considered in the pathogenesis. Inhibitors of vascular calcification include matrix GLA protein (MGP), osteoprotegerin, pyrophosphate, and fetuin-A.

Figure 88-5 Benign nodular calcification (calcinosis cutis). Firm subcutaneous nodule adjacent to the elbow.

MGP requires vitamin K–mediated γ-carboxylation for its functional activity. As a consequence, coumarin anticoagulants and vitamin K deficiency may antagonize MGP function and stimulate vascular calcification. Levels of both osteoprotegerin and fetuin-A decline with inflammation. Finally, several lines of evidence indicate that a hypercoagulable state secondary to an absolute or functional protein C or protein S deficiency may be involved in the pathogenesis of CUA.[11]

Epidemiology and Risk Factors

Although hard epidemiologic data are lacking, the incidence of CUA may be increasing. This might in part result from increased physician awareness and the high-risk profile of contemporary dialysis patients. The estimated incidence ranges from 1 to 4 per 100 patient-years.

Female gender, Caucasian race, obesity, diabetes, use of coumarin anticoagulants, and dialysis vintage are established risk factors. In a recent case control study, the incidence of CUA was shown to be 10-fold higher in dialysis patients treated with warfarin or coumarins. Probable risk factors include low serum albumin concentrations, the use of calcium salts and vitamin D analogues, and exposure to high doses of iron salts. There is no correlation between the severity of any of these factors and the development of CUA.[11]

Clinical Manifestations

Calcific uremic arteriolopathy is typically characterized by areas of zoster-like tenderness and ischemic necrosis of the dermis, subcutaneous fat, and, less often, muscle. These ischemic changes lead to livedo reticularis or violaceous, painful, plaque-like subcutaneous nodules on the trunk, buttocks, or proximal extremity—that is, in areas of greatest adiposity (proximal CUA; Fig. 88-6, *A*). The early purpuric plaques and nodules progress to ischemic or necrotic ulcers with eschars that often become infected. Proximal CUA is frequently precipitated by a specific event, such as local skin trauma or a hypotensive episode. CUA can also affect the hands, fingers, and lower extremities, thereby mimicking atherosclerotic peripheral vascular disease (distal CUA; Fig. 88-6, *B*). Peripheral pulses are preserved distal to the area of necrosis. Myopathy, hypotension, fever, dementia, and infarction of the central nervous system, bowel, or myocardium have been described in association with cutaneous necrosis. This condition is termed *systemic CUA*.[11,12]

Pathology

The histologic features of CUA are suggestive but not pathognomonic. Specimens from incisional biopsies of early lesions show subtle histologic changes. Late lesions characteristically show epidermal ulceration, dermal necrosis, and mural calcification with intimal hyperplasia of small and medium-sized blood vessels in the dermis and subcutaneous tissue (Fig. 88-7).

Diagnosis and Differential Diagnosis

Many clinicians base the diagnosis of CUA on physical examination findings only. Although ulceration is an obvious presentation of CUA, increasing awareness of the condition should allow diagnosis at an earlier, nonulcerative stage when a distinct subcutaneous tenderness can be felt below the early skin lesions.[12] Biopsies are discouraged by most but not all experts because of potential ulceration in the region of the incision and the risk of sample error. Other potentially useful diagnostic procedures include measurements of transcutaneous oxygen saturation, bone scintigraphy (Fig. 88-8), and xeroradiography.[12]

The following conditions should be considered in the differential diagnosis: herpes zoster, systemic vasculitis, peripheral vascular disease, pyoderma gangrenosum, atheroemboli, cryoglobulinemia, warfarin-induced skin necrosis, and systemic oxalosis. A skin biopsy should performed when clinical circumstances do not suggest CUA or when detailed clinical and laboratory examinations, including the assessment of coagulation and immunologic parameters, point to an alternative diagnosis.

Natural History

Despite intensive combined treatments, the prognosis of patients with CUA remains poor; the overall 1-year survival is 45% and the 5-year survival is 35%, with a relative risk of death of 8.5 compared with other dialysis patients. Patients with ulcerative or proximal CUA have the worst prognosis. Infection accounts for up to 60% of the mortality.[12]

Prevention and Treatment

Preventive approaches include attention to calcium, phosphorus, PTH homeostasis, and nutritional state. Specific therapeutic regimens have been limited to uncontrolled case series (Box 88-1). A reasonable plan of intervention should include an aggressive program of wound care and prevention of superinfection, adequate pain control, and correction of underlying abnormalities in serum calcium and phosphorus concentrations. This includes cessation of vitamin D supplementation, intensification of the dialysis regimen, and use of a low-calcium dialysate and non–calcium-containing phosphate binders (e.g., sevelamer, lanthanum carbonate). Furthermore, local tissue trauma, including subcutaneous injections, should be avoided. Parathyroidectomy is effective in the control of CUA in some series but not in others and should be reserved for patients with severe hyperparathyroidism.[11] In such patients, calcimimetic agents may be a suitable noninvasive alternative. Vitamin K supplementation is advised in patients with warfarin- or coumarin-associated CUA. Novel and promising therapies include sodium thiosulfate and bisphosphonates. Sodium thiosulfate has recently been licensed as an orphan drug for CUA by the European Medicines Agency. It enhances the solubility of calcium deposits[12] because exchange of calcium for sodium results in extremely soluble calcium thiosulfate. Besides being a chelator of calcium, sodium thiosulfate is also a potent antioxidant. Sodium thiosulfate is given intravenously at the

Figure 88-6 Proximal (A), and distal (B, C) calcific uremic arteriolopathy.

end of every HD session (12.5 to 25 g during 30 to 60 minutes). Apart from nausea and vomiting, the therapy is well tolerated. The major side effect of sodium thiosulfate infusion is the development of metabolic acidosis. The optimal duration of treatment and potential effects of long-term treatment on bone are unknown.

NEPHROGENIC SYSTEMIC FIBROSIS

Definition

Nephrogenic systemic fibrosis (NSF), formerly known as nephrogenic fibrosing dermopathy, is a scleroderma-like fibrosing disorder that develops in the setting of renal failure. The fibrotic process affects the dermis, subcutaneous tissues, fascia, and other organs, including striated muscles, heart, and lungs.[17]

Pathogenesis

Gadolinium-based contrast (GBC) agents have recently been identified as the cause of NSF; exposure to gadolinium before the onset of disease was confirmed in more than 95% of reported cases. Free gadolinium ions are highly toxic to tissues. The toxic effects of gadolinium are circumvented by sequestration of the metal by chelates, large organic molecules that form a stable complex with gadolinium and make the ion biochemically inert and nontoxic. Under normal circumstances, GBC agents are eliminated by the kidney through glomerular filtration. Evidence points toward aberrant activation of circulating fibrocytes as a central event in the genesis of NSF. Other investigators have suspected that the strongly profibrotic mediator transforming growth factor β may be involved in the pathogenesis of NSF.

Epidemiology

Nephrogenic systemic fibrosis is a rare disorder. Since the identification of the first patients with NSF in 1997, the NSF registry has confirmed more than 215 patients from medical centers worldwide. NSF equally affects men and women. The risk for development of NSF after GBC agent exposure is related to the degree of renal failure and stability of the chelate. The incidence of NSF in patients with

severe renal dysfunction (glomerular filtration rate below 30) varies from 0.19% to 4%. Gadodiamide (marketed as Omniscan in the United States), the linear nonionic chelate–based formulation, maintains the highest risk on the basis of epidemiologic data and animal studies. Gadopentetate, the linear ionic chelate–based product, probably has a medium risk, less than linear nonionic chelates but more than macrocyclic chelates. Other factors reported to be associated with NSF (without definitive proof) include coagulation abnormalities and deep venous thrombosis, recent surgery (particularly vascular surgery), hyperphosphatemia, and the use of high doses of recombinant erythropoietin. Angiotensin-converting enzyme (ACE) inhibitors might protect against NSF. It may be expected that the ban of the linear gadolinium chelates gadodiamide, gadoversetamide, and gadopentetate in individuals with renal dysfunction (estimated glomerular filtration rate [eGFR] <30 ml/min/1.73 m^2) will result in the progressive disappearance of NSF in the near future.

Treatment Options in Patients with Calcific Uremic Arteriolopathy (CUA)

1. **Reduction of procalcifying factors**
   - Intensified (e.g., daily, hemodialysis; switch from peritoneal dialysis to hemodialysis; low-calcium dialysate)
   - Avoidance of vitamin D and calcium supplements; administration of calcium-free phosphate binders; bisphosphonate administration (caution if adynamic bone disease is suspected)
   - Parathyroidectomy (in case of hyperparathyroidism) or administration of cinacalcet
2. **Improving the status of calcification inhibitors**
   - Halt vitamin K antagonists (warfarin)
   - Aggressive treatment of infections or other proinflammatory stimuli to increase fetuin-A levels (a negative acute-phase protein)
   - Experimental:
     - *Administration of high-dose vitamin K_2?*
     - *Administration of fetuin-A (e.g., by fresh frozen plasma or plasma exchange?)*
3. **Prevention or reversal of calcium-phosphate precipitation**
   - Administration of sodium thiosulfate
4. **Supportive measures**
   - Avoidance of additional local tissue trauma by atraumatic wound care with gentle debridement of necrotic tissue and avoidance of subcutaneous injections
   - Anticoagulation (heparin and low-molecular-weight heparins)
   - Adequate pain management
   - Adequate infection control

Box 88-1 Treatment options in patients with CUA (calciphylaxis). Theoretical options based on pathophysiologic considerations, which have not been tested in clinical practice, are printed in italics. *(Modified from reference 16.)*

Clinical Manifestations and Natural History

The lesions of NSF are typically symmetric and develop on limbs and trunk. A common location is between the ankles and midthighs and between the wrists and mid-upper arms bilaterally. On occasion, swelling of the hands and feet, sometimes associated with bullae, is noted. The primary lesions are skin-colored to erythematous papules that coalesce into erythematous to brawny plaques with a *peau d'orange* appearance (Fig. 88-9, *A*). These plaques have been described as having an ameboid advancing edge. Nodules are sometimes also described. Involved skin becomes markedly thickened and woody in texture. Joint contractures may develop rapidly, with patients becoming wheelchair dependent within days to weeks of onset (Fig. 88-9, *B*). Patients often complain of pruritus, causalgia, and sharp pains in the affected areas.[13] Although NSF has not been reported as a cause

Figure 88-9 Nephrogenic systemic fibrosis. A, *Peau d'orange* appearance. **B,** Swelling of the hands, accompanied by palmar erythema, blisters, and contracture of the fingers.

of death, the impairment of mobility seen in this disorder has led to fractures that ultimately resulted in a protracted hospital course and death.

Pathology

The histopathologic changes in affected skin include marked proliferation of spindle cells, the presence of numerous dendritic cells, and accumulation of mucinous material and thick collagen bundles (Fig. 88-10). Most dermal spindle cells in NSF have the immunophenotype of a circulating fibrocyte, a recently characterized circulating cell that expresses markers of both connective tissue cells and circulating leukocytes. Metastatic calcification and NSF may be found in the same lesion.

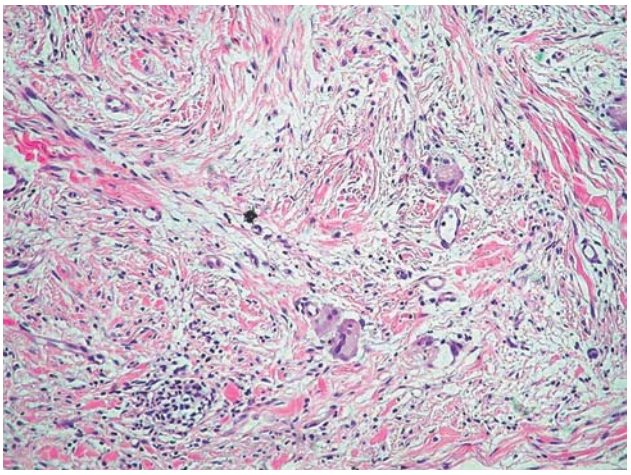

Figure 88-10 Histopathologic features of nephrogenic systemic fibrosis. Haphazardly arranged dermal collagen bundles with surrounding clefts and a strikingly increased number of similarly arranged spindled and plump fibroblast-like cells.

Diagnosis and Differential Diagnosis

The gold standard of diagnosis is histopathologic examination of skin biopsy specimens from an involved site. Skin lesions can also be visualized by [^{18}F]-fluorodeoxyglucose whole-body positron emission tomography. NSF resembles other fibrosing skin disorders including scleromyxedema, scleroderma, eosinophilic fasciitis, eosinophilia-myalgia syndrome, and Spanish toxic oil syndrome. The specific distribution of cutaneous involvement, the occurrence in the setting of renal failure, the history of recent exposure to linear GBC agents, and the unique histopathologic features distinguish NSF from the other fibrotic disorders.

Treatment and Prevention

There is no consistently effective therapy for NSF. There is variable evidence for the efficacy of plasma exchange. Other therapeutic modalities that have been used (or are under investigation) include imatinib, oral and topical corticosteroids, selective histamine blockade, calcipotriene ointment, cyclophosphamide, cyclosporine, thalidomide, interferon alfa, photopheresis, and PUVA (psoralen ultraviolet A) therapy. Intense physiotherapy is advised in every patient to prevent or to reverse limb disability related to contractures of the joints. At present, prevention of NSF seems more important than any of the currently available interventions, and widespread clinical awareness of this condition is required. Avoidance of linear GBC agents in high-risk patients (acute kidney injury [AKI] and patients with CKD with an estimated glomerular filtration rate <30 ml/min/1.73 m^2) is the best measure to prevent this catastrophic complication. If GBC agent exposure is required, use of the smallest dosage of a macrolytic chelate is strongly advised. HD (three sessions within 72 hours) should be considered after GBC agent exposure in patients who are already on this modality.

CHAPTER 89

Acquired Cystic Kidney Disease and Malignant Neoplasms

Anja S. Mühlfeld and Frank Eitner

DEFINITION

Acquired cystic kidney disease (ACKD) was first recognized in 1847 by John Simon in patients with chronic Bright disease. He described the development of cystic renal changes with cysts ranging from "mustard seed to as large as cocoa nuts" and also noted that they "run a slow and insidious progress during life, and often leave in the dead body no such obvious traces as would strike the superficial observer." ACKD was "rediscovered" by Dunnill and colleagues[1] in 1977 in kidneys from dialysis patients.

Acquired cystic kidney disease consists of chronic kidney disease of any cause and must be differentiated from other types of cystic kidney disease (see Chapters 46 and 47). It is usually defined as more than three to five macroscopic cysts in each kidney of a patient who does not have a hereditary cause of cystic disease. ACKD is associated with renal neoplasms with such high frequency that some authors consider ACKD preneoplastic.[2]

PATHOGENESIS

Most cysts are lined by a single layer of epithelium composed of flat nondescript cells, cells with abundant cytoplasm and hyaline droplets, or small cuboidal cells resembling those from distal tubules or collecting ducts.[2] Some authors have argued that the presence of a brush border on the luminal membrane suggests that the cysts arise primarily from proliferation of proximal tubular epithelial cells. Although the mechanisms of tubule transformation into cysts are not entirely clear, tubular epithelial cell hyperplasia is currently viewed as a central early event in ACKD pathogenesis (Fig. 89-1).[3] Various factors have been implicated in the development of tubular hyperplasia, including plasticizer, ischemia, and uremic metabolites. However, the most important factor appears to be slow, progressive parenchymal loss, which could explain why the development or progression of ACKD does not appear to be influenced by the type of underlying renal disease or the choice of dialysis modality. The loss of intact nephrons is a strong stimulus for compensatory growth of the remaining, still intact nephrons, which is achieved by initial hypertrophy and later by hyperplasia. In these hyperplastic tubules, a cyst will develop if transepithelial fluid secretion continues, and if it is a result of anatomic distortion or obstruction, the distal outflow is impaired.

With the continuing presence of mitogenic stimuli, the epithelial layer of the cyst becomes multilayered and atypical cells form intracystic papillary structures or mural adenomas. Activation of protooncogenes, chromosomal abnormalities, and additional factors such as genetic background, environmental chemicals, and sex hormones thereafter probably account for the transition of the proliferative process into malignant growth (see Fig. 89-1).[3]

EPIDEMIOLOGY

Among patients starting maintenance dialysis treatment, prevalences of ACKD ranging from 5% to 20% have been described. ACKD can occur in some patients even before dialysis is initiated. In both chronic hemodialysis and peritoneal dialysis patients, prevalence then increases at a similar rate and reaches 80% to 100% after 10 years of treatment (Fig. 89-2).[4-7] Children are also prone to the development of ACKD. Several but not all studies have reported an increased frequency or faster progression in men than in women. The rate of progression appears to slow after 10 to 15 years of dialysis.

The frequency of ACKD as well as of renal tumors in dialysis patients may be underestimated on the basis of imaging methods alone. Renal cysts are detectable by ultrasound with a minimum size of 0.5 cm. Data obtained from 260 native nephrectomy specimens at the time of transplantation with a median dialysis duration of 1.0 year identified ACKD in 33%, renal adenomas in 14%, and renal cell carcinomas (RCCs) in 4% of the specimens.[8]

CLINICAL MANIFESTATIONS

Acquired cystic kidney disease can manifest as unilateral or bilateral cysts, which are mostly cortical and variable in size and number. Rarely, severe ACKD can become macroscopically indistinguishable from adult polycystic kidney disease (PKD). In contrast to hereditary cystic diseases, the cysts of ACKD are strictly confined to the kidneys. The disease is usually asymptomatic and discovered accidentally during abdominal imaging procedures. Alternatively, it may manifest with potential complications or consequences of ACKD:

- Cystic hemorrhage with or without hematuria; bleeding may occur with cyst rupture with subsequent perinephric hemorrhage or retroperitoneal hemorrhage, which may in rare patients be severe enough to lead to hypovolemic shock.
- Calcifications in or around cysts and, in rare patients, stone formation (calcium-containing stones or β_2-microglobulin stones).
- Cyst infection, abscess formation, or sepsis.
- Erythrocytosis in advanced cases, similar to the erythrocytosis observed in PKD.
- Malignant transformation.[9]

Acquired Cystic Kidney Disease–Associated Renal Cell Carcinoma

Malignant transformation, the most feared complication of ACKD, accounts for about 80% of the renal cell neoplasms observed in uremic patients. In an unselected series of chronic dialysis or transplant patients, the cumulative incidence of RCC complicating ACKD

is probably below 1%, although rates up to 7% have been reported in some small studies. These data indicate an up to 40-fold increased risk for RCC in ACKD patients compared with RCC in the general population. Risk factors include male gender (male-female ratio, 7:1), African American ethnicity, long duration of dialysis, and severe ACKD with marked organ enlargement. It is unknown whether the risk of malignant transformation differs between hemodialysis and peritoneal dialysis patients.

About 85% of ACKD-associated RCCs are asymptomatic at the time of diagnosis. The remaining cases mostly manifest with bleeding, usually gross hematuria, from the tumor. In cases in which nephrectomy had to be performed in dialysis patients for intractable hematuria, RCCs not visualized before surgery were diagnosed in about one third of the patients.

Compared with sporadic RCCs, ACKD-associated RCCs are characterized by younger age of the patient, male predominance, more frequent multicentric and bilateral manifestation, and less frequent metastases.[2]

PATHOLOGY

Cystic changes in ACKD are typically bilateral but may vary between kidneys. Most ACKD kidneys are smaller than normal. An increase in size above normal can be observed in patients with cyst hematoma formation or malignant transformation. The cysts are usually restricted to the renal cortex. The size of the cysts ranges from microscopic to about 2 cm; about 60% of the cysts are smaller than 0.2 cm.[2] Preneoplastic changes can be detected in ACKD kidneys, including atypical cyst-lining cells forming multiple cell layers and intracystic nodular formations.

Up to 25% of kidneys with ACKD harbor tumors, about one third of which are carcinomas. RCCs arising from ACKD are multicentric in about 50% of cases and bilateral in about 10%. There is a unique

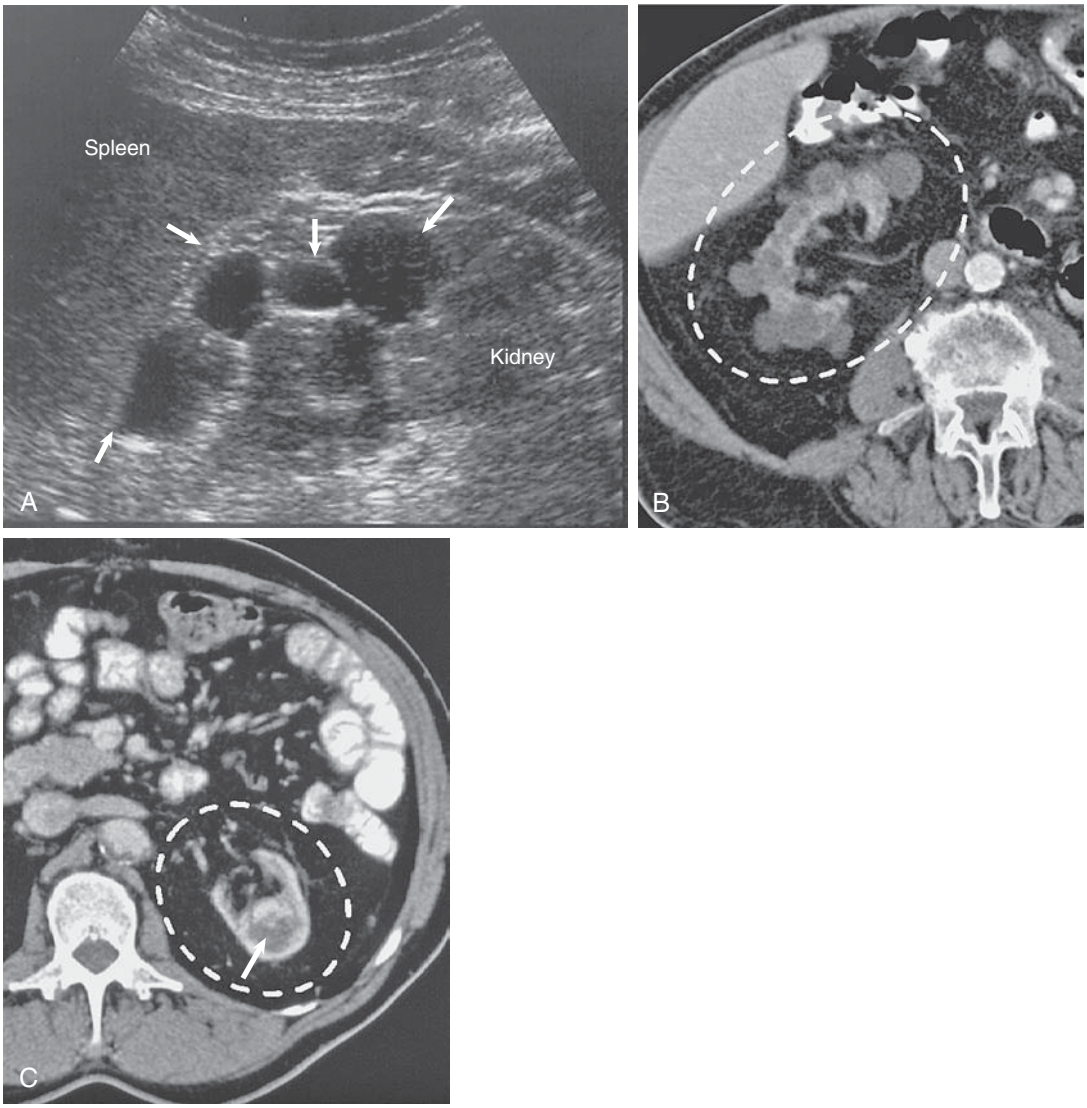

Figure 89-3 Imaging studies in acquired cystic kidney disease (ACKD). A, Ultrasound image of the left native kidney of a patient after 16 years of chronic hemodialysis (HD). Multiple cysts are present in the renal cortex *(arrows).* **B,** Computed tomography (CT) image of a patient after 5 years of chronic HD demonstrating multiple cysts within the right kidney *(dashed circle).* **C,** Contrast-enhanced CT image of a renal transplant patient who developed a renal cell carcinoma *(arrow)* originating from the left native kidney with ACKD *(dashed circle).*

histologic pattern in tumors arising in kidneys with ACKD, termed *ACKD-associated carcinoma.* They are characterized by a typical microcystic architecture, eosinophilic cytoplasm with Fuhrman grade 3 nuclei, and a frequent association with intratumoral oxalate crystals. In addition, these tumors commonly exhibit papillary architecture and clear cytoplasm.[10]

In patients with end stage renal disease without ACKD, the most common histologic type is clear cell carcinoma (44%) and the second most common is ACKD-associated carcinoma (23%).[9] Clear cell carcinoma seems to be the most frequent type in patients with a dialysis duration of less than 10 years, whereas ACKD-associated carcinoma is the predominant tumor type in patients with dialysis duration of more than 10 years.[11,12]

Renal cell carcinomas in renal transplant patients tend to be smaller and to exhibit a lower T stage and a lower grade at diagnosis compared with patients with end-stage renal disease. Tumors are more often multifocal and bilateral, and the papillary subtype occurs more often.[13,14] Because of the earlier stage at detection, the prognosis of RCC after renal transplantation generally is more favorable.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic approach to ACKD usually involves ultrasound, which is a sensitive means of detecting ACKD or large RCCs (Fig. 89-3).[4,5] However, the differentiation between simple cysts and renal carcinomas can be difficult given the echogenicity of end-stage kidney parenchyma and the complexity of cysts in ACKD. Computed tomography (CT) scanning, in particular with early contrast enhancement, is superior to ultrasound in detecting small malignant lesions (see Fig. 89-3).[4,5,15] A classification of renal cysts based on their appearance in CT scans, introduced by Bosniak, is now widely accepted and is also applied to ultrasound and magnetic resonance imaging (MRI; Table 89-1).[17] Criteria that favor the diagnosis of RCC as opposed to a simple cyst include thickened and irregular walls, the presence of septa or renal tissue within the lesions, contrast enhancement, multilocularity, and large size (>4 cm). Given the risk for the development of nephrogenic fibrosis, gadolinium-enhanced MRI cannot currently be recommended for dialysis patients and renal transplant patients with a glomerular filtration rate (GFR)

Renal Cyst Classification System		
Category	**Synonymous**	**Description**
I	Benign simple cyst	Hairline-thin cyst wall; no septa; no calcifications; no solid components; no contrast enhancement
II	Benign cyst	Minimal regular thickening of the cyst wall; few, hairline-thin septa; smooth, hairline-thin calcifications in wall or septa; no contrast enhancement
IIF	Moderately complex cyst	Minimal regular thickening of the cyst wall; multiple, minimal smooth thickening septa; thick, nodular calcifications in wall or septa; no contrast enhancement
III	Indeterminate cystic mass	Irregular thickening of cyst wall; multiple, measurably thick, irregular septa; thick, nodular, irregular calcifications in wall or septa; contrast enhancement present
IV	Clearly malignant cystic mass	Gross irregular thickening of cyst wall; irregular gross thickening of septa; thick, nodular irregular calcifications in wall or septa; contrast enhancement present in tissue and cysts

Table 89-1 Renal cyst classification system. *(Modified from reference 16.)*

below 60 ml/min. The diagnostic value of MRI without contrast enhancement in this setting is not well defined. A small study has evaluated contrast-enhanced ultrasound for the assessment of complex cysts in renal transplant recipients and compared this method with standard ultrasound. The authors found a benefit of contrast-enhanced ultrasound, especially in correctly characterizing Bosniak I and II cysts.[18]

Because of the risk of malignant transformation, screening for ACKD on a regular basis, as well as regular follow-up imaging in patients with established ACKD, has been advocated. A proposal for ACKD and tumor screening is outlined in Figure 89-4. However, the cost of screening must be weighed against the risk-benefit ratio of nephrectomy in dialysis patients. A decision analysis[19] concluded that screening for ACKD (by either ultrasound or CT scanning) in young patients with a life expectancy of 25 years offers as much as a 1.6-year gain in life expectancy. This is similar to the gain obtained in young healthy people who stop smoking. In contrast, in ACKD patients older than 60 years, no significant gain in life expectancy is achieved by regular screening.[20] In a different analysis of 797 dialysis patients who had developed RCCs (90% identified by screening, 10% by clinical symptoms), screening provided a mean survival benefit of 3.3 years after adjustment for age and dialysis vintage.[20] Screening during transplant evaluation by ultrasound followed by CT in the case of suspicious lesions is recommended on the basis of recent data showing a prevalence of renal cancer in up to 4% of the patients and concerns about the role of immunosuppression in accelerating tumor growth.[21]

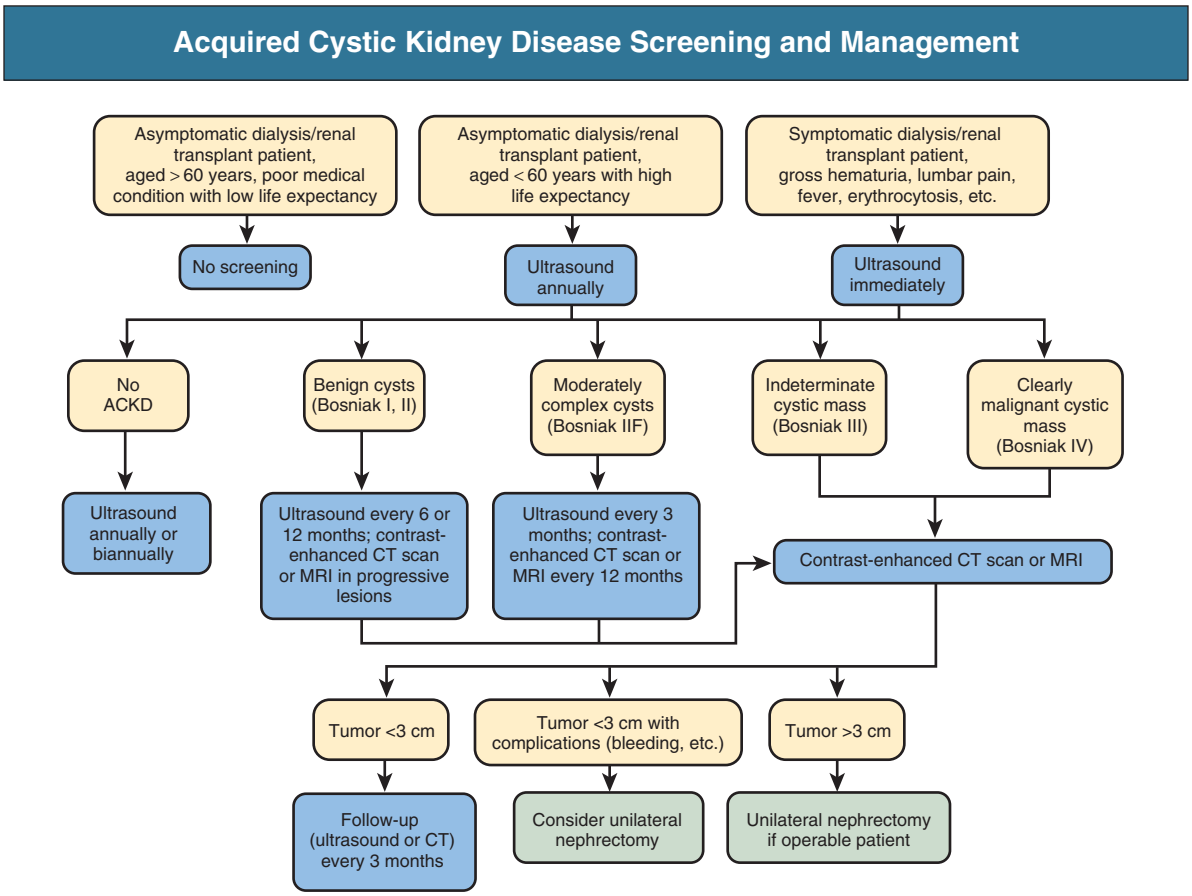

Figure 89-4 Proposed approach to acquired cystic kidney disease (ACKD) screening and management of suspected renal cell carcinoma. *CT,* Computed tomography; *MRI,* magnetic resonance imaging. *(Modified from references 9, 19, and 24.)*

NATURAL HISTORY

Cystic dilations of renal tubules may develop microscopically once the creatinine clearance falls below 70 ml/min.[22] As discussed earlier, ACKD thereafter progresses and reaches a prevalence of nearly 100% after more than 10 years of dialysis (see Fig. 89-2). A CT study demonstrated a constant increase in kidney volume that seems to reach a plateau after about 20 years of hemodialysis, and at least partial regression may occur after ultra-long-term hemodialysis.[23] In malignant transformation, tumor growth rates are highly variable. The incidence of metastases at diagnosis (15% to 30% of patients) and 5-year survival rates (35%) are comparable to those observed in RCC in the general population. Death is usually associated with widespread metastases and accounts for about 2% of the deaths in renal transplant patients.

After renal transplantation, the course of ACKD is variable. It is not established whether renal transplantation affects the natural history of RCC complicating ACKD, although immunosuppression has been suggested as a risk factor for RCC in transplant patients with ACKD.[9] A prospective, single-center ultrasound screening of the native kidneys in 561 renal transplant recipients identified ACKD in 23%.[24] The mean duration of dialysis was 4 to 5 years, and the mean time after transplantation was 9 years. In this cohort, ACKD was slightly less frequent than had been reported in dialysis patients, possibly indicating that renal transplantation might inhibit the development of ACKD.[24] The prevalence of RCCs among all 561 patients was 4.8%. However, among the patients with ACKD, RCCs were detected in almost 20%, whereas among the patients without ACKD, RCCs were detected in only 0.5%.[24]

TREATMENT

Treatment of ACKD is warranted only when complications such as hemorrhage, cyst infection, or malignant transformation develop. Whereas the first two complications may be handled conservatively and only rarely require surgery, malignant transformation should raise the question of nephrectomy. Given the perioperative morbidity and mortality of nephrectomy, in particular in multimorbid dialysis or transplant patients, it is not surprising that the threshold for surgical intervention in cases of RCC is still controversial.

Most authors agree that tumors larger than 3 cm in diameter justify nephrectomy, because with tumors above this size, RCCs in the general population frequently metastasize (see Fig. 89-4).[7] However, this strategy is based on an extrapolation from otherwise healthy persons, and a more aggressive approach may be required under certain circumstances. This is particularly true because tumor size in ACKD is often difficult to establish by imaging studies (given its frequent multilocular development) and because metastases have been described in ACKD even when renal tumors were not detected by imaging studies.

In the case of tumors of less than 3 cm in diameter with no complications, the slow tumor growth may justify observation with repeated imaging studies (see Fig. 89-4). Patients with high life expectancy or patients listed for transplantation might be considered for nephrectomy also in case of tumors with diameters less than 3 cm. In general, tumor enlargement should be used as an indication for nephrectomy if it is permitted by the patient's status.

A prophylactic contralateral nephrectomy, in the case of unilateral tumors, is not routinely recommended because of the morbidity associated with the procedure, the worsening of anemia, and the loss of residual renal function in those who are not considered transplant candidates. A delay before transplantation is generally not suggested in patients who have had an asymptomatic RCC associated with ACKD in their nephrectomy. In such a setting, a contralateral nephrectomy can be recommended to decrease the potential risk of neoplastic growth and to avoid a delay in transplantation.

Most authors perform screening for renal masses in transplant recipients and perform nephrectomy in case of a suspicious mass or RCC in the native kidneys. However, although immunosuppression is possibly associated with the development of RCC, it does not seem to diminish the likelihood of cure, especially because RCCs in transplant patients, possibly as a result of regular screening for malignancy, tend to be detected at an earlier stage.[25] In addition, nephrectomy in renal transplant recipients can be safely performed without a high risk of surgical complications.[26]

MALIGNANT NEOPLASMS IN DIALYSIS PATIENTS

Even if the risk of malignant transformation of ACKD is disregarded, dialysis patients have a slightly higher cancer risk compared with the general population. Analysis of more than 800,000 dialysis patients in three registries from the United States, Europe, and Australia and New Zealand revealed that most of the increased risk was a result of cancers of the kidney, bladder, and endocrine organs (Fig. 89-5).[27] In addition to the specific risk associated with malignant transformation of ACKD, some of the increased risk is directly related to the underlying renal disease or to the immunosuppression that may have been administered to patients with immune-mediated renal disease. Cyclophosphamide therapy, for example, may predispose to bladder and ureteral cancer that presents after patients have been initiated on dialysis. Renal disease or immunosuppressive therapy may underlie the apparent risk of dialysis patients for development of multiple myeloma (see Fig. 89-5). In addition, patients with analgesic nephropathy or Chinese herb or aristolochic acid nephropathy are

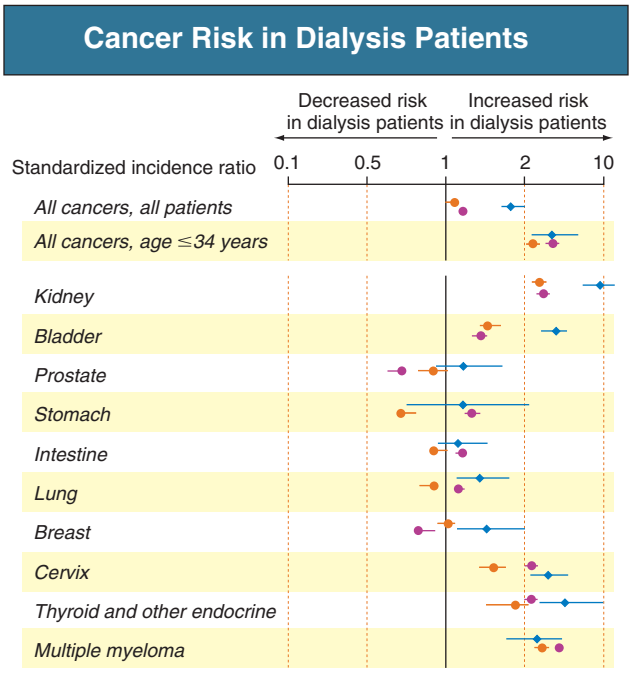

Figure 89-5 Cancer risk in dialysis patients. Relative risk of cancer (plus 95% confidence interval) compared with the general populations in 831,804 dialysis patients from Australia and New Zealand *(blue diamonds),* Europe *(orange circles),* and the United States *(purple circles). (Modified from reference 27.)*

at high risk for development of transitional cell carcinoma of the upper urinary tract.[28] Particularly after renal transplantation, these tumors tend to be less differentiated and in an advanced stage, and therefore the patients have a relatively poor outcome. For this reason, patients with analgesic nephropathy and aristolochic acid nephropathy should be screened for the presence of transitional cell carcinoma before transplantation and annually after transplantation. It has been advocated that screening should include cystoscopy, retrograde ureteral catheterization with washings and brushings, and sonography imaging.[29] Other malignant neoplasms that have been observed at increased frequencies in dialysis patients include carcinoma of the cervix and thyroid and other endocrine neoplasias (see Fig. 89-5). In addition, at least in the United States Renal Data System (USRDS) database, dialysis patients have a 1.5- to 2-fold increase in the risk for non-Hodgkin lymphoma, Hodgkin disease, and leukemias.[27] This suggests that female dialysis patients should undergo gynecologic screening including cervical smear in the same intervals as suggested for the general population. Regular thyroid ultrasound is probably also justified, although no formal decision analysis is available to support this recommendation; lymphoma and leukemia screening will be difficult to impose, and clinical vigilance is advocated.

Dialytic Therapies

CHAPTER 90

Approach to Renal Replacement Therapy

Hugh C. Rayner and Enyu Imai

TREATMENT OPTIONS FOR RENAL REPLACEMENT THERAPY

The number of patients receiving renal replacement therapy (RRT) each year, measured as a rate per million population, varies enormously among countries (Fig. 90-1). These rates have risen steadily over the last decade, although this has slowed more recently in some countries. The RRT incidence rate is the product of a complex mix of factors: the incidence and prevalence of diseases that may lead to end-stage renal disease (ESRD), most notably diabetes mellitus[1]; the effectiveness of chronic kidney disease (CKD) management to slow progression to ESRD; the level of kidney function at which RRT is commenced; and, last, the availability of resources to provide RRT.

Renal replacement therapy is a major undertaking for any patient. It is costly and time-consuming and once started may continue for many years. Each ESRD treatment option requires preparation, both physical and psychological. All patients likely to reach ESRD, and their families and care givers, need education about their future options in a form that they find accessible. This chapter sets out an approach to these challenging issues.

PREDICTION OF THE START OF DIALYSIS

Preparation for ESRD treatment requires two things: (1) identification of those patients who are at high risk of reaching ESRD and (2) prediction of the likely time when RRT may be needed. Diabetes, heavy proteinuria, declining estimated glomerular filtration rate (eGFR) and previous episodes of acute kidney injury make it more likely that a patient will progress to ESRD. Prediction of ESRD is made easier by a graphic display of eGFRs, derived from creatinine by the Modification of Diet in Renal Disease (MDRD) or Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula, or from cystatin C.[2,3] The graph tells the story of a patient's CKD and is much easier to understand than columns of figures (Fig. 90-2). The trajectory of the eGFR accurately reflects changes in the true GFR over time.[4]

MULTIDISCIPLINARY CARE IN ADVANCED CHRONIC KIDNEY DISEASE

Advanced CKD care aims to address a number of issues: preservation of remaining kidney function; prevention or treatment of complications of CKD; involvement of the patient and his or her family and care givers in making an informed choice among peritoneal dialysis (PD), hemodialysis (HD), and conservative kidney management; creation of dialysis access in good time; and, in appropriate patients, preparation for kidney transplantation, ideally before dialysis is started.

Patients need time, often months, to understand and make decisions about dialysis and its implications.[5] The best approach is to transfer patients with declining GFR to a multidisciplinary team at least 12 months before the predicted date of dialysis. Unfortunately, it is often difficult to predict the future trajectory of eGFR.[6] eGFR can remain between 20 and 30 ml/min/1.73 m^2 for many years, particularly in elderly patients, and so discussions about dialysis may be premature and cause unnecessary anxiety. Conversely, intercurrent illness can cause a sudden drop in GFR and precipitate urgent dialysis. Symptoms and complications of CKD become more common and severe as eGFR falls below 20 ml/min/1.73 m^2. Patients with more stable eGFR may be transferred to multidisciplinary care when this threshold is crossed.

Advanced CKD care is best delivered by a multidisciplinary team including a dietician, nurse educator, pharmacist, physical therapist, occupational therapist, social worker, and sometimes a trained peer-support volunteer.[7] Patients receiving this additional care have better biochemical results, are more likely to start dialysis in a planned way with less hospitalization, and may even have improved survival rates once they have started dialysis.[8,9] In addition to being good clinical practice, these programs make good financial sense because the savings in inpatient costs outweigh the costs required to run the clinics.

Lack of access to effective predialysis care is a significant issue in the United States. Forty-two percent of new ESRD patients in 2011 had not seen a nephrologist before beginning therapy, and this is associated with a reduction in use of arteriovenous (AV) fistulas as vascular access.[60] Among these patients, only 10.5% began hemodialysis with a mature fistula compared with 50.2% of those who had received more than 1 year of nephrologist care.

Predialysis Education Programs

Predialysis programs approach the choices in ESRD care through shared decision making. Whereas clinicians are expert in the technical aspects of dialysis and transplantation, the patient knows best about his or her own needs and preferences. Patients with advanced CKD may not gain sufficient knowledge and understanding to make good decisions from conventional office consultations, even when they have been seen on multiple occasions by a nephrologist.[10]

Patient education should follow the principles of adult learning: first, assess the patient's existing level of knowledge and understanding; second, build on this knowledge by the delivery of appropriate information in an appropriate form; and third, establish that the patient has understood and accepted the information given. Education can be delivered both individually and in groups. The clinician is encouraged to send a personal letter to the patient summarizing the issues because this enhances the educational value of consultations. This should be copied to the patient's family doctor to enhance coordination of care. In a group education session, patients may

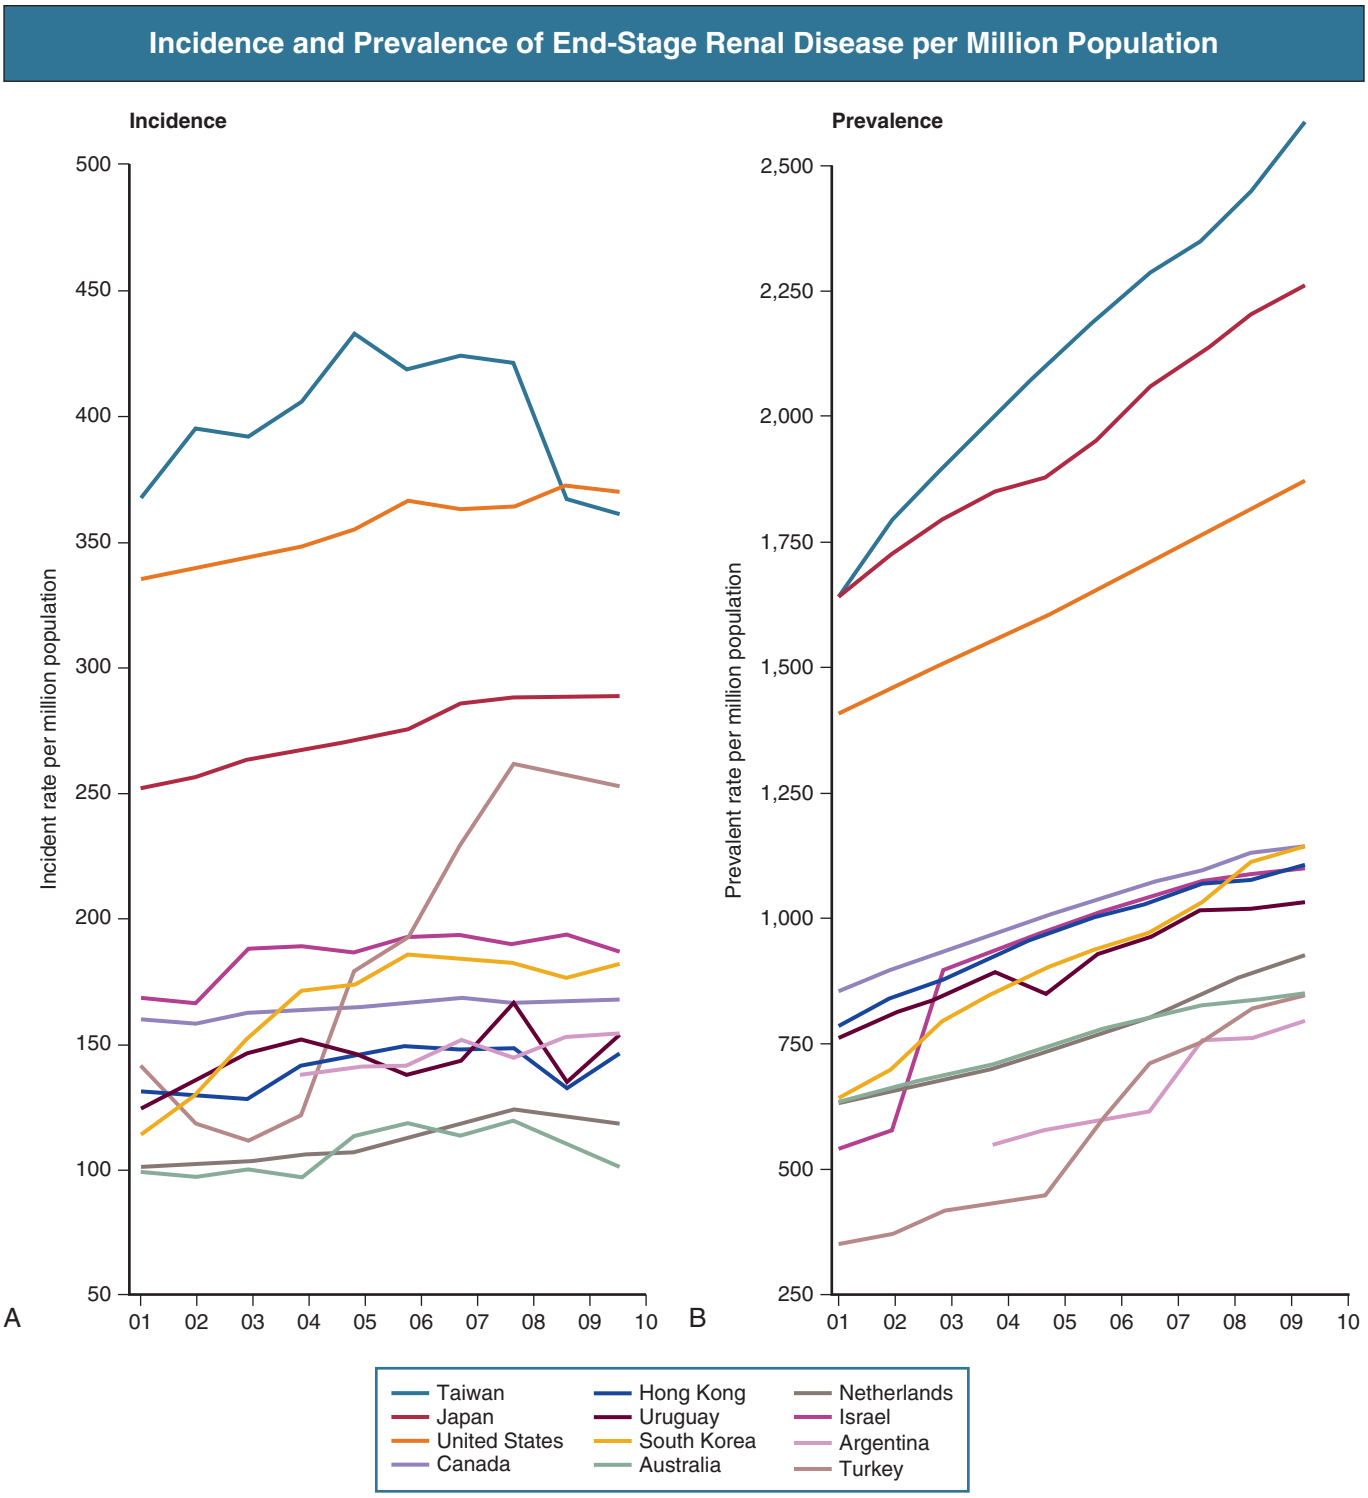

Figure 90-1 Incidence (A) and prevalence (B) of end-stage renal disease per million population. All rates are unadjusted. Data from Argentina (2005 to 2007), Japan, and Taiwan are dialysis only. *The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government. *(From reference 60.)*

learn more from fellow patients within a support group than from the group's facilitator. Furthermore, patient support groups help patients and their relatives appreciate that they are not alone in facing the demands of ESRD.

Representatives of all members of the multidisciplinary team, both medical and nonmedical, should deliver the predialysis program. For example, a controlled trial in California studied the value of social worker input to the predialysis program in reducing unemployment.[11] In the intervention group, patients and their relatives met regularly with a licensed social worker both before and after starting dialysis, to explore strategies for continuing the patient's current employment. Blue-collar workers in the intervention group were 2.8 times more likely to continue working. Patients in work had a better quality of life, greater self-esteem, and a more positive

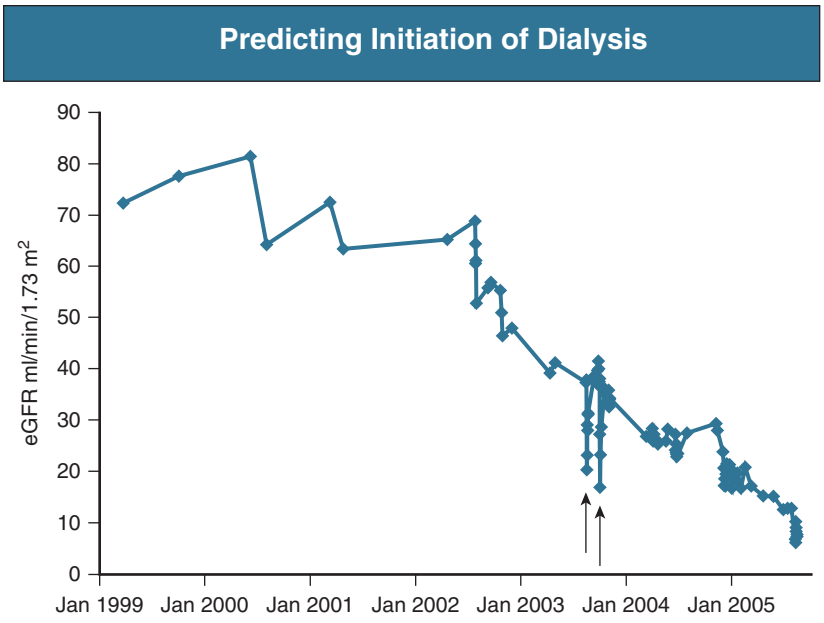

Figure 90-2 Predicting initiation of dialysis. Graph of estimated glomerular filtration rate *(eGFR)* over time for a patient with diabetes and progressive chronic kidney disease. The graph displays sequential eGFR values, telling the story of this patient's CKD. 1996: Diabetes mellitus diagnosed. 2000: Blood pressure 196/108 mm Hg and proteinuria detected. 2002: Acute myocardial infarction. 2005: Dialysis started. The *arrows* indicate episodes of radiocontrast-induced acute kidney injury following a computed tomography scan and a coronary angiogram.

attitude toward work. Because it is difficult for dialysis patients to regain jobs once they are lost, this result is particularly valuable for the long-term rehabilitation of patients.

In addition to engaging in face-to-face sessions, patients should be directed to the wide range of educational materials available. A number of books have been written specifically for dialysis patients. Many national organizations provide web-based patient information and produce printed and audiovisual material—for example, the National Kidney Foundation in the United States (www.kidney.org). Decision aids can help patients think through their options and choose the treatment that best meets their needs and priorities.

Education About Transplantation

For those who are suitable, transplantation offers the best prospect for improved survival and quality of life, especially in younger patients.[12] Even in older patients with greater comorbidity, transplantation can improve survival and be cost-effective.[13]

The options of transplanting kidneys from a deceased or living donor should be discussed, as well as combined kidney and pancreas transplants for people with diabetes. Although outcome data from the local transplanting centers should be made available, published data can be used to inform patients (www.ustransplant.org/annual_reports/current/survival_rates.htm).

The ideal time for the transplant to be performed is before dialysis is ever begun: preemptive transplantation. A U.S. study[14] showed that preemptive transplantation was associated with a 52% reduction in the risk of graft failure during the first year after transplantation, an 82% reduction during the second year, and an 86% reduction during subsequent years, compared with transplantation after dialysis. Increasing duration of dialysis was associated with increasing odds of rejection within 6 months of transplantation, possibly because of immunologic stimulation during long-term dialysis.

WHEN SHOULD DIALYSIS BE STARTED?

The eGFR at the start of dialysis has steadily increased over recent years and varies among countries. Mean eGFR of Japanese patients at the start of dialysis increased from 5.0 ml/min/1.73 m^2 in 1989 to 6.5 ml/min/1.73 m^2 in 2007. In the United Kingdom, the mean eGFR at the start of dialysis increased from 6 ml/min/1.73 m^2 in 1997 to 8.5 ml/min/1.73 m^2 in 2012 (www.renalreg.com, UK Renal Registry 2011 Report). In the United States, 17.7% of patients started dialysis with an eGFR of 10 to 15 ml/min/1.73 m^2 in 2000; by 2011 this had increased to 29%, with a further 16% starting with an eGFR of more than 15 ml/min/1.73 m^2.[60]

Aging of the population of CKD patients may contribute to earlier initiation of dialysis. In Japan the median age at initiation of dialysis increased from 59 to 69 years from 1989 to 2007.[15] A higher-threshold eGFR may be used in diabetics, as they tend to tolerate uremia poorly and are frequently troubled by sodium retention and fluid overload. Other measurements to be considered include a rising serum phosphate, falling serum bicarbonate, and protein-energy malnutrition that persists despite vigorous attempts to optimize dietary intake. A fall in serum albumin is a late sign of reduced protein intake and debility.[7]

Arbitrary guidelines have been established to gain Medicare approval for dialysis reimbursement in the United States. These include eGFR below 15 ml/min/1.73 m^2 for patients older than 18 years and below 20 ml/min/1.73 m^2 (Schwartz formula) for those younger than 18 years. Alternatively, adults should have a serum creatinine level above 8 mg/dl (700 µmol/l; >6 mg/dl [530 µmol/l] in diabetes). Patients may also qualify for Medicare if they do not meet these criteria but have uremic symptoms (nausea, vomiting, pericardial pain, acidosis, or hyperkalemia) or pulmonary edema refractory to diuretics.

Limitations of a Purely Clinical Approach to the Initiation of Dialysis

Waiting for patients to develop uremic symptoms carries the risk that the patient will start dialysis in a malnourished state with an increased risk of mortality. Renal failure itself is a catabolic state, and it is commonly difficult for patients on dialysis to regain lost weight.

Given the chronic nature of renal disease, patients frequently remain unaware of the severity of their illness. Protein intake may fall spontaneously with the result that symptoms of uremia do not develop, but this is at the expense of a loss of lean body mass. Similarly, patients may gradually reduce their activities as their exercise

tolerance declines. It is only when dialysis is started that many patients appreciate how ill they have become.

Lack of awareness can be avoided by carefully questioning the patient for insidious symptoms of uremia. For example, patients should be asked to compare their current eating habits and lifestyle with those 6 to 12 months previously. Close friends and relatives provide a useful third-party view of the patient's well-being.

Limitations of a Purely "Lab Result–Based" Approach in the Initiation of Dialysis

Routine early initiation of dialysis would need to confer significant benefits to justify the added inconvenience to the patient, the additional risk of dialysis-related complications, and the additional cost. Because dialysis treatment has a finite life, either from loss of peritoneal function or failure of vascular access, starting treatment earlier will bring forward the time when further procedures or a change of modality is necessary.

Moreover, there is likely to be resistance from many patients to the suggestion that they should start dialysis when they have no symptoms of uremia. The nephrologist would need complete confidence in the laboratory values as well as in the evidence supporting early commencement of dialysis to persuade a reluctant, asymptomatic patient.

Starting dialysis is the first step in a lifelong commitment to renal replacement therapy. Patients will be asked to comply with a wide variety of inconvenient and sometimes unpleasant treatments. A high level of compliance is required for a successful outcome, and, particularly in the United States, there is concern about the level of noncompliance that is associated with increased mortality.[16] The commitment to dialysis is likely to be greater if the patient feels better after it has started.

A prospective study in The Netherlands provides useful data to help the patient and nephrologist agree when to commence treatment.[17] Patients who started dialysis with less residual renal function (5 ml/min/1.73 m^2 vs. 7 ml/min/1.73 m^2) had a poorer quality of life in the early period after starting dialysis. However, this difference was no longer present by the end of the first 12 months of treatment. This has subsequently been confirmed in a randomized controlled trial that showed no difference in survival or quality of life between patients who started dialysis at an eGFR (MDRD equation) of 9.0 ml/min/1.73 m^2 and those who started 6 months later at an eGFR of 7.2 (Fig. 90-3).[18] Starting dialysis earlier was not associated with better quality of life and incurred higher health care costs.[19] One advantage in the early-start group was that a higher proportion of patients who had chosen PD actually started dialysis with PD (80% vs. 70%, $P = .01$).[20]

CHOICE BETWEEN PERITONEAL DIALYSIS AND HEMODIALYSIS

The majority of patients with ESRD are suitable for treatment with either PD or HD. It is difficult to envisage an ethically acceptable trial in which patients are allocated randomly to PD or HD, and the various possible modifications within each modality make a simple comparative trial impractical. Retrospective and prospective nonrandomized comparative studies have failed to indicate a consistent survival advantage for either modality.[20] There is some evidence that PD may be inferior to HD over the longer term in patients with coronary heart disease and congestive heart failure.[21,22] This contradicts a commonly expressed opinion that PD is gentler for such patients because it avoids rapid fluid shifts and causes less stress on the heart. Change in treatment from PD to HD is associated with an increased risk of hospitalization and mortality.[23] A planned change from PD to HD may not be associated with this increased risk, although this has not been studied systematically in a large population. Patients having PD for longer than 7 years are at an increased risk of encapsulating peritoneal sclerosis.[24] This may prompt a planned change to HD.

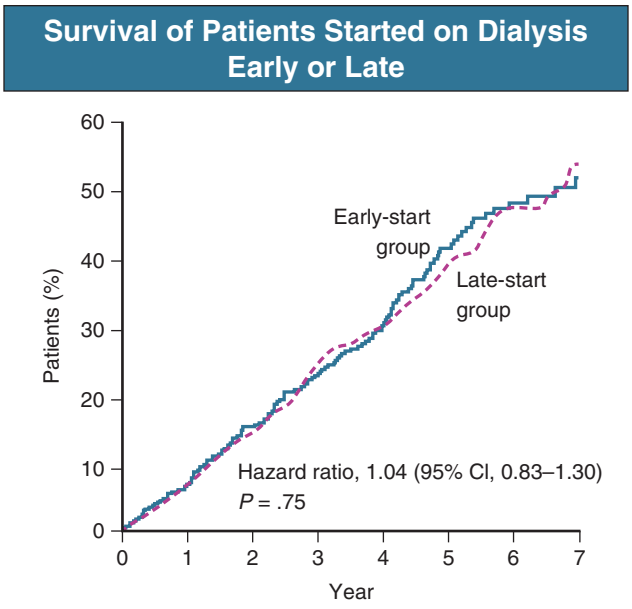

Figure 90-3 Survival of patients started on dialysis early or late. Data from the IDEAL Study. Kaplan-Meier curves showing no difference in time to death after early or late dialysis start. *CI,* Confidence interval. *(From reference 18.)*

Contraindications to Dialysis Modalities

Absolute Contraindications	Relative Contraindications
Peritoneal Dialysis	
Loss of peritoneal function producing inadequate clearance	Recent abdominal aortic graft
Adhesions blocking dialysate flow	Ventriculoperitoneal shunt
Surgically uncorrectable abdominal hernia	Intolerance of intra-abdominal fluid
Abdominal wall stoma	Large muscle mass
Diaphragmatic fluid leak	Morbid obesity
Inability to perform exchanges in absence of suitable assistant	Severe malnutrition
	Skin infection
	Inflammatory bowel disease
Hemodialysis	
No vascular access possible	Difficult vascular access
	Needle phobia
	Advanced cardiac failure
	Coagulopathy

Table 90-1 Contraindications to dialysis modalities. Absolute and relative contraindications to hemodialysis and peritoneal dialysis. *(Adapted from reference 25.)*

Contraindications to Peritoneal Dialysis

There are a few situations in which PD is contraindicated (Table 90-1). Relative contraindications to PD are discussed in the following sections.

Fresh Intra-abdominal Foreign Body

Patients with prosthetic aortic grafts have been successfully treated with PD. HD is usually used initially for up to 16 weeks to allow the

graft to be covered with epithelium and so avoid the risk of graft infection via peritoneal dialysate. However, this risk must be balanced against that of bacterial seeding from the patient's HD access.

Body Size Limitations and Intolerance of Intra-abdominal Fluid Volume

Body size can be a problem at both ends of the spectrum. Small patients may be intolerant of the volume of dialysate needed to achieve adequate dialysis, particularly if they have negligible residual renal function. Alternative methods of fluid exchange such as nocturnal automated PD can be used to overcome this limitation. It may also be difficult to achieve adequate clearances in patients with a body mass index exceeding 35 kg/m^2. Discomfort resulting from increased intra-abdominal volume can be significant in patients with chronic respiratory disease, low-back pain, or large polycystic kidneys. In general, it is hard to predict a patient's tolerance of intra-abdominal fluid, and so these limitations usually appear after a patient has started PD.

Bowel Disease and Other Sources of Infection

The presence of ischemic bowel disease, inflammatory bowel disease, or diverticulitis is likely to increase the incidence of peritonitis as a result of organisms passing through the bowel wall into the peritoneum. Abdominal wall infection may lead to peritonitis via the exit site and catheter tunnel.

Screening for methicillin-resistant *Staphylococcus aureus* (MRSA) before all elective surgical procedures is good practice. Nasal carriage of *S. aureus* increases the risk of subsequent staphylococcal exit site infection and peritonitis, and clearance of nasal *S. aureus* with topical mupirocin cream has been shown to significantly reduce the risk of staphylococcal infection at the exit site.[26]

Severe Malnutrition or Morbid Obesity

Patients should ideally commence PD in an adequate nutritional state. Severe malnutrition may lead to poor wound healing and to leakage from the catheter tunnel. In addition, peritoneal protein losses during dialysis may exacerbate hypoalbuminemia. At the other end of the spectrum, it may prove difficult to satisfactorily place a peritoneal catheter through the abdominal wall in patients with morbid obesity. Thereafter, absorption of glucose from the dialysate, which may average as much as 800 kcal/day, may contribute to further weight gain.

Contraindications to Hemodialysis

Contraindications to HD are few (see Table 90-1). As discussed in Chapter 91, access to the circulation can usually be obtained, even in patients with extensive vascular disease or previous surgery. An aversion to needle puncture of the AV fistula is common in the early stages but can usually be overcome by careful use of local anesthetic and nursing encouragement. Severe coagulopathy may make management of anticoagulation for the extracorporeal circuit difficult.

HOME HEMODIALYSIS

In the last two decades, the use of home HD has declined. For example, in the United Kingdom the percentage of the dialysis population on home HD fell from 35% in 1984 to 3% in 2010. New Zealand, Australia, and Denmark are the only countries with a significant proportion of patients on home HD (Fig. 90-4). There are a number of reasons for the fall in home HD. First, HD usually requires the presence of an assistant throughout the period of dialysis in case

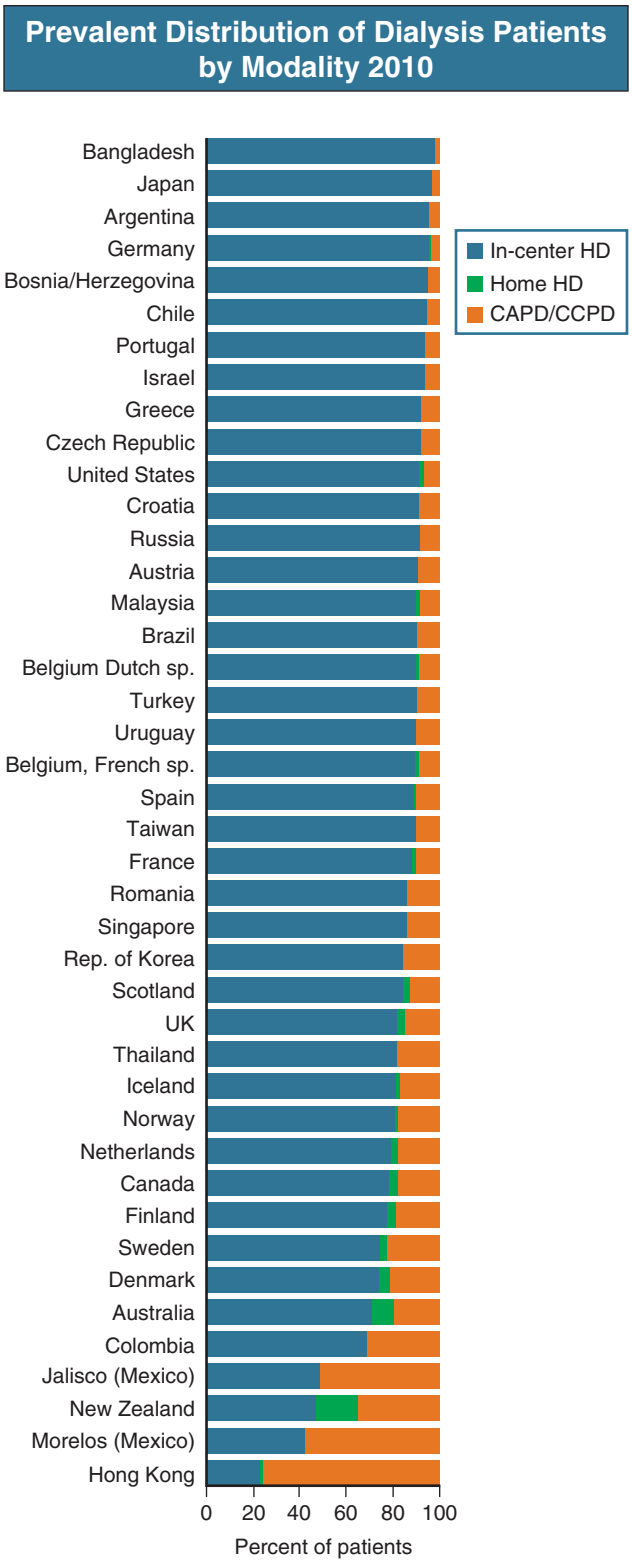

Figure 90-4 Prevalent distribution of dialysis patients by modality, 2010. All data are unadjusted for case mix. Data were supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author and in no way should be seen as an official policy or interpretation of the U.S. Government. *CAPD/CCPD,* Continuous ambulatory peritoneal dialysis or continuous cycling peritoneal dialysis. *(Modified from reference 60.)*

the patient becomes hypotensive or unconscious. Because an increasing proportion of new dialysis patients are elderly, there may be no one available who is able or willing to take on this responsibility. Second, there is the added cost of installing a dialysis machine and its associated water treatment, which is not required for PD. However, the subsequent running costs are less for at-home than for in-center HD. With improvements in dialysis machine technology, home HD may become cheaper and more widespread.

Home HD can provide significant benefits. It removes the inconvenience of traveling to and from the dialysis facility and gives patients the freedom to dialyze at a time that suits them. Although no randomized controlled trial has compared hospital and home HD, comparative studies where correction has been made for differences in comorbidity suggest that patients on home HD have a better outcome in terms of morbidity and mortality.[27] Patients are able to perform more frequent treatments per week, and some dialyze overnight. More frequent dialysis significantly reduces the time taken to recover after each treatment, reduces dietary restrictions and antihypertensive medications, and leads to an improved quality of life.[28]

PATIENT CHOICE OF HEMODIALYSIS OR PERITONEAL DIALYSIS

In the facility of one of the authors in Birmingham, United Kingdom, all patients entering the ESRD program are given "modality-neutral" counseling and allowed to select their preferred mode of treatment.[29] Of patients without a medical contraindication to PD, 45% have selected PD. These relative proportions are similar to those found in a U.S. study of patients' choices after counseling.[30] Independent predictors for choosing HD are increasing age, comorbidity, and male sex. Independent predictors for choosing PD include marriage, counseling before the start of dialysis, and an increasing distance from the base unit.[31] However, although 45% of patients chose PD, not all actually start dialysis on this modality. Patients who require urgent dialysis invariably receive HD rather than PD. Once started on HD, only a small proportion of patients transfer to PD, even if this was their original preference. Patients presenting late for dialysis should still benefit from an education program about their options for long-term treatment.[32]

The major differences in dialysis modality among countries (see Fig. 90-4) suggest that the type of dialysis patients receive is more often determined by physicians and organizational factors rather than by patients. Possible factors affecting these decisions are discussed in the following sections.[33,34]

Reimbursement of Physicians and Funding of Dialysis Facilities

The arrangements by which doctors and dialysis facilities are reimbursed for the cost of providing treatment vary widely around the world. There are also large differences between the levels of payment for HD and PD in many countries. In countries such as the United Kingdom and Canada, where facilities are publicly funded from taxation, the use of more expensive types of dialysis—for example, high-volume hemodiafiltration—is limited. Conversely, in places such as Hong Kong, where dialysis is available only in the private sector, more patients are treated by PD because it is less expensive. In HD facilities, an arrangement whereby payment depends on the number of patients treated creates an incentive to increase patient numbers. If the patient's nephrologist has a financial interest in the HD facility, this may directly influence the decision on which modality of treatment to recommend.

Physician Preference

In a United States Renal Data System (USRDS) survey reported in 1997, only 25% of HD patients remembered having PD discussed with them. In contrast, 68% of patients on PD reported discussions about HD. It is interesting to note that a much greater proportion of patients on HD felt that the choice had been made by the medical team rather than by themselves or by joint decision. Since then, there has been a marked decline in the proportion of dialysis patients treated by continuous ambulatory peritoneal dialysis (CAPD) in the United States, from 14% in 1995 to 7% in 2010. This compares with 35% in New Zealand in 2010.

IMPORTANCE OF DIALYSIS ACCESS

Ideally, every patient would make an informed choice between PD and HD after a period of in-depth counseling and preparation, and dialysis access would be established in advance of starting dialysis. Sadly, dialysis is frequently started in less than ideal circumstances. Late presentation with ESRD is a worldwide phenomenon, indicating that no system of health care has overcome the problems of identifying patients with progressive CKD and bringing them to the attention of nephrologists in a timely manner (Fig. 90-5).

Reports from both Europe and the United States document the excess morbidity and mortality associated with patients presenting late with ESRD and requiring emergency dialysis.[9] Compared with nonemergency patients, their length of hospital stay is significantly greater, and during this time there is a higher incidence of major complications and death. A significant part of the increased mortality is related to the use of a catheter rather than an AV fistula. In the United States, many incident patients have received an AV graft rather than a fistula because grafts can be cannulated more easily and earlier than fistulas (Fig. 90-6).[35]

International data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) show that the risk of death is higher for patients dialyzing in units that use catheters in a high proportion of their patients.[36] The risk is also increased, but to a slightly lesser extent, if AV grafts are commonly used. The detrimental effects of central venous catheters persist even after the catheter has been removed. The survival rate associated with subsequent AV fistulas is significantly worse in patients who have had a previous catheter in place compared with those who started directly on a fistula, even after correction for case mix and comorbidity, possibly because of development of central venous stenosis after removal of the catheter.[35] There is wide variation among countries in the time required for permanent access to be created and used.[35] If a fistula can be created swiftly and used as soon as it is mature, perhaps after only 2 weeks, the need for a catheter may be avoided. Details of HD access surgery are discussed in Chapter 91, and PD catheter placement is discussed in Chapter 96.

DECISION WHETHER TO OFFER RENAL REPLACEMENT THERAPY

Availability of Dialysis Facilities

Renal replacement therapy is unavailable to the majority of the world's population with ESRD.[37] The practice of rationing dialysis has been candidly documented in a report from a South African center[38] in which more than half the patients with ESRD assessed from 1988 to 2003 were not offered dialysis; socioeconomic factors such as age, race, employment, and marital status outweighed medical factors in the decision to begin treatment.

Percentage of patients on HD for less than 60 days (mean vintage 32 to 38 days in each country) using an arteriovenous fistula *(AVF),* an arteriovenous graft, or an intravenous catheter, by country. *(From reference 61.)*

Selection of Patients by Physicians and Nephrologists

Incidence rates of RRT have increased over recent decades. Not all of this increase is attributable to more patients developing ESRD. A long-term study from California has shown a steady increase in the likelihood of people going on to receive RRT that could not be explained by an increase in age, diabetes, high blood pressure, proteinuria, or reduced eGFR.[39] This indicates a greater enthusiasm for use of RRT over recent years.

In the developed world, the practice of starting dialysis in patients who are very elderly or dependent on others for their care or who have multiple comorbid conditions varies significantly among countries and among nephrologists within those countries.[40] For example, the percentage of patients who were living in a nursing home or who were unable to eat independently within 90 days of starting dialysis is much higher in the United States (11.6%) and Japan (19.2%) than in France (1.3%), Germany (6.4%), Italy (4.7%), Spain (2.0%), and the United Kingdom (1.5%).

Severe cognitive impairment in a patient would much more strongly influence a nephrologist in the United Kingdom not to start dialysis than in the United States.[40] Furthermore, nephrologists in the United States were much more likely than those in the United Kingdom and Canada to start dialysis in patients with dementia or in a persistent vegetative state, if pressured to do so by family members. In a Japanese study, cognitive impairment was present in 9.9% of chronic dialysis patients.[41] Fear of litigation was particularly influential in persuading nephrologists to offer treatment.

The Renal Physicians Association (RPA) in the United States has issued guidelines for decisions to not initiate or to discontinue dialysis[42] and provides a comprehensive toolkit to support shared decision making (www.renalmd.org./End-Stage-Renal-Disease) (Fig. 90-7). It has also provided a systematic approach to conflict resolution if there is disagreement regarding the benefits of dialysis (Fig. 90-8).

RATIONING VERSUS RATIONAL DIALYSIS TREATMENT

On the grounds that the greatest good should be derived from the limited resources available, it has been argued that patients who are expected to survive for only a few months should not be offered dialysis. This is supported by the view that it is preferable to avoid suffering by not starting dialysis than to withdraw treatment when the patient's condition becomes distressing. Withdrawing dialysis seems more like actively causing death than withholding dialysis, whereby death is allowed to occur naturally.

This utilitarian approach to the allocation of resources goes against instincts to act in the patient's best interest and may be unacceptable to many physicians. Furthermore, it does not take into account the value of even a short extension of life that allows the patient and his or her family to prepare for death. It also makes only a small contribution to minimizing the use of resources because the costs of an HD program are in proportion to the length of time for which the patient continues to receive treatment.

Against this ethical background, are there any objective criteria that can be applied to identify patients who are unsuitable for dialysis? One criterion to be dismissed is age. Although advanced age was used as a simple exclusion criterion in the early days of dialysis, the elderly are now the most rapidly growing section of the dialysis population.

Predictive Factors

Studies have attempted to identify other predictive factors. A Canadian study of patients starting dialysis[43] used a comorbidity scoring system to quantify factors likely to predict early death. The predictive value of this scoring system was compared with the value of an estimate made by the patient's nephrologist of the probability that the patient would die within 6 months. It was not possible to predict early death accurately using either the comorbidity scoring system or the clinician's opinion. Indeed, it was impossible even to identify the small proportion of patients with a very poor prognosis. Clinicians were more accurate than the scoring system in identifying patients with less than a 50% risk of death by 6 months, but they tended to overestimate the risk of death in the worst prognostic groups. For example, 30% of patients whose predicted probability of death was considered to be 80% or higher survived for more than 6 months.

In a U.S. study, HD patients were categorized by risk factors for mortality; however, even patients in the highest risk category still had a 1-year survival of more than 50%.[44] A U.K. study[45] identified a high-risk group using factors associated with poor survival in a statistical model, which included poor functional status at presentation, comorbidity, and underlying disease. Although these patients had a 1-year survival of only 19%, some survived at least 2 years.

ADVISING PATIENTS ABOUT PROGNOSIS ON DIALYSIS

Despite these uncertainties, an individual patient should be given an estimate of his or her likely future on dialysis. The RPA has suggested the following criteria to help identify patients older than 75 years who have a poor prognosis on dialysis[42]:

1. Clinicians' response of "No, I would not be surprised if my patient died in the next 6 months."
2. High comorbidity score.
3. Significantly impaired functional status (e.g., Karnofsky Performance Status score less than 40).
4. Severe chronic malnutrition (i.e., serum albumin less than 2.5 g/dl with the bromcresol green method).

Quality of life is also strongly predictive of mortality, even after statistical correction for these comorbid factors.[46]

For patients whose prognosis is particularly uncertain, or when there is disagreement between the views of the patient and those of the dialysis team, a time-limited trial of dialysis may be offered. This may give the patient and his or her family a better understanding of what life on dialysis entails and may allow time for further discussion among all parties. The duration of the trial should be judged for each individual, and clinical and biochemical parameters such as serum albumin should be reviewed regularly.

Most people would agree that patients who are certain to have an unacceptable quality of life should not be subjected to the discomfort of HD.[47] Patients choosing conservative kidney management are spared the inconvenience and discomfort of travelling to the dialysis unit and surgical procedures. Although their survival may be shorter than if they were to start dialysis (adjusted median survival 13 months shorter for conservative management than for HD), most of this time difference (11 months) would be made up of days having dialysis treatment. The quality of life is better without dialysis, and patients are more likely to die at home.[48,49]

Many of the symptoms and complications of ESRD—anemia, acidosis, pruritus, insomnia, depression, fluid overload, and hypertension—can be treated with medication and a low-protein diet,[50] so a decision not to start dialysis is not the same as a decision to withhold active treatment. Conservative therapy is best delivered by the specialist predialysis multidisciplinary team and should include a dietician, a social worker, and psychological support. The team should have close links with palliative care specialists so that there is a smooth transition from active medical therapy to end-of-life care.[42]

PATIENT WHO DOES NOT WANT DIALYSIS

Nephrologists may be presented with the dilemma of a mentally competent patient whom they would normally treat, but who does not wish to have dialysis. From an ethical viewpoint, a patient's decision not to start dialysis or to discontinue it is justified on the principle of individual autonomy—legally, in the United Kingdom, on the basis of the individual's common-law right to self-determination, and in the United States on the constitutional right of liberty. When the patient is able to express a clear wish, the physician is obliged to respect this, because to treat a patient against his or her will constitutes an assault. The physician nonetheless must ensure that all reversible factors have been addressed, such as unfounded fears about what dialysis will entail or a depressive illness affecting the patient's judgment, and ideally should request a psychiatric evaluation. It is not uncommon for patients to express a strong desire not to have dialysis, particularly if they are relatively asymptomatic, only to change their mind when they become more symptomatic. At this late stage, the basic will to survive comes to the fore. An advance directive written by the patient should never be held as a reason against a change of mind.

DISAGREEMENT ABOUT A DECISION TO DIALYZE

There will inevitably be differences of opinion about the benefits of dialysis to individual patients. Dialysis nurses may disagree with the nephrologist's decision to treat a patient. If the dialysis nurses and doctors are functioning well as a team, they should feel able to express these reservations and have the issue adequately discussed. It is very demoralizing for individual staff and the team as a whole if they feel pressured into giving treatment that they feel is inappropriate.

The nephrologist may remain unwilling to offer dialysis despite the insistence of the patient or, more often, the patient's care providers, the legal agent, or another doctor (see Fig. 90-7). Dialysis must never be given at the insistence of others if it is against the patient's clearly expressed wishes. However, if the patient insists on treatment against the nephrologist's advice, dialysis should usually be given while a resolution is reached. Extensive discussions and explanations of the treatment options and prognosis may be needed to gain a better understanding of the reasons behind the differing views. Helpful advice may be obtained from another physician, particularly the patient's family doctor, who will have a broader understanding of the patient's circumstances. It may be appropriate to involve a psychologist, social worker, or religious counselor. It may be necessary to refer the case to a formal ethics committee, if one exists locally, to clarify the issues of disagreement and enable a resolution. A physician cannot be compelled to offer treatment against his or her professional judgment, but the physician is ethically and legally obliged to attempt to transfer the care of the patient to another physician. Only as a last resort, if no alternative dialysis unit can be found and after adequate advance notice has been given, should dialysis be withdrawn.

MANAGEMENT OF DISRUPTIVE PATIENTS ON DIALYSIS

Most nephrologists have had experience of treating a small number of patients who, for one reason or another, will not comply with the discipline required for maintenance dialysis and who become disruptive to the staff and other patients. This behavior can range from noncompliance with treatment, which harms the patient but is merely inconvenient to the staff, to verbal or even physical aggression toward the staff and other patients in the unit. The impact of this small number of patients can be very great.[51]

The strategy for dealing with such patients must be tailored to the individual. However, useful suggestions for resolving conflict have been provided by the RPA (Box 90-1). They emphasize the

Suggested Steps for Dealing with Disruptive Patients

Identify and document problem behaviors and discuss them with the patient
- Seek to understand the patient's perspective.
- Identify the patient's goals for treatment.
- Share control and responsibility for treatment with the patient.

Educate the patient so that he or she can make informed decisions.

Involve the patient in the treatment as much as possible.

Negotiate a behavioral contract with the patient.
- Consult a psychiatrist, psychologist, or social worker for assistance in patient management or determination of decision-making capacity.
- Be patient and persistent; try not to be adversarial.
- Allow the patient to express concerns, but do not tolerate verbal abuse or threats to staff or patients.
- Contact law enforcement officials if physical abuse is threatened or occurs.
- If satisfactory resolution has not occurred with the above strategies, contact the local ESRD Network to discuss the situation and ensure due process.
- As a last resort, consider transferring the patient to another facility or discharging the patient.

Consult with legal counsel before proceeding with plans for discharge, and do not discharge without advance notice and a full explanation of future treatment options.

Box 90-1 Suggested steps for dealing with disruptive patients. *ESRD,* End-stage renal disease. *(Adapted from reference 42.)*

importance of understanding, information, patience, and persistence. However, the bottom line for patients who are aggressive toward staff while on dialysis must be that they are taken off treatment and sent home.

RESUSCITATION AND WITHDRAWAL OF DIALYSIS

Cardiopulmonary Resuscitation

If patients are to be fully involved in decision making about their treatment, two sensitive issues need to be discussed—cardiopulmonary resuscitation (CPR) and the possibility of withdrawal of dialysis.[52] The two are not necessarily linked; patients may wish to continue with dialysis but express a desire that resuscitation not be attempted should they experience a cardiac arrest. Such a decision would be supported by evidence on the outcome of CPR in dialysis patients; only six of 74 dialysis patients who received CPR survived to hospital discharge, and at 6 months after CPR only two were still alive, significantly fewer than 23 of 247 "control" patients not on dialysis still alive at 6 months. This difference was not explained by age or comorbid conditions.[53] Successful CPR often resulted in a "poor-quality" death, with 20 of the 27 successfully resuscitated dialysis patients dying a few days later on mechanical ventilation in an intensive care unit.

A decision not to attempt CPR must be carefully documented in the patient's medical and nursing records, and all nursing staff must be made aware of it. It is important to be clear what is meant by "cardiac arrest" and for there to be agreement on how the nursing staff should respond should the patient experience a hypotensive "crash" while on dialysis. These notes may form part of a complete advance directive, as discussed later.

Withdrawal of Dialysis

As discussed earlier, it is not possible to predict accurately which patients will gain prolonged benefit from dialysis. Many nephrologists, therefore, operate a liberal policy of offering dialysis to all patients with ESRD who wish to have it. This policy ensures that no patients are denied dialysis but has the inevitable consequence that a number of patients will be started on dialysis who subsequently do not enjoy an acceptable quality of life. The possibility of withdrawing dialysis needs to be addressed if these patients are not to suffer unreasonably.

Rates of withdrawal vary widely among countries and cultures. Withdrawal rates in Italy and France are much lower than in the United Kingdom and the United States.[52] In the United States, African Americans have about one third the withdrawal rate of Caucasians. Rates of withdrawal vary among dialysis units and are significantly associated with the medical director's opinion about whether withdrawal is allowed or facilitated in that unit.[52] This suggests that patients' wishes are not always fully included in these decisions. Patients may be very reticent to express a wish to withdraw from dialysis. Many see it as their duty as a patient to go along with the treatment recommended by their physician and do not wish to appear ungrateful for the efforts that are being made to keep them alive. Their physician may be the last member of the team to learn about the patient's views, and it is very important that good communication exists within the multidisciplinary team so that any clues that the patient gives are acted on.

Staff should adopt a proactive approach and raise the issue of withdrawal of dialysis with patients who are not thriving. Qualitative research suggests that raising the subject of death with patients does not destroy their hope for the future.[54] Early discussion of these issues can lead to a more satisfactory outcome for patients, relatives, and staff when the patient eventually dies.[55] In the United States, formal advance directives play an important part in these discussions, and helpful guidance on how to conduct sensitive and interviews has been published.[56] In the United Kingdom, dialysis teams may enter patients on an at-risk register so that they can receive appropriate assessment and care.[57]

When a patient is no longer competent to make a decision, an advance directive can provide a clear legal basis for the decision to stop dialysis. Indeed, in the absence of clear and convincing written evidence, some U.S. states insist that dialysis must be continued. In other U.S. states and the United Kingdom, the physician is given the task of deciding on the patient's behalf. Helpful advice for dialysis staff and patients wishing to complete an advance directive is available in the RPA clinical practice guideline toolkit.[42]

Once a patient has expressed a wish for dialysis to be withdrawn or the issue has been raised by his or her relatives, the first priority must be to identify any reversible factors that may improve the patient's health sufficiently for the decision to be reversed. In particular, any depression must be identified and treated.[58] Once all these factors have been ruled out, the process of withdrawing dialysis should be managed according to some key principles (Box 90-2).

Withdrawing dialysis should not be seen as an admission of failure but as a final stage in the process of renal replacement therapy. The opportunity for patients to complete unfinished emotional and financial business can make the subsequent bereavement period much less traumatic. Managing this terminal phase can be uniquely rewarding, particularly if it allows a patient and his or her family and care givers to prepare themselves for the patient's death.[59]

Principles Underlying Withdrawal of Dialysis

- The ultimate responsibility for the decision rests with the physician, not the relatives or care givers.
- The patient's interests and dignity should be protected at all times.
- The process should not be rushed. If there is any doubt about the correctness of the decision, treatment should continue.
- There should be an open discussion among the multidisciplinary team to avoid any damaging disagreements.
- The psychological needs of the health care team should not be overlooked.
- Palliative care must be given in the most appropriate environment—for example, a hospice or, ideally, the patient's own home.

Box 90-2 Key principles underlying the process of withdrawal of dialysis.

CHAPTER 91

Vascular Access for Dialytic Therapies

Jan H. M. Tordoir

Functional vascular access is needed for all extracorporeal dialytic therapies and remains the lifeline for patients with end-stage renal disease who need chronic intermittent hemodialysis (HD) therapy. The ideal HD access should have a long length of a suitable superficial vein for cannulation in two places more than 5 cm apart with a sufficient blood flow for effective dialysis, usually in excess of 400 to 1500 ml/min. A vascular access should have good primary patency, have a low risk of complications and side effects, and leave opportunities for further procedures in the event of failure. Ideally, a first access should be an arteriovenous (AV) fistula placed peripherally at the wrist. However, upper arm and lower limb access sites are increasingly used because the aging dialysis population, with multiple comorbidities, has poor and diseased arm vessels that may be unsuitable for the creation of a simple wrist fistula.

Vascular access should be performed with minimal delay by a surgeon experienced in vascular access creation and, wherever possible, in advance so that dialysis may start with permanent access rather than with use of a central venous catheter. Central venous catheter use should be minimized because of the increased risk of sepsis, the increased mortality, and the development of central venous stenosis or thrombosis, which compromises further access in the upper limbs. Unfortunately, many patients require a central venous catheter either to start dialysis or as a bridge between the failure of a permanent access and the creation of a new AV fistula.[1]

The need for revisional procedures because of access-related complications, including thrombosis, central venous obstruction, and ischemia, is increasing. A multidisciplinary approach to access creation and maintenance, involving nephrologists, interventional radiologists, access surgeons, and dialysis nurses, is mandatory to meet the burden of HD vascular access on health care facilities and costs.

EVALUATION OF THE PATIENT FOR VASCULAR ACCESS

The earlier a patient with chronic kidney disease (CKD) is seen by a vascular access surgeon, the better the chance for the patient to have a well-functioning access at the initiation of HD. An early decision on the type, side, and site of the first vascular access will be based on the following:

- *Clinical examination* with careful palpation of arterial pulses and venous vasculature. Particular attention is paid to the venous filling capacity, with use of a blood pressure cuff and variable pressures, and to the presence of venous collaterals and swelling. The dominant arm is not necessarily the preferred side, and the decision should be based on the quality of the vessels.
- *Vascular mapping by Doppler ultrasound.* This provides information about the venous vasculature, particularly in obese patients and in the upper arm, and about the diameter of the brachial, radial, and ulnar arteries; detects vascular calcifications; and reveals the blood flow volume in the brachial artery. The resistance index, a measure of arterial compliance, can be calculated from the differences between the high-resistance triphasic Doppler signal with clenched fist and the low-resistance biphasic waveform after the fist is released. A preoperative resistance index of 0.7 or higher in the feeding artery indicates insufficient arterial compliance (often associated with arterial calcification) so that the chance of successful creation of an AV fistula is reduced. Current guidelines recommend ultrasound mapping in all patients. Additional angiography is needed only in very difficult cases or in patients with previous ipsilateral central vein catheters to rule out central vein obstruction; the use of radiocontrast media should be minimized.

Preservation of veins during the earlier stages of CKD is crucial for the success of vascular access. Patients should be instructed to protect their veins, restricting blood sampling to the dorsum of the hand whenever possible.

PRIMARY AUTOLOGOUS VASCULAR ACCESS

Radiocephalic Arteriovenous Fistula

A well-functioning distal radiocephalic AV fistula in the nondominant arm is the ideal permanent access for HD. This usually gives an adequate blood flow and a long length of superficial vein for needling. It also leaves proximal sites for further procedures in the event of failure. A distal radiocephalic AV fistula should be possible in a majority of incident patients but may be compromised if the cephalic and antecubital fossa veins are unusable because of thrombophlebitis from previous intravenous cannulas or venipunctures. For this reason, it is essential that these veins be avoided for intravenous cannulas, which should be restricted to the dorsum of the hand in all patients with CKD, except in the emergency situation when rapid access to the circulation is required.

A radiocephalic AV fistula is usually created at the wrist but can be created more proximally in the forearm if distal vessels are inadequate (Fig. 91-1). On occasion, three or four radiocephalic AV fistulas can be created at progressively more proximal sites in the forearm before a brachiocephalic AV fistula is created. The radiocephalic AV fistula at the wrist was initially described by Brescia and Cimino in 1966 as a side-to-side anastomosis, but an end-to-side configuration is preferred by most to reduce the risk of venous hypertension in the radial aspect of the hand.

The primary patency of radiocephalic fistulas varies from center to center, but recent publications report high primary failure rates varying from 5% to 41% and 1-year primary patency rates of 52% to 71% (Table 91-1).[2-7] Early thrombosis and nonmaturation of an AV fistula in the older comorbid population, who have poor upper limb vessels, are the major causes of these high primary failure and low patency rates. The patency of radiocephalic AV fistulas is poorer in women, so a proximal AV fistula might be preferable if the cephalic vein or radial artery is small.

Biuckians et al[7]	2008	80	37	63

Table 91-1 Early failure and 1-year patency rates of radiocephalic AV fistulas.

Nonmaturation of Radiocephalic Arteriovenous Fistula

The autogenous radiocephalic AV fistula needs time to mature and for the vein to enlarge to a size at which it can be needled for dialysis. Usually 6 weeks for maturation is advised. Earlier cannulation can damage the thin veins. Nonmaturation rates vary from 25% to 33%. The essential components of a successful AV fistula are a sufficient vein diameter of 4 to 5 mm for needling and a high blood flow so that blood can be drawn from the fistula at 300 to 400 ml/min. In reality, this requires a fistula flow of about 600 ml/min to prevent excessive recirculation and to permit adequate dialysis within the usual 4-hour time frame of HD treatment. Fistulas that fail immediately are the consequence of poor selection of vessels or poor technique. Regular duplex ultrasound investigation early after AV fistula formation, especially in fistulas that are not maturing, can detect poor flow, stenosis, and accessory branches, guiding the interventional radiologist and surgeon to the appropriate treatment.

SECONDARY AUTOLOGOUS VASCULAR ACCESS

Although a primary radiocephalic AV fistula is preferable, the first-choice procedure is increasingly an upper arm AV fistula with use of an autogenous superficially located arm vein, especially in the dialysis population with associated comorbidities such as diabetes mellitus, coronary heart disease, and peripheral arterial occlusive disease.[1]

The upper limb is preferred to the lower limb for vascular access because of the ease of cannulation, comfort for the patient, and considerably lower incidence of complications. Similarly, autogenous conduits are preferable to the use of prosthetic grafts because of improved patency and lower risk of infection.

Forearm Cephalic and Basilic Vein Transposition and Elevation

Vein transposition or elevation increases the possibilities for creating a forearm fistula. The cephalic vein is preferred, but if it is unsuitable, the more deeply located basilic vein can be transposed from the ulnar to the radial side along a straight subcutaneous course from the elbow to the radial artery. Alternatively, a basilic vein–to–ulnar artery anastomosis can be performed with additional volar transposition to facilitate needling for dialysis.

Different surgical techniques, with or without transposition, have been advocated according to the forearm artery and vein location. In one study,[8] 91% fistula maturation was achieved with a range of techniques; 15% were suitable for a straightforward AV fistula, 33% required vein transposition from dorsal to volar for anastomosis to the appropriate artery, and the remaining 52% required superficial transposition of a vein on the volar aspect of the forearm before arterial anastomosis. Primary patency rates were 84% at 1 year and 69% at 2 years.

Needle cannulation may be difficult, particularly in obese patients. A forearm cephalic vein that is too deeply located may be made accessible for cannulation by transposition or elevation. In one study, the elevation technique was applied in obese patients with radiocephalic AV fistulas and cannulation difficulties; the primary failure rate was 15%, with a 1-year patency rate of 84%. After operation, all patients could be successfully cannulated for dialysis.[9]

Recently surgical lipectomy or liposuction has been advocated to facilitate cannulation of deeply located fistulas.[10]

Elbow and Upper Arm Cephalic Vein Arteriovenous Fistula

The brachiocephalic and antecubital fistulas are two possible AV anastomoses in the elbow region. In addition, anastomosis between the transposed cephalic vein and brachial artery 2 cm proximal to the elbow may be executed, which provides an optimal situation for cannulation along the cephalic vein (Fig. 91-2). The outcome of the brachiocephalic AV fistula is usually good, with a high primary function rate and good long-term patency; studies showed a 10% early failure rate caused by nonmaturation and an 80% 1-year patency rate.[11,12] Two-year primary, assisted primary, and secondary patency rates were 40%, 59%, and 67%, respectively. (Primary patency is functioning access without any intervention; assisted primary patency is functioning access after preemptive intervention for flow decline; secondary patency is functioning access after intervention for thrombosis.) Predictors of failure include diabetes mellitus and a history of contralateral forearm AV graft (indicating poor vessels). Therefore the primary patency of brachiocephalic fistulas is comparable to that of radiocephalic fistulas. The early failure and 1-year patency rates of brachiocephalic AV fistulas are shown in Table 91-2.[11-15]

Upper Arm Basilic Vein Arteriovenous Fistula

The upper arm basilic vein is usually inaccessible for dialysis cannulation because of its medial and deep position. Therefore the basilic vein needs to be superficialized and transposed to an

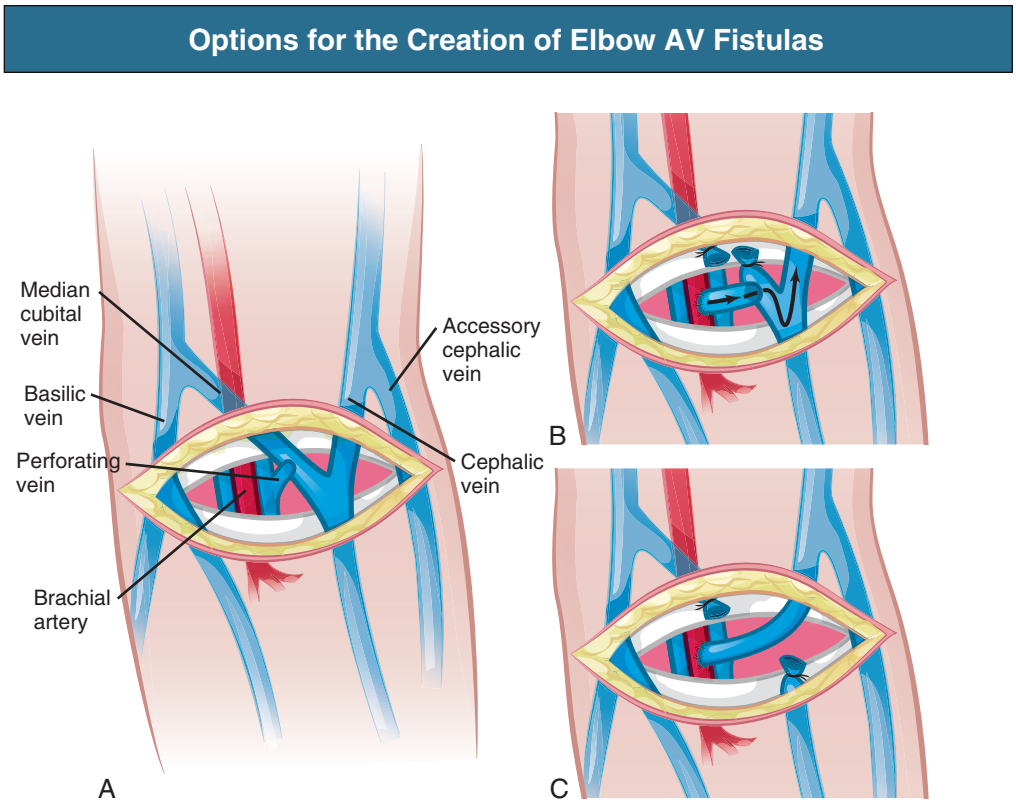

Figure 91-2 Options for the creation of elbow arteriovenous (AV) fistulas. **A,** Brachiocubital AV fistula. **B,** Brachiocubital AV fistula with ligation of proximal cubital vein. **C,** Brachiocephalic AV fistula.

Table 91-3 Early failure and 1-year patency rates of brachiobasilic AV fistulas.

anterolateral position. The original technique of brachiobasilic AV fistula construction is a two-step approach. First, a brachiobasilic anastomosis is constructed, and in the second operation, usually after 6 weeks, the arterialized vein is mobilized into a subcutaneous position, becoming accessible for needling (Fig. 91-3); at the present time the brachiobasilic AV fistula creation may be performed as a one-stage surgical procedure, with elevation or transposition of the vein to a subcutaneous and anterolateral position at the time of creation of the AV anastomosis. A nonrandomized study comparing the different techniques of brachiobasilic AV fistula creation reported 86% to 90% 1-year patencies in all groups, with only 5% to 7% nonmaturation rates.[16] Primary failure rates of 2% to 23% with 1-year patencies varying from 55% to 89% have been reported (Table 91-3).[13,17-20] In comparison with brachiocephalic fistulas, brachiobasilic AV fistulas are more likely to mature, although they are more susceptible to late thrombosis. However, a randomized study showed similar patencies of brachiocephalic and brachiobasilic AV fistulas.[13]

The technique of subcutaneous placement of the basilic vein has several advantages over forearm or upper arm graft implantation, with less infection and thrombosis. A meta-analysis comparing brachiobasilic AV fistulas with prosthetic grafts has shown superiority of the brachiobasilic AV fistula in primary and secondary patency rates, and it should therefore be used early in difficult access cases before the use of prosthetic grafts.[21]

NONAUTOGENOUS PROSTHETIC VASCULAR ACCESS

When autogenous AV fistula creation is impossible or the fistulas have failed, graft implantation should be considered as a vascular access conduit. Xenografts such as the ovine sheep graft (Omniflow) are popular materials as an alternative access conduit, with acceptable patency and low infection rates. The most frequently used implants are prosthetic grafts made of either polyurethane (Vectra)

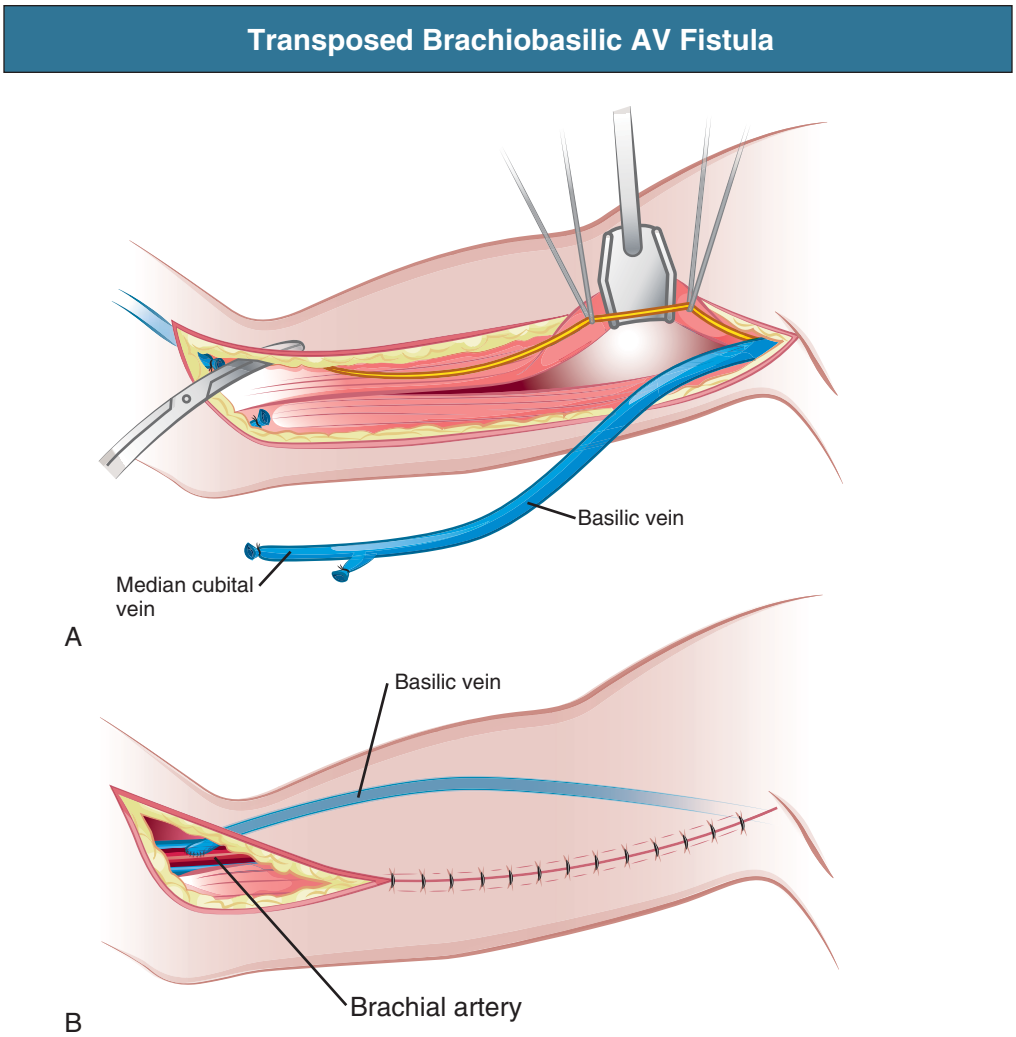

Figure 91-3 Transposed brachiobasilic arteriovenous (AV) fistula. A, Dissection of the basilic vein. **B,** Anterolateral transposition and brachial artery anastomosis.

or polytetrafluoroethylene (PTFE). These prosthetic grafts can be implanted in a wide variety of locations and configurations in the upper limb (Fig. 91-4). At present, early cannulation of PTFE grafts (within 24 hours of surgery) is feasible because of newer graft compositions. Short-term functional patency is usually good, but stenosis (mostly at the graft-vein anastomosis) may lead to thrombotic occlusion within 12 to 24 months. The primary patency rates of prosthetic AV grafts vary from 60% to 80% at 1 year and from 30% to 40% at 2 years of follow-up. Secondary patency ranges from 70% to 90% and from 50% to 70% at 1 and 2 years, respectively.[22-25] Intimal hyperplasia, with smooth muscle cell migration and proliferation and matrix deposition, is the major cause of stenosis formation and thrombosis. The cause of the intimal hyperplasia is uncertain, although the high wall shear stress, caused by the access flow, may denude the endothelial cell layer, resulting in platelet adhesion and initiation of a cascade of proteins that stimulate the smooth muscle cells to proliferate and to migrate.

Measures to Improve Graft Patency

Numerous experimental and clinical studies have defined the influence of graft material and graft design on AV graft patency. Modulating the geometry of the arterial inlet or venous outlet of the graft may have a beneficial effect on intimal hyperplasia. Clinical studies using tapered (at the arterial side of the graft) grafts did not improve patency rates, nor did cuff implantation at the venous anastomosis.[26,27] However, primary patency did improve with the use of a cuff-shaped prosthesis (Venaflo).[28] Grafts such as polyurethane, which are more distensible, could in principle influence intimal hyperplasia by the better matching of the stiff prosthesis with the compliant vein at the anastomotic site; however, in clinical studies, this feature was not of proven benefit.[29]

PHARMACOLOGIC APPROACHES FOR ACCESS PATENCY

Aspirin, ticlopidine, and dipyridamole have some beneficial effect in maintaining patency of AV fistulas and grafts but increase the risk of hemorrhage.[30] Clopidogrel may also be effective in reducing thrombosis of AV grafts and fistulas. Warfarin reduces AV graft thrombosis but increases the risk of hemorrhage.[31] A large trial showed that dipyridamole plus aspirin had a significant but modest effect in reducing the risk of stenosis and improving the duration of primary unassisted patency of newly created AV grafts.[32] In a large randomized study, clopidogrel improved primary radiocephalic fistula function but not maturation.[33] Given the available evidence, antiplatelet agents should be used routinely in patients with AV

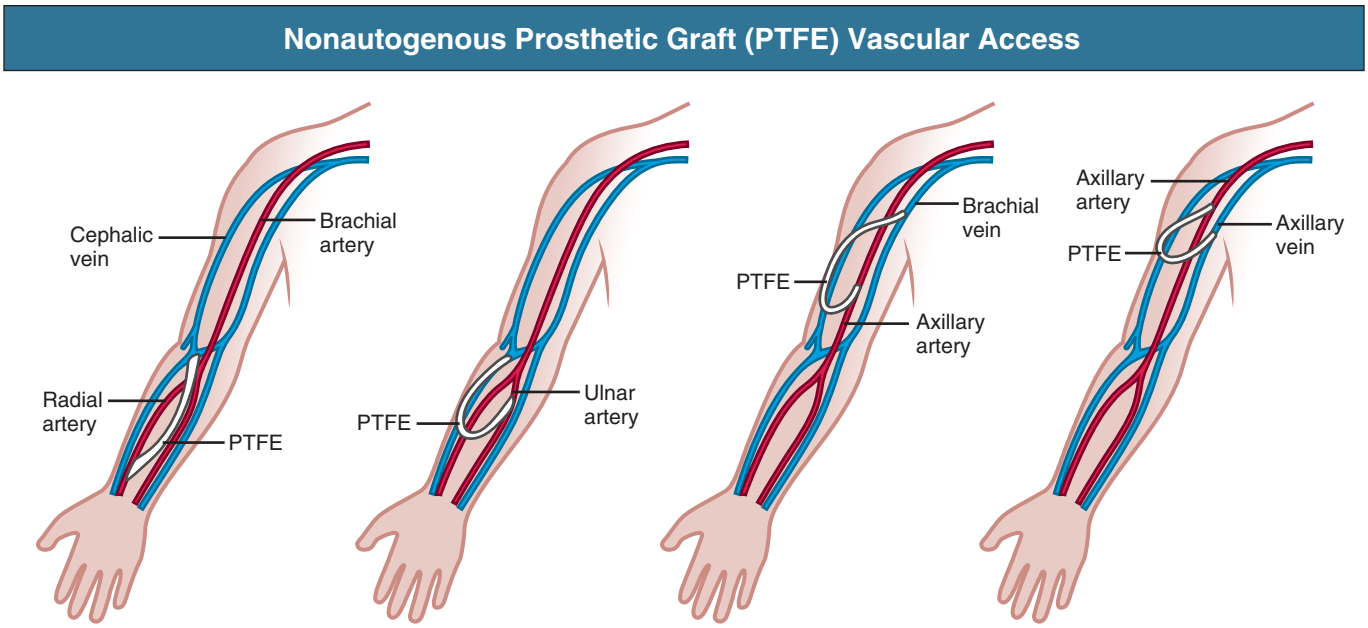

Figure 91-4 Nonautogenous prosthetic graft (polytetrafluoroethylene *[PTFE]*) vascular access. Straight and loop configuration in upper limb.

grafts but not fistula. There is no role for the routine use of warfarin (coumadin), particularly in view of the recent evidence of adverse effects of warfarin in HD patients.

There have been suggestions that other drugs, such as calcium channel blockers and angiotensin-converting enzyme inhibitors, might be associated with improved AV fistula patency, but this requires confirmation with randomized studies.[34] Fish oil reduced AV graft thrombosis in one randomized trial.[35]

Efforts have been made to inhibit the development of intimal hyperplasia pharmacologically with the cytotoxic agent paclitaxel. Paclitaxel wraps have been shown to reduce prosthetic graft intimal hyperplasia in animal models but have yet to be clinically evaluated.

LOWER LIMB VASCULAR ACCESS

Probably the only indication for lower limb vascular access is bilateral central venous or caval obstruction, which endangers the outflow of upper limb AV fistulas. Saphenous and superficial femoral vein transposition is a primary option for thigh AV fistulas, although this carries a relatively high risk of distal ischemia. If clinical evaluation indicates incipient ischemia, primary flow reduction by tapering of the anastomosis is indicated to prevent ischemia.[36] Prosthetic graft implantation in the thigh bears a high risk of infection and septicemia.

VASCULAR ACCESS COMPLICATIONS

Nonmaturation of Arteriovenous Fistulas

Fistulas that fail immediately do so as a consequence of poor selection of vessels, poor surgical technique, or postoperative hemodynamic instability. Vascular abnormalities, including stenoses, occlusions, and accessory veins, will be identified in virtually all early failures, and more than half of the stenoses are in the perianastomotic area of nonmatured fistulas. Arterial inflow stenoses of more than 50% vessel diameter reduction coupled with poor flows are seen in less than 10% of nonmaturing fistulas, but if identified, they should undergo angioplasty. If this fails to improve fistula flow rates, it is unlikely that surgical bypass will be of help. Anastomotic and swing segment (in which the vein has been mobilized and swung over to the artery) stenosis may be treated percutaneously or surgically, depending on local expertise.

The diameter of the angioplasty balloon is chosen to correspond to the diameter of the vessel next to the stenotic or occlusive lesion and is usually not smaller than 5 mm for venous stenoses and not smaller than 4 mm for arterial or anastomotic stenoses. Ultrahigh-pressure balloons inflatable up to 36 atm are used when necessary to abolish the waist of the stenosis on the balloon. Apart from local infection, contraindications to balloon angioplasty are anastomotic stenoses in fistulas less than 4 to 6 weeks after surgical construction, which increases the risk of anastomotic disruption at angioplasty. Percutaneous balloon angioplasty is further discussed in Chapter 92.

The surgical approach is to reconstruct the AV fistula, usually with use of local anesthesia. The anastomosis is exposed and ligated; the vein can then be divided, mobilized proximally, and reanastomosed to the proximal radial artery.

A prospective nonrandomized study of 64 patients showed that outcomes were similar with angioplasty or surgery.[37] Restenosis rates were significantly higher after angioplasty, but overall costs of treatment were similar.

Nonmatured fistulas are rescued by angioplasty of stenoses or occlusions, ligation of accessory veins, or both. Accessory veins can be obliterated through coil embolization, percutaneous ligation, or surgical ligation. The use of coils with a diameter of 1 mm in excess of the target vessel diameter will prevent coil dislocation. Although ligation of accessory veins is usually performed in a single surgical intervention, three variants of vein ligation in a stepped approach have also been described.[38] By use of this approach, surgery is limited to ligation of the accessory veins if the AV fistula appears to be of adequate size to allow cannulation. If the fistula is still considered to be too small, the median cubital vein is ligated. If the AV fistula is still believed inadequate, temporary banding of the main venous channel is performed. Apart from surgical ligation, accessory veins can also be ligated percutaneously. In predialysis

patients the risk of renal function deterioration as a result of radiocontrast load can be overcome by performance of ultrasound-guided angioplasty.[39]

Stenosis and Thrombosis

The development of vessel stenosis in both autogenous AV fistulas and prosthetic AV grafts is usually initiated by intimal hyperplasia caused by migrating and proliferating vessel smooth muscle cells, which form extracellular matrix. Progressive stenosis leads to access flow deterioration and subsequently thrombotic occlusion. Prophylactic repair of access stenoses may prevent thrombosis and prolong access patency.

Autogenous Fistula Stenosis or Thrombosis

Arteriovenous fistula stenosis should be treated if the vessel diameter is reduced by more than 50% and is accompanied by a reduction in access flow (25% flow decline between measurements or absolute flow below 500 ml/min) or in measured dialysis dose. Other indications for intervention are difficulties in cannulation and prolonged bleeding time after decannulation, indicating high intra-access pressure caused by outflow vein stenosis. Venous pressure above 250 mm Hg with a blood flow of 200 ml/min is also suggestive of stenosis. In AV fistulas, 55% to 75% of the stenoses are close to the AV anastomosis, 25% in the venous outflow tract and 15% in the arterial inflow. In brachiocephalic and brachiobasilic AV fistulas, the typical location for stenosis (besides the anastomosis) is at the junction of the cephalic with the subclavian vein (cephalic arch) and the basilic with the axillary vein (junctional stenosis). Initial evaluation of suspected access stenosis is by ultrasound; angiography is used subsequently when intervention is planned.

Endovascular treatment by percutaneous transluminal angioplasty (PTA) is the first option for arterial inflow and venous outflow stenoses and junctional stenoses, with the option of stent placement.[40] These techniques are discussed further in Chapter 92. Some stenoses may not be sufficiently dilated by conventional balloons (12 to 16 atm), and in these patients, cutting balloons or ultrahigh-pressure balloons (up to 36 atm) may be applied. Drug-eluting balloons may prevent restenosis; however, outcome data for this approach are not yet available. Anastomotic stenoses in forearm and upper arm fistulas are primarily treated with PTA; however, surgical revision with a more proximal reanastomosis for swing segment stenosis is indicated in failed PTA of radiocephalic AV fistula.

Fistula thrombosis should be treated as soon as possible because timely declotting allows immediate use of the access without the need for a central venous catheter; fistula salvage usually requires intervention within 6 hours (grafts may be salvaged up to 24 hours). The duration and site of AV fistula thrombosis as well as the type of access are important determinants of treatment outcome. Thrombi become progressively fixed to the vein wall, which makes surgical removal more difficult. When the clot is localized at the anastomosis in radiocephalic and brachiocephalic fistulas, the outflow vein may remain patent because of continuing flow in its tributaries, making it possible to create a new proximal anastomosis.[41]

Thrombolysis can be performed mechanically or pharmacomechanically.[42-44] Whereas the immediate success rate is higher in AV grafts than in autogenous AV fistulas (99% vs. 93% in forearm fistulas), the primary patency rate of the forearm AV fistula at 1 year is much higher (49% vs. 14%). One-year secondary patency rates are 80% in forearm and 50% in upper arm AV fistulas.

In AV fistulas, the combination of a thrombolytic agent (urokinase or tissue plasminogen activator [tPA]) with balloon angioplasty resulted in an immediate success rate of 94%.[43]

Arteriovenous Graft Stenosis or Thrombosis

The most common cause of graft dysfunction and thrombosis is venous anastomotic stenosis. Because grafts should be implanted only in patients with exhausted peripheral veins, vein-saving procedures such as PTA or patch angioplasty are preferred to graft extensions to more central venous segments. When a stent or a patch fails, graft extension is still possible. Graft monitoring by access flow measurement is recommended; with preemptive endovascular treatment, this may diminish graft thrombosis but does not extend graft patency.

Intragraft (or midgraft) stenoses are found in the cannulation segment of grafts. They result from excessive ingrowth of fibrous tissue through puncture holes. These stenoses can be treated by PTA, graft curettage, or segmental graft replacement. When only a part of the cannulation segment is replaced, the access can be used for HD without the need of a central venous catheter. When restenosis occurs in a nonexchanged part of the graft, this can be replaced after healing of the new segment.

Prosthetic graft thrombosis can be treated with various percutaneous techniques and tools, including combinations of thromboaspiration, thrombolytic agents such as tPA, and mechanical thrombectomy. An initial success rate of 73% and primary patency rates of 32% and 26% at 1 and 3 months, respectively, are reported.[45-48] It is important to perform thrombolysis as soon as possible to avoid the need for a central venous catheter and as an outpatient procedure to decrease costs, whenever possible. Postprocedural angiography to detect and to correct inflow, intra-access, or venous outflow stenosis is mandatory.

When endovascular treatment fails or is not possible, surgical thrombectomy may be performed with a Fogarty catheter after venotomy, with correction of the underlying obstruction. On-table angiography should be performed after completion of thrombectomy of both the arterial and venous limbs of the graft.

Central Venous Obstruction

In the majority of patients, central vein obstruction is a result of previously inserted central venous catheters or pacemaker wires. In 40% of patients with subclavian vein and 20% with jugular vein catheters, venous stenosis or occlusion will develop. Chronic swelling of the access arm is the most important sign, usually with prominent superficial collateral veins around the shoulder. The indications for intervention by PTA and stent placement are severe and disabling arm swelling, finger ulceration, and pain or inadequate HD. Contrast angiography of the access and complete venous outflow tract must be performed because the central veins can be difficult to examine with ultrasound in their retroclavicular position.

Endovascular Intervention

Endovascular intervention is the first option for central venous obstruction treatment. PTA alone results in low primary patency rates of 10% or less at 1 year, and numerous restenoses may develop. Primary or additional stent implantation gives a much better outcome, with 1-year patency rates up to 56% or higher.[49,50] Reinterventions are usually required to maintain patency and to achieve long-term clinical success.

Stent placement should avoid overlapping the ostium of the internal jugular vein because this vein is essential for future placement of central venous catheters. Similarly, a stent placed in the innominate vein should not overlap the ostium of the contralateral vein; otherwise, contralateral stenosis may occur and preclude future use of the contralateral limb for access creation.

Surgical Intervention

When interventional treatment of central venous obstruction fails, surgical revision with bypass grafting is indicated. Surgical bypass to the ipsilateral jugular vein or contralateral subclavian or jugular vein is the first option in these patients. Alternative surgical approaches for upper limb vascular accesses with compromised venous outflow are axillary vein to femoral, saphenous, or popliteal vein and right atrial bypasses.[51] In case of bilateral obstruction of the mediastinal veins, including the superior vena cava, it will not be possible to sustain upper limb access, and lower limb access will be required.

Ultimately, ligation of the upper limb access can be considered, which will relieve local symptoms but loses a valuable dialysis access.

Vascular Access–Induced Ischemia

Vascular access–induced upper limb ischemia is a serious complication that without prompt intervention may lead to amputation. The incidence of symptomatic ischemia varies from 2% to 8% of the HD population.[52] Elderly patients, diabetics, and patients with peripheral or coronary arterial occlusive disease are most at risk of ischemia. In addition, previous ipsilateral vascular access increases the risk. Access-induced ischemia occurs more often with proximally located fistulas. These high-flow AV fistulas induce a steal phenomenon with lowering of distal perfusion pressures, and when collateral circulation is inadequate, symptoms may occur. Pain during HD is a characteristic early symptom. A grade 1 to 4 classification for access-induced ischemia can be used to outline the severity of the disease; this ranges from minor symptoms to finger necrosis.

- Grade 1: pale and blue or cold hand without pain
- Grade 2: pain during exercise or HD
- Grade 3: ischemic pain at rest
- Grade 4: ulceration, necrosis, and gangrene

For grades 1 and 2, conservative treatment of ischemia is advocated. With grades 3 and 4, interventional treatment is mandatory.

Diagnosis of Ischemia

Physical examination, including observation and palpation of peripheral vessels, may be inadequate and misleading for the diagnosis of symptomatic ischemia. Additional noninvasive testing with measurement of digital pressures and calculation of the digit-brachial index, transcutaneous oximetry ($TcPO_2$), ultrasound of forearm arteries, and access blood flow measurement are important steps in the diagnosis and decision-making process. Finally, contrast angiography with visualization of the upper extremity arterial tree from the proximal subclavian artery to the distal palmar arches with and without AV fistula compression to enhance distal flow is obligatory to outline the strategy for treatment and to determine whether interventional or surgical options are preferred.

Endovascular and Surgical Management of Ischemia

The treatment strategy depends on the cause of the ischemia. Inflow arterial obstruction and distal arterial lesions are recanalized with small-caliber balloons or stent placement[53]; high-flow AV fistulas are suitable for flow-reducing procedures such as access banding and arterial inflow reduction by an interposition graft to a smaller forearm artery (revision using distal inflow) (Fig. 91-5).[54,55] Steal in itself may be cured by ligation of the artery distal to the AV anastomosis (distal radial artery ligation). In most patients, it is necessary to add a saphenous vein or prosthetic graft bypass to the forearm arteries to augment distal hand perfusion (distal revascularization and interval ligation; Fig. 91-6). The results of these procedures are usually good, with relief of symptoms and preservation of the access site (Table 91-4).[56-60] A simpler alternative to the distal

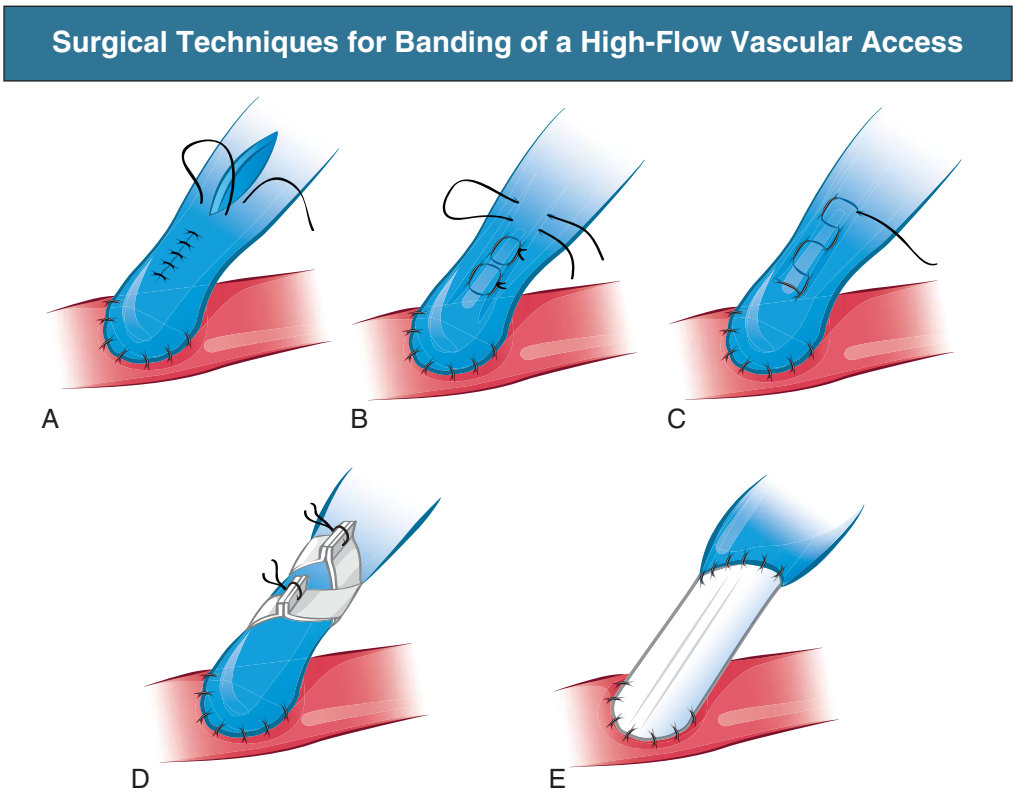

Figure 91-5 Surgical techniques for banding of a high-flow vascular access. A, Open venoplasty. **B,** Interrupted mattress suturing. **C,** Continuous mattress suturing. **D,** PTFE banding. **E,** polytetrafluoroethylene (PTFE) interposition graft. The choice of technique is made by the surgeon on a case-by-case basis.

revascularization–interval ligation procedure is the proximal AV anastomosis technique, in which the AV anastomosis at the elbow is disconnected and moved to the axilla, with anastomosis to the axillary artery by means of a graft interposition.[61] The minimally invasive limited ligation endoluminal-assisted revision procedure has been described; this procedure uses a minimally invasive percutaneous technique with banding of the access over a 4-mm balloon.[62]

Intraoperative digital pressure measurement or $TcPO_2$ is mandatory to guarantee an adequate surgical intervention with acceptable outcome. A digital-brachial pressure index above 0.60 or $TcPO_2$ above 40 mm Hg is indicative of sufficient distal hand perfusion. In some patients, AV fistula ligation and transition to chronic catheter dialysis access or a change in renal replacement modality to peritoneal dialysis may be the only solution.

Distal Revascularization-Interval Ligation (DRIL) for Ischemia in an Upper Arm Vascular Access

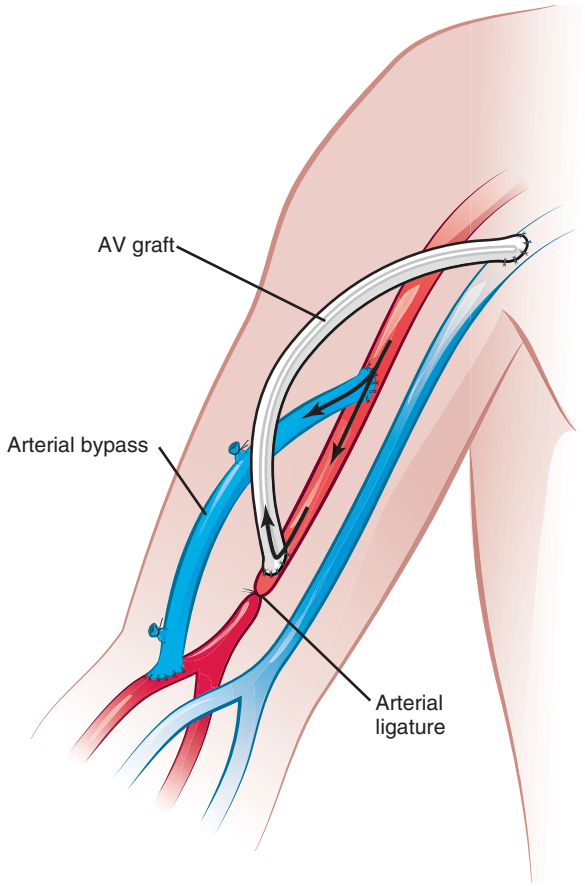

Figure 91-6 Distal revascularization–interval ligation for ischemia in an upper arm vascular access. *AV,* Arteriovenous.

CENTRAL VENOUS CATHETER ACCESS

Central venous catheters are still widely used as vascular access for HD. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS)[63] indicate that 25% of HD patients in the United States are dialyzed with catheters; in other countries the use of catheters is even more common (Belgium, 41%; United Kingdom, 28%). Central venous catheters are the preferred vascular access only for patients who present with acute kidney injury and for patients with chronic kidney disease without permanent AV access or with failed vascular access. Two types of catheters are used in practice: nontunneled catheters for short-term dialysis, with a limited use and high morbidity; and tunneled cuffed catheters, which can be used up to several months with lower morbidity. The physical characteristics (i.e., design and geometry) not only influence the performance (blood flow rate, recirculation, and resistance) but also affect the overall efficiency of the HD therapy and the morbidity risk (infection, thrombosis).

Nontunneled Catheters

Single- or double-lumen catheters are usually made of polymers (polyethylene, polyurethane), enabling a simple and direct implant possibility. The length of the catheter must be chosen in accordance with the insertion site. The femoral route requires catheters of 30 to 35 cm in length for the distal tip to be located in the inferior vena cava. The internal jugular vein route needs shorter catheters of 20 to 25 cm in length, with tip location at the inferior vena cava–right atrium junction. The subclavian vein should not be used because of the very high risk of subsequent venous stenosis. For sufficient blood flow rates to be achieved, the diameter of these catheters must be ideally 12 to 14 French. It is recommended that the use of nontunneled catheters not exceed 7 days.

Tunneled Catheters

Tunneled central venous catheters have two lumens, each having a length of 40 cm, 10 cm of which is tunneled under the skin; the cannulae are made of synthetic polymer with a large internal lumen and a Dacron cuff to ensure subcutaneous anchoring. The catheter characteristics rely on the type of polymer, design, and geometry (double-lumen catheters, dual catheters, split catheters). The use of

a tunneled central venous catheter is associated with reduced morbidity as well as better and constant performance compared with uncuffed catheters.[64]

Both tunneled and nontunneled catheters are inserted percutaneously by the Seldinger technique and ultrasound guidance. These techniques are described in Chapter 92. The internal jugular vein and femoral vein routes are preferred because of ease of implantation and low risk of complications, such as central vein stenosis (Fig. 91-7).

Catheter Infection

Catheter-related bloodstream infections are a significant cause of morbidity and mortality in HD patients. Results of the Hemodialysis (HEMO) study indicate that patients with central venous catheters have an increased relative mortality risk of 3.4 compared with patients with AV fistulas. Switching from central venous catheters to AV fistulas decreases the relative mortality risk to 1.4.[65] The most likely explanation for this increased mortality risk is infection and sepsis related to the central venous catheter, including exit site infection. Typical infection rates are three episodes of infection per 1000 tunneled catheter–days and higher with nontunneled catheters.[66] These localized infections can progress to metastatic complications of osteomyelitis, septic arthritis, epidural abscess, and endocarditis. Various societies have issued recommendations for the management of catheter infections.[67] A recommended treatment algorithm is shown in Figure 91-8.

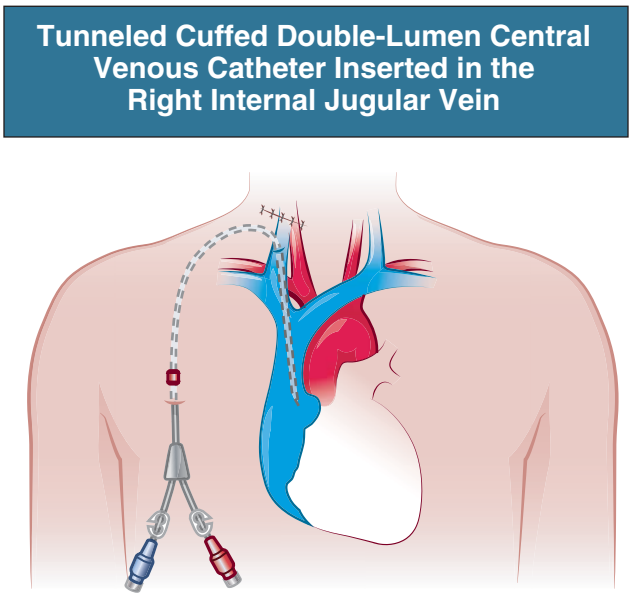

Figure 91-7 Tunneled cuffed double-lumen central venous catheter inserted in the right internal jugular vein.

Infections Involving Temporary Catheters

When a temporary dialysis catheter becomes infected, it should always be removed. There is no role for trying to salvage temporary catheters.[67]

Exit Site Versus Tunnel Track Infections

An exit site infection is a localized cellulitis confined to the 1 to 2 cm where the catheter exits the skin. The majority of these infections respond well to systemic antibiotics and meticulous exit site care, and the removal of the catheter is generally not required.[67] However, exit site infections can progress to tunnel track infections, which involve the potential space surrounding the catheter more than 2 cm from the exit site (Fig. 91-9). Patients with a tunnel track infection sometimes but not always have an associated exit site infection; untreated, they can rapidly develop bacteremia. Patients with a tunnel track infection present with fever as well as local signs of pain, swelling, fluctuance, and erythema along the track of the catheter. Because tunnel track infections involve a potential space, in an area with limited vascular supply, and an implanted synthetic material, they respond poorly to antibiotics alone and require catheter removal.[67]

Catheter-Associated Bacteremia

When a patient with a dialysis catheter has a fever, catheter infection must always be considered. If the patient does not have a clear and

convincing alternative explanation for the fever, blood culture specimens should be obtained peripherally as well as through the catheter, and the patient should be started on antibiotic therapy, which is subsequently adjusted on the basis of culture results.[67] The most common organism is *Staphylococcus aureus,* although a wide range of gram-positive and gram-negative organisms have been reported (Table 91-5). The percentage of patients with methicillin-resistant *S. aureus* (MRSA) varies greatly among centers, with higher rates associated with greater antibiotic use. An aminoglycoside or a cephalosporin is a good choice for gram-negative coverage; however, local microbiologic epidemiology must be taken into consideration, especially with regard to antibiotic resistance.

Catheter Removal

The decision to remove a tunneled cuffed dialysis catheter because of an episode of catheter-associated bacteremia is not straightforward. The clinical condition of the patient and response to initial therapy, the presence of metastatic complications, the infecting organism, and the availability of other vascular access sites must all be taken into consideration before a treatment plan is selected (see Fig. 91-8).

The conventional approach is to remove the catheter with interval replacement at a different site after the infection has resolved. Although this is effective, it leads to an additional temporary catheter if dialysis is needed before the catheter can be replaced. Attempts to "salvage" an infected catheter with systemic antibiotic therapy lead to resolution of infection in only about 30% of patients. Another treatment option is to combine systemic antibiotics with antibiotic "lock" solutions. Many different cocktails of antibiotics mixed with either heparin or citrate have been tested; a popular regimen is vancomycin 2.5 mg/ml, gentamicin 1 mg/ml, and heparin 2500 U/ml. Infection clearance rates of 50% to 70% are reported with antibiotic locking.

Several studies have reported that exchange of the catheter over a guidewire 48 hours after initial antibiotic treatment is more effective than treatment with antibiotics alone and is as effective as removal of the catheter and delayed replacement, with the advantages of only one invasive procedure and preservation of the venous access site.[68] There are no published randomized trials of antibiotic locking or catheter exchange over a guidewire.

Prevention of Infection

The most important measure to prevent catheter infection is meticulous handling of the catheter at all times. The catheter should be inserted with use of maximal sterile precautions. The dialysis nurses need procedures for accessing the catheters under strict sterile conditions, and it is of the utmost importance that these catheters never be accessed by untrained personnel. Data from randomized trials indicate that antibiotic lock solutions significantly reduce the incidence of infection.[69] Topical application of mupirocin ointment to tunneled exit sites has been reported to reduce the incidence of catheter-associated bacteremia.

Catheter Obstruction

Catheter obstruction may be caused by endoluminal fibrin deposits, restricting the catheter lumen or obstructing catheter side holes at the tip, or external fibrin sleeves surrounding the catheter, resulting in inadequate flow and excessive extracorporeal blood pressure alarms during the dialysis session. Depending on the location of the fibrin clot (arterial or venous line), there may be high negative arterial pressure (obstruction at the arterial catheter line) or high positive venous pressure (obstruction at the venous catheter line).

Prevention of clot formation in the catheter tip during the interdialytic period is crucial. This is achieved by installing an antithrombotic lock solution (trisodium citrate 30% is superior to standard heparin or low-molecular-weight heparin).[70] A certain amount of the antithrombotic lock solution may leak into the circulation through side and central catheter holes, facilitating catheter clot formation while increasing risk of hemorrhage. Regular use of low-dose warfarin or antiplatelet agents has failed to improve catheter function in dialysis patients in randomized trials.

To correct catheter dysfunction, it is recommended that the catheter lumen be cleaned periodically by application of a fibrinolytic agent (urokinase) as a lock solution or by continuous infusion on both arterial and venous lines. Occluded catheters are reopened either by a mechanical method (brush) or pharmacologically (urokinase). Removal of the fibrin sleeve may be achieved by lasso wire stripping or by infusion of a fibrinolytic solution (urokinase) for 3 to 6 hours. Alternatively, the catheter may be exchanged over a guidewire.

CHAPTER 92

Diagnostic and Interventional Nephrology

W. Charles O'Neill, Haimanot Wasse, Arif Asif, and Stephen R. Ash

A variety of procedures are essential to the care of nephrology patients and include ultrasound, renal biopsy, insertion of hemodialysis and peritoneal dialysis (PD) catheters, creation of arteriovenous (AV) fistulas, and diagnostic and interventional procedures on hemodialysis accesses. These procedures have traditionally been performed by other specialists, and this may lead to fragmented care. The desire to provide greater continuity of care has led an increasing number of nephrologists to perform these procedures—the field of diagnostic and interventional nephrology. It is most developed in the United States, where the American Society of Diagnostic and Interventional Nephrology (www.asdin.org) has established training standards and certification procedures. This chapter covers ultrasound, insertion of dialysis catheters, and interventions on vascular access, focusing on the applications of these procedures and their performance by nephrologists. Renal biopsy is covered in Chapter 6, and placement of AV fistulas and AV grafts in Chapter 91.

ULTRASOUND

An important reason for nephrologists to be involved in ultrasound procedures is that many of the findings on ultrasound are not specific and require clinical correlation. The role and interpretation of ultrasound are further covered in Chapter 5.

Applications and Limitations of Ultrasound

Ultrasound is an excellent tool for examination of the kidneys and urinary tract. Under optimal conditions, both kidneys, the renal artery and vein, the proximal and distal ureter (when enlarged), and the bladder can be visualized. The ureter is usually apparent only when it is dilated. The middle portion of the ureter is usually obscured by overlying bowel but still may be visible when it is very dilated. In transplants, the entire ureter can be visualized, even when it is not markedly dilated, because of the proximity to the probe and the lack of overlying bowel. In very ill patients who cannot be optimally positioned or cannot control their breathing or have abdominal wounds or distention, views of the kidneys may be limited, but it is still possible in most of these patients to determine whether hydronephrosis is present.

Chronic Kidney Disease

Ultrasound is indicated in any patient with chronic kidney disease (CKD) to establish renal size and to rule out polycystic kidney disease or urinary tract obstruction. Small, echogenic kidneys indicate severe irreversible disease, eliminating the need for a biopsy.[1]

Acute Kidney Injury

Although the diagnostic yield is very low in patients in whom the basis for renal failure is likely to be acute tubular necrosis or prerenal causes, ultrasound is still indicated in certain patients to rule out obstruction and to identify preexisting CKD.[2]

Renal Transplant

Ultrasound is indicated when there is an acute decline in renal transplant function, because urinary obstruction is common in this setting.[3] In the immediate post-transplantation period, Doppler evaluation of renal blood flow should also be performed to rule out thrombosis. Additional indications in transplant patients are pain, swelling, ipsilateral leg edema, and infection. Another important indication in both native and transplanted kidneys is guidance for percutaneous biopsy, nephrostomy, or drainage of fluid collections.

Renal Biopsy

Ultrasound is the method of choice to guide percutaneous renal biopsy.[4] Except in rare patients, computed tomography offers no advantages over ultrasound[5] and results in unnecessary irradiation. This is discussed further in Chapter 6.

Urinary Bladder

Ultrasound is the procedure of choice for measurement of postvoid residual volume because it is painless and sufficiently accurate[6] and, when a scanner is readily available, a simple task. Additional indications include checking the location and patency of Foley catheters and examination of the distal ureters. Placement of the catheter in the proximal urethra is uncommon but not rare, and obstruction of catheters is frequent, so examination of the bladder should always be considered when urine output decreases. Prostatic hypertrophy, prostatitis, bladder carcinoma, mucosal edema, blood clots, stones, stents, and other foreign bodies can be recognized with ultrasound, but transabdominal ultrasound is not the appropriate test to rule out bladder cancer (which requires cystoscopy) or prostatic cancer (which requires transrectal ultrasound and biopsy).

Hemodialysis Access

Ultrasound is essential in the management of vascular access, including guidance of catheter insertion, evaluation of fistula dysfunction, preoperative vein mapping, and monitoring of access flow. Of these, the first two can be readily performed by nephrologists. Guidance of catheterization is best performed with a dedicated scanner but can be done with any scanner that has a vascular probe and does not require Doppler imaging. Examination of dysfunctional fistulas is also straightforward and does not necessarily require Doppler analysis. Vein mapping and monitoring of access flow are both best performed by an experienced vascular technician.

Renovascular Ultrasound

Doppler ultrasound of renal arteries and veins is a difficult study requiring an experienced operator and is not usually practical for nephrologists. Tracings from segmental arteries are more easily obtained and can be useful in diagnosis of renal artery stenosis and vein thrombosis. However, measurement of resistive index can be unreliable and nonspecific (it can be influenced by external factors such as systemic blood pressure and heart rate) and is of questionable usefulness in the evaluation of acute renal failure either in native

kidneys or transplanted kidneys. Doppler ultrasound is useful in distinguishing between cystic and vascular lesions and between renal vein and ureter.

Equipment

Important considerations in the choice of equipment are image quality, probe type and frequency, cost, size, portability, and output. Image quality is difficult to quantitate and is related to the number of elements (crystals) in the probe and the number of channels that can be processed. Probes should be electronic and in the frequency range of 2.0 to 5.0 MHz (up to 7.5 MHz for pediatric use) for abdominal imaging. Preferably, these should be variable frequency, curvilinear probes. Probes for vascular imaging are usually linear probes with a frequency of 7.5 to 12 MHz. For grayscale renal ultrasound, portable, lightweight scanners with good image quality are available; Doppler capability can add to the cost but is increasingly being offered as a standard feature. Larger and more expensive scanners are difficult to maneuver and have additional features that are of little use to the nephrologist. Controls on the scanner allow adjustment of scanning depth, focal length, time-gain compensation, sound intensity, and grayscale. Although this seems a daunting number of variables, adjustment is usually straightforward and mostly empiric. Images can be printed directly or digitally stored.

Procedure

Description of the scanning procedures cannot substitute for hands-on training because scanning is an acquired skill that requires practice. Ideally, the patient should be fasting for abdominal scanning to minimize interference from intestinal gas, but this is not essential for examination of kidneys and is of no consequence for examination of the bladder or transplanted kidneys. There must be an airtight connection between the probe and the skin, which is accomplished by placing gel on the probe or skin and applying firm pressure against the skin. To avoid compression of the vessels, minimal pressure should be applied for vascular examinations, with the use of more gel. Gel specifically designed for ultrasound should be used because other gels, such as lubricating gel, give poorer image quality. Ambient light should be dimmed to optimize viewing of the monitor.

The patient should be flat in the supine or lateral decubitus position with imaging through the abdomen for examination of native kidneys. Initial attempts should be made with the patient in the supine position before resorting to the lateral decubitus position. Imaging through the back is not recommended for diagnostic imaging because of sound attenuation by muscle and fascia and limitations on angling of the probe. Placement of the ipsilateral arm over the head, removal of pillows from under the head, and deep inspiration aid in moving overlying ribs superiorly. Transplanted kidneys and the urinary bladder are examined with the patient in the supine position, but he or she need not be completely flat.

Initially, longitudinal images should be obtained to determine maximal kidney length. On the right side, this view should be obtained through the liver if possible (Fig. 92-1, *A*). The probe should be oriented so that the upper pole is toward the left side of the image. The probe should then be rotated 90 degrees to obtain transverse views (Fig. 92-1, *B*), and the kidney is scanned from pole to pole to ensure visualization of the entire kidney. Examination of each kidney should include longitudinal images with adjacent liver or spleen if possible as well as transverse images through the mid-kidney and each pole.[7] Measurements other than length are of no clinical usefulness, and measurements of kidney volume are inaccurate and no better than length in judging kidney size.[8] Sagittal and transverse views of the urinary bladder are obtained with the probe just superior to the symphysis pubis and angled inferiorly (Fig. 92-1, *C* and *D*). Volume is obtained by multiplying the two transverse dimensions and the sagittal length by 0.523.[6] The technique for renal biopsy is discussed in Chapter 6.

Training and Certification

There are no data on what constitutes adequate training for renal ultrasound. Training is required for both performance and interpretation and should include didactic, hands-on, and supervised components. The last can vary considerably, depending on case volume and particularly type because any quantity of studies will be inadequate if the findings are all normal. Thus, the number of studies required for competence is inversely related to the frequency of pathology. Minimal qualifications for physician-sonographers have been established by the American Institute of Ultrasound in Medicine[9] and the American College of Radiology,[6] but neither organization has developed guidelines for limited abdominal ultrasound. The American Society of Diagnostic and Interventional Nephrology (www.asdin.org) has established training standards for ultrasound limited to kidneys and bladder that specify 50 hours of training and 125 studies (at least 80 being supervised and the remaining having confirmatory follow-up).[10] Because renal ultrasound is not usually a formal component of nephrology training, a course for nephrologists has been established in the United States (http://medicine.emory.edu/divisions/renal_medicine/renal-ultrasound/index.html).[7] Training and certification are available in vascular ultrasound but are not limited to applications specific to nephrology. Such training is important for vascular studies of kidneys but is not necessary for examination of dysfunctional AV fistulas and grafts (unless flow is measured) because this does not require Doppler analysis. There are currently no guidelines or training established for vascular ultrasound related to nephrology.

PERITONEAL DIALYSIS CATHETERS

Successful PD is dependent on proper catheter insertion and management. The feasibility, safety, and success of these procedures when they are performed by nephrologists have been well documented,[11-13] and this leads to greater use of PD. Chronic PD catheters are constructed of silicone rubber with a 5-mm external diameter and internal diameters of 2.6 to 3.5 mm. Some commonly used designs of PD catheters are shown in Figure 96-6. The intraperitoneal portion can be straight, straight with perpendicular silicone disks, or curled with side holes or T shaped with linear grooves or slots rather than side holes. These designs are created to diminish outflow obstruction. The subcutaneous portion is either straight or bent and has one or two extraperitoneal Dacron cuffs that prevent fluid leaks and bacterial migration around the catheter. The subcutaneous catheter shapes all provide a lateral or downward direction of the exit site. An upwardly directed exit site collects debris and fluid, increasing the risk of exit site infection. Currently, the method of placement of the catheter has more effect on the outcome than catheter choice does.

Catheter Insertion

The four techniques for PD catheter insertion are dissection (surgical), the Seldinger technique (blind or with fluoroscopy), peritoneoscopic, and laparoscopic.[14] The Seldinger and peritoneoscopic techniques are most frequently used by nephrologists. Peritoneoscopic insertion is a single-puncture technique using a small (2.2-mm

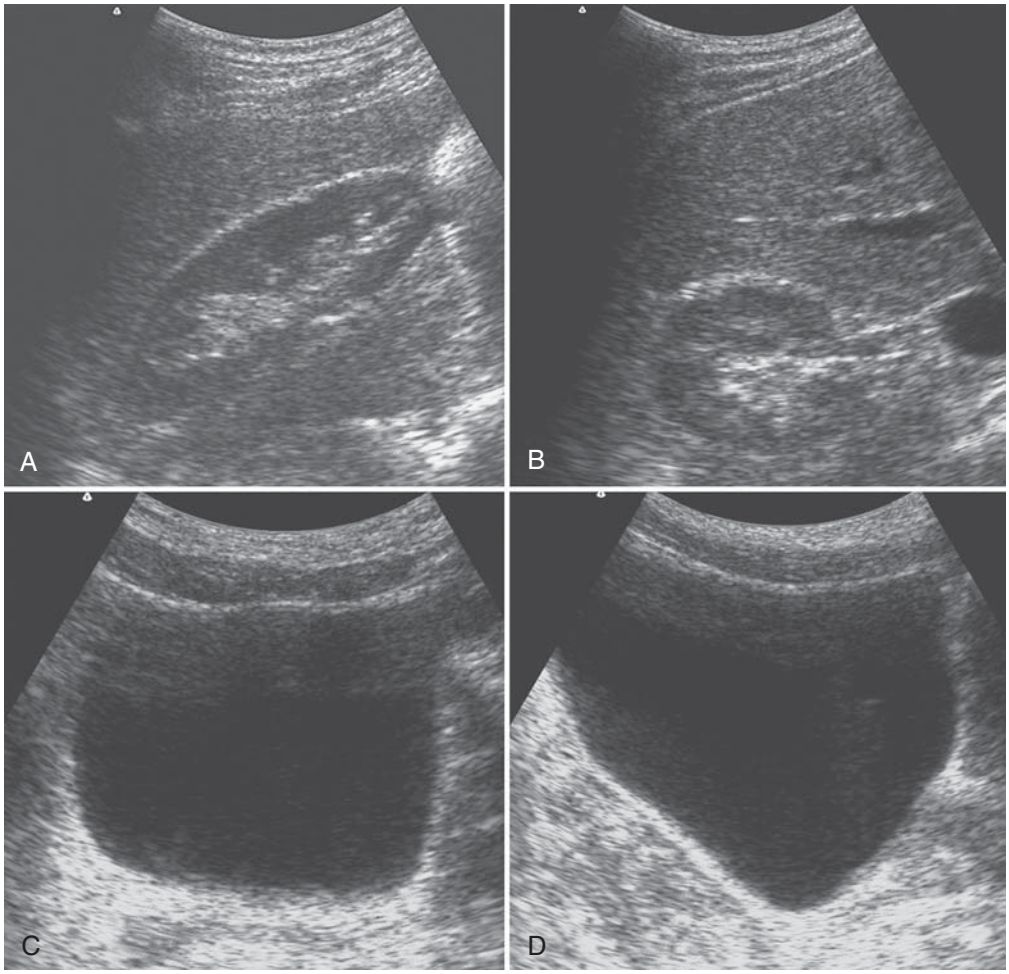

Figure 92-1 Imaging planes for renal and bladder sonography. A, Longitudinal image of right kidney. Upper pole should be on left side of the image. **B,** Transverse image of right kidney through the renal hilum. **C,** Transverse image of urinary bladder. Anteroposterior and mediolateral dimensions are obtained in this plane. **D,** Sagittal image of the urinary bladder. Superior portion of the bladder is to the left. Superoinferior dimension is obtained in this plane.

diameter) optical peritoneoscope for direct inspection of the peritoneal cavity and identification of a suitable site for the optimal intraperitoneal portion of the catheter. Peritoneoscopic placement is usually performed with local anesthesia (sometimes with conscious sedation) and manual infusion of about 1 liter of air. Laparoscopic techniques are performed with the patient under general anesthesia, with larger scopes, multiple insertion sites, and automated gas infusion. Both peritoneoscopic and laparoscopic techniques allow direct visualization of intraperitoneal structures.

The choice of technique must take into account the local experience with complications (pericatheter leakage, outflow failure, exit site and tunnel infection) and long-term catheter function associated with each technique, costs, ease and timely insertion of the catheter, and factors contributing to mortality risk (local vs. general anesthesia). Both randomized and nonrandomized studies have documented that the peritoneoscopic and fluoroscopic Seldinger techniques result in fewer catheter complications (infection, outflow failure, pericatheter leak) and improved catheter survival compared with surgical placement.[12,15] The superior results with peritoneoscopic placement may relate to direct visualization of the abdominal cavity, less tissue dissection, and avoidance of general anesthesia. Because tissue dissection is minimal, the catheter can be used immediately (after 36 hours), although a 2- to 3-week delay is recommended.[16]

For peritoneoscopic insertion (Fig. 92-2), a small skin incision (2 to 3 cm) is made and dissection is carried down only to the subcutaneous tissue.[23] The anterior rectus sheath is identified but not incised. A preassembled cannula with trocar and a spiral sheath is then inserted at a 40- to 50-degree angle into the abdominal cavity through the rectus muscle (Figs. 92-2, *A*, and 92-3). The trocar is then removed and replaced by the peritoneoscope to confirm the intra-abdominal position of the cannula (Figs. 92-2, *B*, and 92-4). Air is then infused (600 to 1000 ml) to separate visceral and parietal peritoneum. Alternatively, a Veress needle can be used.[17] Bowel loops, the dome of the bladder, and any intra-abdominal adhesions are identified. The cannula and spiral sheath are advanced into the pelvis (Fig. 92-2, *C*). The cannula and the peritoneoscope are then removed, the spiral sheath is dilated to 6-mm diameter (Fig. 92-2, *D*), and the catheter is inserted through the sheath by a stylet (Fig. 92-2, *E*). The deep cuff is implanted into the rectus muscle with use of an implanter tool without dissection of the anterior rectus sheath or the muscle (Fig. 92-2, *F*). A tunnel and an exit site are created (Fig. 92-5), and the superficial cuff is implanted into the subcutaneous tissue. The subcutaneous tissue is sutured with absorbable material; the skin is closed with nylon. No sutures are placed on the external rectus sheath or at the skin exit site.

The Seldinger technique using fluoroscopy begins with blunt dissection down to the level of the lateral border of the rectus sheath. A 22-gauge needle from a 5-French micropuncture set is inserted at an angle of 45 degrees, directed toward the lower pelvis into the peritoneum (ultrasound can be helpful). The location of the needle

within the peritoneal cavity is confirmed by injecting 3 to 5 ml of contrast material, which is seen surrounding bowel loops. A micropuncture 0.018-inch wire is then inserted through the needle under fluoroscopy. Once it is in the lower pelvis, a 5-French catheter is placed over the wire. Contrast material can again be injected to confirm the position. A 0.035-inch guidewire is then passed through the catheter, and dilators are advanced sequentially up to the final 18-French dilator and peel-away sheath. The guidewire is removed and the PD catheter is inserted over a metal stylet through the sheath, splitting the sheath as the deep Dacron cuff advances. This cuff is pushed into the rectus muscle while the sheath is in place, and the sheath is then removed around the cuff and catheter. The catheter is tunneled laterally with a tunneling tool.[18,19]

Burying the Peritoneal Dialysis Catheter

If the catheter will not be used immediately, it can be implanted (buried) under the skin for weeks to months before it is tunneled to the outside and used. The catheter is placed in the usual manner, then blocked with a plug and tunneled in a straight line under the skin. In some centers the catheter is tied off with silk suture and coiled into a pouch under the exit site. This allows ingrowth of tissue into the cuffs of the catheter without an opportunity for bacterial colonization and diminishes the incidence of early pericatheter infections.[20,21] Catheters buried in this fashion have been successfully used more than 1 year after insertion.[22] We recommend burial when the catheter will not be used for at least a month.

Complications of Peritoneal Dialysis Catheter Insertion

Bowel perforation is the most feared complication of catheter insertion. The incidence is 1% to 1.4% with surgical insertion[12,13] but 0% to 0.8% with the peritoneoscopic insertion.[11,13] The diagnosis is established by direct peritoneoscopic visualization of bowel mucosa, bowel contents, or hard stool or return of fecal material or emanation of foul-smelling gas through the cannula. Whereas some investigators suggest that this complication should be treated with surgical intervention,[24] successful conservative management of bowel perforation with bowel rest and intravenous antibiotics has also been reported.[19,25] To minimize the risk of perforation, a needle (such as a Veress needle) that is smaller and has a blunt, self-retracting end can be used instead of a trocar to gain access to the abdominal cavity.[17] Previous abdominal surgery is mentioned as a relative contraindication to PD because of intraperitoneal adhesions.[26,27] However, with peritoneoscopy, which can be used to identify intraperitoneal adhesions, assess their extent, and locate a suitable site for catheter placement, the incidence of bowel perforation is no higher than in patients without prior abdominal surgery, and the success rate exceeds 95%.[11,13]

Catheter Repositioning

Migration of the PD catheter to the upper abdomen is a frequent cause of catheter failure. A variety of techniques have been used for repositioning, including guidewire or stylet insertion, Fogarty catheters, and laparoscopy, and are feasible for nephrologists. The long-term success rate is only 27% to 48%,[28,29] probably because the migration of the catheter is the result of encasement by the omentum. Thus, insertion of a new catheter is required in many patients. Fogarty catheter manipulation is perhaps the most cost-effective, safe, and simple method. A Fogarty catheter is advanced into the PD catheter, and the balloon is inflated. Manipulation is performed by tugging movements to reposition the catheter into the pelvic area. Infusion and drainage of dialysate as well as radiography are performed to determine patency and position of the PD catheter, respectively.

Removal of Peritoneal Dialysis Catheters

A Tenckhoff curled or straight PD catheter can be safely removed without need for an operating room or general anesthesia.[16] Local anesthetic is infiltrated at the site of the primary incision, and dissection is carried down to the subcutaneous portion of the catheter by longitudinal incisions with scissors while the catheter is held with toothed forceps. The catheter is clamped with a hemostat, a nylon suture is placed in the catheter beyond the hemostat as a tag, and the catheter is cut between the two. Dissection is continued toward the deep cuff (Fig. 92-6), and additional anesthetic is infiltrated around the deep cuff. For catheters that have been in place for less than a month, blunt dissection is usually sufficient to free the deep cuff. Older catheters require sharp dissection. Exposure of the deep cuff

and the anterior rectus sheath is required. Once the deep cuff is separated from the surrounding tissue, the intraperitoneal portion of the catheter is gently withdrawn from the peritoneal cavity, and the defect in the rectus sheath is closed with an absorbable purse-string suture. The nylon tag is then pulled to expose the remaining subcutaneous portion of catheter segment, and dissection is performed in the direction of the superficial cuff. Once the superficial cuff is free, this portion of the catheter is removed through the primary incision site or the exit site. Absorbable suture material is used to close the subcutaneous tissue; nylon is used to close the skin. The exit site is not sutured.

Training and Certification

The American Society of Diagnostic and Interventional Nephrology has established training guidelines and criteria for certification of physicians in the insertion of PD catheters (www.asdin.org).[10] In addition to appropriate didactic training, there should be two practice insertions (into models, animals, or human cadavers), observation of two insertions into patients, and then six successful insertions into patients as primary operator.

TUNNELED HEMODIALYSIS CATHETERS

Central venous catheters are used as a temporary hemodialysis access, as a bridge to AV fistula or graft use, and when all other permanent access sites have been exhausted. Nontunneled catheters are used when a limited number of dialysis sessions is anticipated or there are contraindications to tunneled catheters (systemic infection, risk of bleeding) and are appropriate for use only in the inpatient setting. Tunneled catheters can be placed in both inpatient and outpatient settings, can be inserted at multiple vein locations, are relatively low in cost, and provide immediate access. However, there are significant disadvantages, including morbidity from infection and thrombosis and the risk of central vein stenosis or occlusion.[30,31] The role of the tunneled dialysis catheter in the provision of vascular access for hemodialysis is discussed further in Chapter 91.

Catheter Insertion

The right internal jugular vein is the preferred catheter location compared with the left internal jugular and subclavian vein sites; it provides a straight route to the right atrium, thereby reducing the risk of central vein stenosis. Catheters may also be placed in the femoral veins.

Catheter insertion is performed in a sterile setting, ideally in an operating room environment with fluoroscopy available or at a minimum in a dedicated procedure room with cardiac monitoring. Before cannulation the vein should be located by ultrasound to detect anatomic variation or venous thrombosis. The patient's neck is then prepared and draped in sterile fashion; under ultrasound guidance, the vein is cannulated with a micropuncture needle (18 to 22 gauge), and a micropuncture guidewire is inserted and positioned in the superior vena cava. The needle is then removed, and the micropuncture dilator is inserted over the guidewire so that it can be replaced with a standard guidewire. The use of the smaller needle rather than the standard 15-gauge needle minimizes trauma to the vein. A small subcutaneous incision is made adjacent to the dilator or guidewire, additional dilation is performed, and the catheter is placed over the guidewire, with care taken to hold the guidewire in place. If a tunneled catheter is to be placed, a catheter exit site is selected inferior to the clavicle and sufficiently lateral to the venotomy to avoid a kink in the catheter. A 1-cm superficial incision is made at this point, and a subcutaneous track adjacent to the venotomy is infiltrated with lidocaine. A double-lumen catheter, generally 28 or 32 cm in length, is attached to the tunneling device and pulled through the subcutaneous tunnel in a curved path. A guidewire is passed through the dilator and into the inferior vena cava. The venotomy site is then serially dilated over the guidewire. The catheter can then be inserted over the guidewire through the venous port. When a split-tip catheter is used, the guidewire is passed in and out of the two venous ports and through an arterial port or through a hollow intracatheter stiffener. Alternatively, a peel-away sheath is placed over the guidewire and the catheter inserted through the sheath after the removal of the guidewire; however, this method has greater potential for blood loss and air embolism. Fluoroscopy is used to confirm tip placement at the level of the right atrium, with the arterial port facing away from the atrial wall, and to ensure that there are no kinks in the catheter (Fig. 92-7). Each port of the catheter is then flushed with saline and locked with the appropriate amount of heparin based on catheter length and priming volume designation, followed by placement of the catheter hub caps.

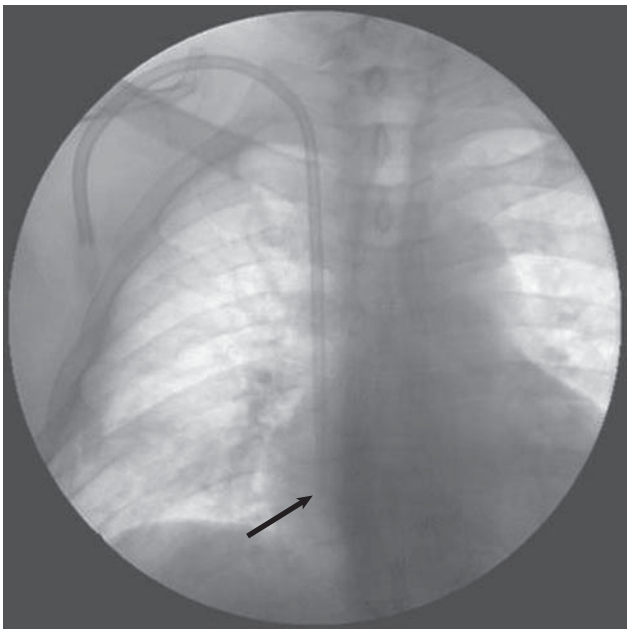

Figure 92-7 Insertion of a venous catheter for hemodialysis. Chest radiograph confirming that the tip of the catheter *(arrow)* is at the junction of the superior vena cava and the right atrium.

Catheter Dysfunction

Catheter dysfunction is defined as the failure to maintain a blood flow sufficient to perform hemodialysis without significantly extending treatment time; this is usually 300 ml/min.[39] Causes of immediate dysfunction include a kink in the catheter, incorrect position or orientation (arterial port against the vessel wall), and errant venous cannulation. These problems should be ascertained and corrected at the time of catheter placement. Catheter thrombosis is the most common cause of late dysfunction. Extrinsic thrombosis is less common than intrinsic thrombosis and is caused by central vein, mural, or right atrial thrombosis. Intrinsic obstruction results from thrombus within the catheter lumen or tip or most commonly from a fibrin sheath. Fibrin sheaths typically develop weeks to months after catheter insertion and result when a sleeve of connective tissue forms at the venotomy site and extends and

encases the catheter tip, creating a flap-valve. First-line treatment of catheter thrombosis includes forceful flush of the catheter with saline. If flow is not restored, a fibrinolytic agent should be instilled. Tissue plasminogen activator (tPA) is commonly used and appears more effective than urokinase in restoring patency and adequate flow.[32,33] Typically, 2 mg of tPA is instilled per occluded catheter lumen with 0.9% sodium chloride without preservative to fill the internal volume of each lumen and is allowed to dwell 30 minutes. If this fails, the catheter should be exchanged. Strategies to minimize dialysis catheter thrombosis are discussed in Chapter 91.

Catheter Exchange and Fibrin Sheath Removal

Catheter exchange over a guidewire is useful in the setting of catheter thrombosis or bacteremia and allows the preservation of the venotomy, tunnel, and exit sites. The tunnel and exit sites must appear free of infection if the same sites are to be used. Catheter exchange should take place within 72 hours of the initiation of antibiotic therapy.[39] Under sterile conditions, the exit site is anesthetized and the cuff is freed. Once the catheter is pulled back 8 to 10 cm, contrast material is injected through the catheter under fluoroscopy to check for a fibrin sheath (Fig. 92-8). To obliterate a sheath, a guidewire is passed down the venous port of the catheter and into the inferior vena cava. The catheter is then removed, and a balloon catheter is inserted over the guidewire to the sheath location and inflated to disrupt the sheath. The guidewire is then wiped with povidone-iodine (Betadine), and a new catheter is inserted over the guidewire. When the catheter tip is beyond the venotomy site, near the superior vena cava, contrast material can be injected again to check for sheath removal before proceeding with catheter insertion.

Training and Certification

The American Society of Diagnostic and Interventional Nephrology guidelines for hemodialysis vascular access procedure certification specify formal didactic training in central venous anatomy, sonographic examination of central veins, fluoroscopy, and catheter design and complications. In addition, practical training for certification includes satisfactory insertion of 25 tunneled long-term catheters. More information may be obtained at www.asdin.org.

PROCEDURES ON ARTERIOVENOUS FISTULAS AND GRAFTS

The most common indications for intervention are inadequate flow during dialysis, thrombosis, and failure of AV fistulas to mature. Specific interventions include angiography, thrombectomy, angioplasty, and stenting. All of these procedures require a dedicated facility, either inpatient or outpatient, with fluoroscopy, monitoring equipment, and staff to assist with the procedures and to deliver conscious sedation. There are many different techniques for AV access procedures and few data to indicate superiority of one method over the other, so the choice is generally one of personal preference and cost. However, the first step should always include a careful physical and ultrasound examination of the access. An examination will generally identify the problem and allow detection of access infection, an absolute contraindication to intervention. Appropriate intervention can then be planned. Monitoring and management of vascular access to minimize stenosis, thrombosis, and failure are discussed further in Chapter 91.

Percutaneous Balloon Angioplasty

Stenosis in AV grafts and fistulas is routinely managed by percutaneous balloon angioplasty, which can be safely performed on an outpatient basis, causes minimal discomfort, and allows immediate use of the access. Not all stenotic lesions are responsive, however, and some require repeated treatment. In fistulas, the stenosis is most commonly located at the "swing point," the portion of the native vein mobilized during creation of the AV anastomosis (Fig. 92-9); in

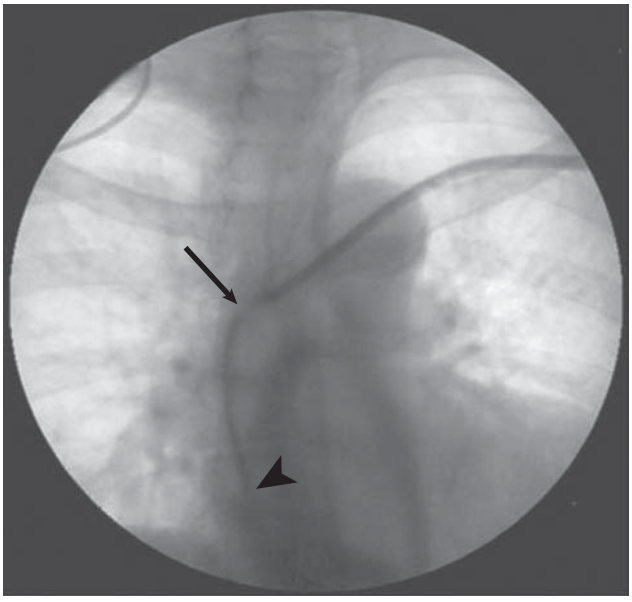

Figure 92-8 Fibrin sheath on a tunneled venous catheter. Contrast material has been injected into a tunneled catheter after the tip *(arrow)* has been pulled back into the innominate vein. The contrast material fills a sheath that extends from the catheter tip as far as the arrowhead.

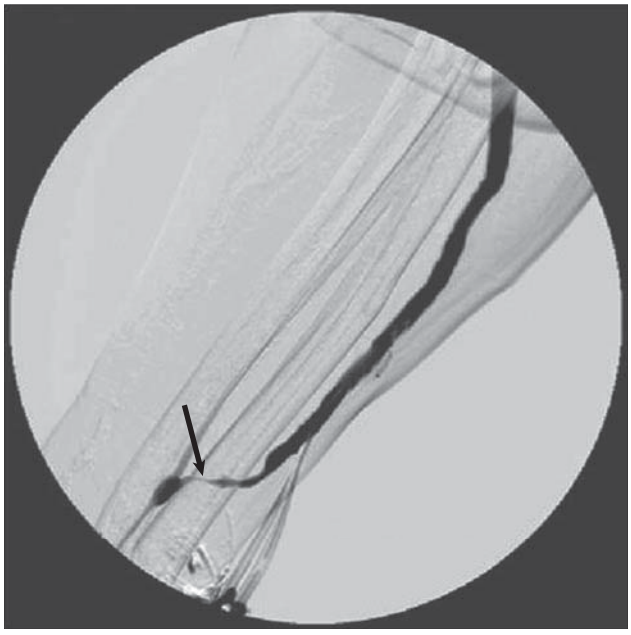

Figure 92-9 Juxta-anastomotic stenosis in a radiocephalic arteriovenous fistula. Contrast material was injected at the arterial anastomosis *(bottom left of image)* and demonstrates a narrowing in the initial portion of the fistula *(arrow)*.

grafts, the venous anastomosis is the most common site of stenosis.[34-38] Angioplasty is indicated if the stenosis is 50% or more and is associated with clinical or physiologic abnormalities.[39] Treatment of stenosis increases access blood flow and longevity, reduces access thrombosis, and reduces vascular access–related hospitalization.[38,40,41] A relative contraindication to angioplasty is a newly created access (<4 to 6 weeks old).

The access is cannulated with an introducer needle, a sheath is inserted, and initial angiography is performed. This should include views of the access, draining veins (peripheral and central), and arterial anastomosis and is used to confirm the location and degree of stenosis. Unless contraindicated, sedation and analgesia are then given with short-acting agents once a lesion has been identified on initial angiography, because angioplasty is painful.

A guidewire is passed through the sheath and across the stenosis. An angioplasty balloon catheter is passed over the guidewire, positioned at the stenotic site, and inflated with a syringe to 18 to 20 atm (Fig. 92-10). A variety of sheaths, guidewires, balloon sizes, and maximum pressures are available. The guidewire is left in place, and angiography is repeated to identify residual stenosis or any complications. Angioplasty is repeated for residual stenosis or when multiple lesions are present and may require a second cannulation of the access in the opposite direction for inflow stenoses. After removal of all devices, hemostasis at the cannulation site is achieved by manual pressure or suture placement. There is no evidence to support the use of antiplatelet agents or anticoagulation after intervention. According to Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, a successful angioplasty is achieved when there is no more than 30% residual stenosis and physical indicators of stenosis have resolved.[39]

Percutaneous Thrombectomy

A variety of techniques are used for thrombus removal. In thromboaspiration—the least costly method, and as effective and efficient as mechanical and pharmacomechanical thrombolysis—low-dose tPA is instilled into the thrombosed access, the clot is manually macerated, flow returns, and angioplasty is used to dilate access stenoses.[42] Thrombectomy by thromboaspiration combines angiography with balloon angioplasty and thrombectomy by clot aspiration. Absolute contraindications to thromboaspiration include access infection and known right-to-left cardiac shunt; relative contraindications include a large clot burden and longstanding access occlusion.

The access is cannulated in an antegrade direction, and a guidewire is passed to the level of the central veins. A straight catheter is inserted over the wire to the central veins, and angiography is performed to confirm central venous patency. Anticoagulation and short-acting sedative and analgesic medications are administered in the central circulation. An angiogram is then obtained as the catheter is pulled back to identify the location of stenosis. The guidewire is then inserted beyond the stenotic lesion, followed by an angioplasty balloon catheter. The balloon catheter is insufflated by hand with a syringe, and the stenotic lesion is dilated. The access is then cannulated in the retrograde direction, a sheath is inserted, and a Fogarty catheter is passed across the arterial anastomosis, inflated, and pulled back through the entire length of the access while clot fragments are aspirated. On return of flow through the access, angiography is performed to evaluate the inflow and the arterial anastomosis, and angioplasty is repeated if necessary. Hemostasis is achieved by manual pressure or a suture at the cannulation sites.

Stents

The precise role of the endovascular stent in AV fistulas and grafts has not been defined. Results from nonrandomized studies differ as to the patency benefit of primary stent use versus angioplasty alone within a stenotic access or central vein.[43-46] Stents are expensive and have often been used in situations in which their use will not extend the life of the access. Stents should be considered in the setting of failed balloon angioplasty (an elastic lesion), when there are few remaining access sites, if the patient is not a surgical candidate for a new access, or when an outflow vein ruptures after balloon angioplasty (Figs. 92-11 and 92-12).[47,48] Finally, a stent may be useful in the setting of an expanding pseudoaneurysm.[49,50]

Training and Certification

The American Society of Diagnostic and Interventional Nephrology guidelines for hemodialysis vascular access procedure certification specify didactic training in venous anatomy, fluoroscopy, procedural equipment, and sedation and analgesia. Requirements for practical training include 25 procedures in both fistulas and grafts of each of the following: angiography, angioplasty, and thrombectomy as primary operator (refer to www.asdin.org for more information). In general, several times that number as secondary operator will be required before one can become a primary operator.

CHAPTER 93

Hemodialysis: Principles and Techniques

Peter Kotanko, Martin K. Kuhlmann, and Nathan W. Levin

Despite the widespread use of peritoneal dialysis and renal transplantation, hemodialysis (HD) remains the main renal replacement therapy in most countries. Currently more than 2 million patients are treated with HD in about 28,500 dialysis units worldwide. Despite substantial advances in our understanding of the biology of chronic kidney disease (CKD) and the risk factors for poor outcome on HD and improvements in dialysis technology, the annual mortality in HD patients varies from 5% to 25% internationally, depending on demographic and possibly genetic factors.

DIALYSIS SYSTEM

The aim of the HD system is to deliver blood in a fail-safe manner from the patient to the dialyzer, enable the efficient removal of uremic toxins and excess fluid, and deliver the cleared blood back to the patient. The main components of the dialysis system are the extracorporeal blood circuit, the dialyzer, the dialysis machine, and the water purification system.[1] The dialysis machine delivers dialysis fluid with the intended flow rate, temperature, and chemical composition. It has monitoring and safety systems for air, blood, conductivity, and pressure; blood and dialysate pumps; a heating system; a dialysate mixing and degassing unit; and a volumetric ultrafiltrate balancing system. The role of the water purification system is to produce water for dialysis that complies with international chemical and microbiologic standards.

DIALYZER DESIGNS

The dialyzer provides controllable transfer of solutes and water across a semipermeable membrane. The flows of dialysate and blood are separated and countercurrent. The dialyzer has four ports, one inlet and one outlet port each for blood and dialysate. The semipermeable dialysis membrane separates the blood compartment from the dialysate compartment. The transport processes across the membrane are diffusion (dialysis) and convection (ultrafiltration). The removal of small solutes occurs primarily by diffusion, whereas larger components such as β_2-microglobulin are more effectively removed by convection. The hollow fiber dialyzer is currently the most effective design; it delivers high dialysis efficiency with low resistance to flow in a small device.

DIALYSIS MEMBRANES

Membranes vary with respect to chemical structure, biophysical properties such as transport characteristics, and biocompatibility (Table 93-1).

Materials

The original widely used membrane material was cellulose, which is made up of repetitive polysaccharide units containing hydroxyl groups. In cellulose acetate 80% of the hydroxyl groups are replaced by acetate radicals. Synthetic tertiary amino compounds are added during cellulose membrane synthesis to form cellulosynthetic membranes. More recent membranes are not cellulose based but instead are built of entirely synthetic materials, such as polyacrylonitrile, polysulfone, polycarbonate, polyamide, and polymethylmethacrylate. These synthetic membranes provide superior biocompatibility and are widely used.

Transport Properties

Transport of molecules across the dialysis membrane occurs because of (1) the concentration gradient (diffusive transport) and (2) the hydrostatic pressure gradient across the membrane (convective transport) and is dependent on membrane pore size. Dialyzer efficiency in terms of urea removal depends on the surface area (usually 0.8 to 2.1 m^2). High-efficiency dialyzers have a high surface area irrespective of pore size and possess a superior clearance for small molecules but may have small pores and thus a low ability to remove large molecules such as β_2-microglobulin. The dialyzer mass transfer area coefficient (K_oA) for urea is a measure of the theoretically maximal possible urea clearance (in milliliters per minute) at infinite blood and dialysate flow rates. Dialyzer efficiency can be categorized according to K_oA for urea as low (<500 ml/min), moderate (500 to 700 ml/min), and high (>700 ml/min). In contrast to the dialyzer clearance of a substance, its K_oA is independent of flow rates in the blood and dialysate compartments. High-flux dialyzers have pores large enough to allow the passage of larger molecules such as β_2-microglobulin (molecular weight 11800 d). Water permeability is defined by the ultrafiltration coefficient (K_{uf}) in milliliters of transmembrane ultrafiltration per hour per millimeter of mercury of transmembrane pressure (ml/h/mm Hg). K_{uf} is high in high-flux dialyzers, with K_{uf} up to 80 ml/h/mm Hg. During high-flux HD, backfiltration (the flow of dialysate into the blood because of higher hydrostatic pressure on the dialysate side) can occur at the distal end of the dialyzer blood compartment and may result in a transfer of 5 to 10 liters of dialysate into the blood during a treatment; it is compensated for by an increased blood water removal at the proximal part of the dialyzer. Therefore, water quality is of paramount importance when high-flux dialyzers are used.

In the prospective, randomized Membrane Permeability Outcome (MPO) study a survival benefit of high-flux membranes was seen among patients with serum albumin levels of 4 g/dl or lower, and in diabetic patients.[2] These results are in contrast with the results of the Hemodialysis (HEMO) study, which did not show any effect in patients with hypoalbuminemia, but did show survival benefit in

Dialysis Membrane Properties			
Membrane	**Membrane Name (Example)**	**High or Low Flux**	**Biocompatibility**
Cellulose	Cuprophane	Low	Low
Semisynthetic cellulose			
Cellulose diacetate	Cellulose acetate	High and low	Intermediate
Cellulose triacetate	Cellulose triacetate	High	Good
Diethylaminoethyl-substituted cellulose	Hemophane	High	Intermediate
Synthetic polymers			
Polymethylmethacrylate	PMMA	High	Good
Polyacrylonitrile methacrylate copolymer	PAN	High	Good
Polyacrylonitrile methallyl sulfonate copolymer	PAN/AN-69	High	Good
Polyamide	Polyflux	High and low	Good
Polycarbonate-polyether	Gambrane	High	Good
Ethylene vinyl alcohol copolymer	EVAL	High	Good
Polysulfone	Polysulfone	High and low	Good

Table 93-1 Dialysis membrane properties.

patients on dialysis for longer than 3.7 years before the trial.[3] These differences may be related in part to population characteristics (race, recruitment of incident of prevalent patients), or to the fluxes achieved.

SAFETY MONITORS

Safety monitors are integral parts of the dialysis machine. Pressure monitors are integrated in most machines to monitor the system pressure in critical positions (Fig. 93-1)[1]:

- Between the arterial side and the blood pump (prepump arterial pressure) to assess the suction pressure; overly negative values may signal reduced arterial inflow and access problems.
- Between the blood pump and the dialyzer inlet (postpump to assess the dialyzer inflow pressure); a high pressure may signal dialyzer clotting.
- Between the dialyzer outlet and the air trap (venous pressure) to control the return pressure; a high pressure may point toward an obstruction in the venous limb. It is important to consider that in the event of venous needle displacement, the venous pressure will remain positive because of the needle's flow resistance, and a pressure alarm may not occur.

A venous air detector and air trap are located downstream of the venous pressure monitor. A positive signal at the air detector automatically clamps the venous line and stops the blood pump. A blood leak detector is placed in the dialysate outflow line. Dialysate temperature is constantly monitored. Dialysate is produced by a proportioning system that mixes acid and bicarbonate concentrates with purified water. The osmolarity of the dialysate translates into conductivity, which is measured by the dialysis conductivity monitor. The ultrafiltration rate must be controlled precisely, in most machines by a volumetric control system.

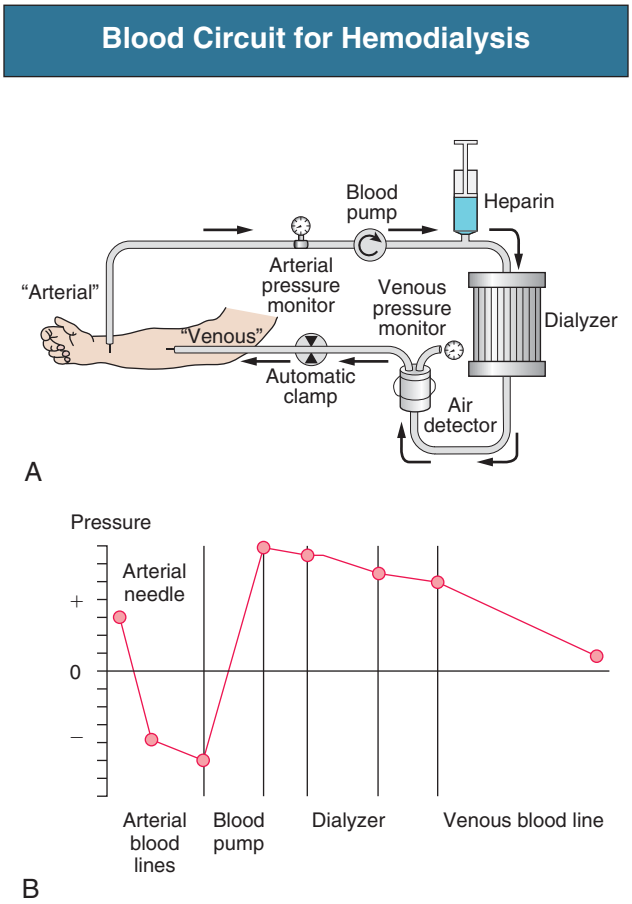

Figure 93-1 Blood circuit for hemodialysis. A, The blood circuit. **B,** The pressure profile in the blood circuit with an arteriovenous fistula as the vascular access.

ANTICOAGULATION

Either unfractionated heparin or, in some countries, low-molecular-weight heparin (LMWH) is used to prevent blood clotting in the extracorporeal circuit. Constant infusion of heparin, repeated boluses of heparin, or a single bolus of LMWH may be used. LMWH has not been approved by the U.S. Food and Drug Administration (FDA) for use in dialysis patients in the United States. A number of alternative modalities are available for patients at high risk for bleeding or who have contraindications to heparin, such as saline flushes, regional citrate anticoagulation (RCA), prostacyclin, danaparoid, argatroban (direct thrombin inhibitor), and lepirudin (recombinant hirudin). Lepirudin has the disadvantage of an extremely prolonged half-life in dialysis patients. In some institutions, RCA is used routinely, especially in patients with recent surgery, coagulopathies, thrombocytopenia, active bleeding, pericarditis, or heparin-associated side effects (such as heparin-induced thrombocytopenia type 2, pruritus, rapidly progressive osteoporosis,

and alopecia). Neutrophil activation may be reduced with RCA compared with heparin anticoagulation. Heparin requirements may be reduced with the use of citrate-containing dialysate.[4]

A typical routine prescription of constant infusion heparin is to administer an initial bolus of 2000 IU followed by a heparin infusion (800 to 1200 IU/h) ending 30 to 60 minutes before the end of the session. Applying the repeated-bolus method, an initial heparin bolus of, for example, 4000 IU is followed by, for example, 1000 to 2000 IU after 2 hours. Although the half-life of LMWH may be prolonged in renal failure, it has proved safe with fewer bleeding episodes, if appropriate dose reductions are made. LMWH has become the anticoagulant of choice in many centers for routine HD. LMWH is given as a bolus at the beginning of the session. Routine monitoring of whole-blood partial thromboplastin time, activated clotting time, or factor Xa is usually not necessary.

DIALYSATE FLUID

Water and Water Treatment

A standard 4-hour HD session exposes the patient to 120 to 160 liters of water. Therefore, water quality is of paramount importance to the patient's well-being. A typical water purification plant is shown in Figure 93-2. Water from municipal sources is filtered to remove particulate matter. Activated carbon, with high surface area, adsorbs substances such as endotoxins, chlorine, and chloramines. Downstream water softeners use a resin coated with sodium ions, which are exchanged for calcium and magnesium ions, before the water enters the reverse osmosis (RO) system. During RO, water is pumped at high pressure (15 to 20 bar) through a tight membrane. The small pore size of these membranes (0.05 to 0.5 nm) provides an absolute barrier for molecules larger than 100 to 300 d. This process rejects over 99% of all bacteria, viruses, pyrogens, and organic materials. Thereafter water is pumped into the RO storage tank and from there into a loop that supplies the dialysis stations. Common faults include carbon filters with inadequate capacity and recharging with inadequate frequency. Optional ultraviolet irradiation, to be placed upstream of a filter, is used to damage bacteria.

Standards for chemical quality of water are widely accepted, but there is less consensus regarding acceptable levels of bacterial and endotoxin contamination.[5] At the very least, endotoxin concentrations below 0.25 endotoxin units (EU)/ml are suggested, and many support the use of 0.06 EU/ml or lower. Municipal water supplies may contain a variety of contaminants that are toxic to HD patients. Substances added to the water supply such as aluminum and chloramines cause significant morbidity. Aluminum accumulation may result in a severe neurologic disorder (speech abnormalities, muscle spasms, seizures, and dementia), bone disease, and erythropoietin-resistant anemia. Plasma aluminum concentration should be monitored regularly; levels should be below 1 µmol/l, and levels above 2 µmol/l should prompt the search for excessive exposure. Chloramines have been associated with hemolysis and methemoglobinemia. Copper and zinc may leach from plumbing components and may cause hemolysis. Lead has been associated with abdominal pain and muscle weakness. Nitrate and nitrite may cause nausea and seizures. High concentrations of calcium may cause the hard water

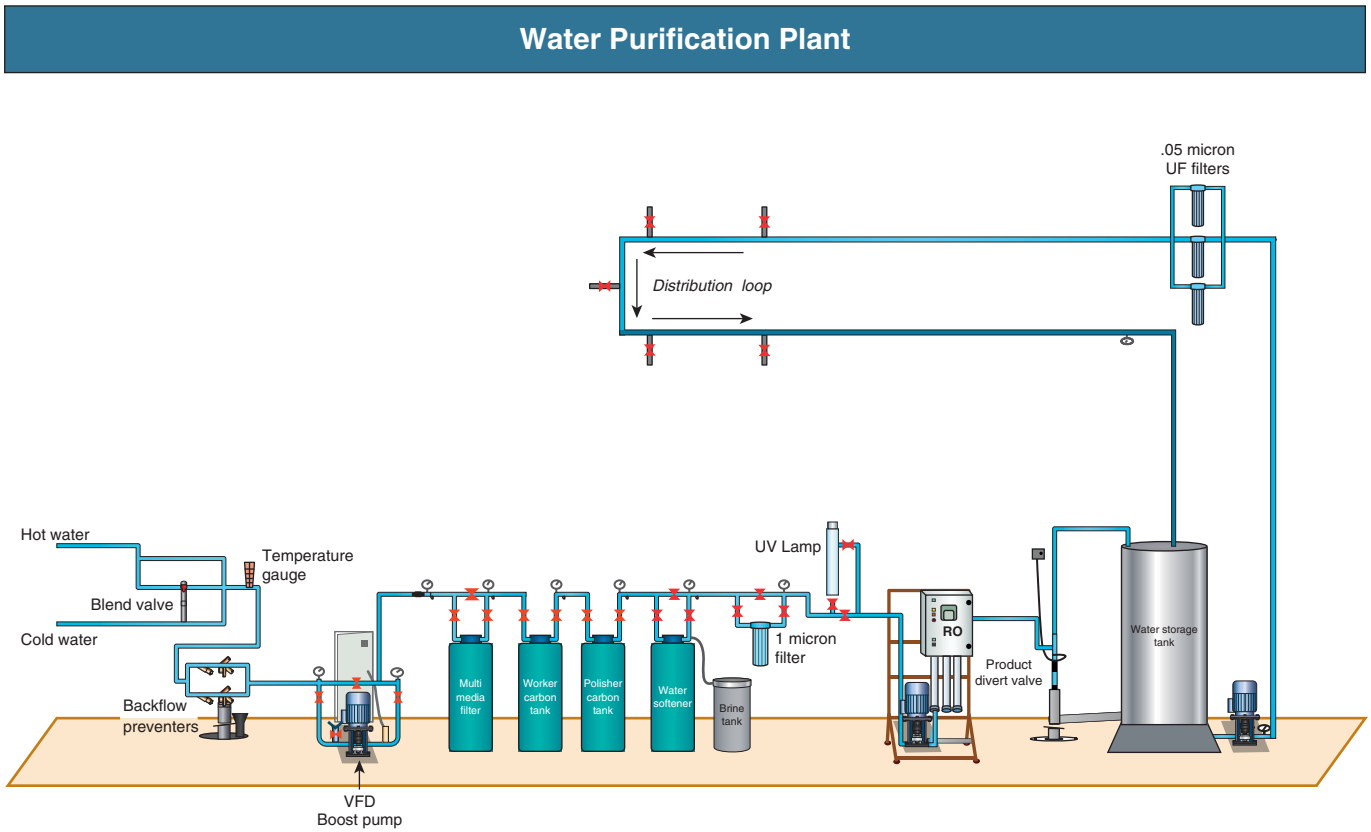

Figure 93-2 Water purification plant. The four main functional domains are water supply, water pretreatment, primary purification, and delivery to the loop. A series of filters and water softeners are the key technical pretreatment components, whereas reverse osmosis (RO) is the main component of the primary purification. Note that several features are optional, for example, the water storage tank. *UF,* Ultrafiltration; *UV,* ultraviolet light; *VFD,* variable frequency drive. *(Original artwork by Rob Levin and Randy Hux, New York, USA.)*

syndrome, characterized by acute hypercalcemia and hypomagnesemia, hemodynamic instability, nausea, vomiting, muscle weakness, and somnolence.

Gram-negative bacteria produce endotoxins (pyrogenic lipopolysaccharides from the outer bacterial cell wall), and fragments of these endotoxins may be responsible for some dialysis-related symptoms. Exposure to bacteria and endotoxin is associated with rigors, hypotension, and fever. Low levels of microbiologic contaminants may be a major cause of chronic inflammation in HD patients. Extracellular matrix secreted by bacteria forms the biofilm, a coating on surfaces, which protects them from antibiotics and disinfectants. The microbiologic standards for HD water, dialysis fluid, and substitution fluid vary among countries (Table 93-2).[5] The harm done by endotoxins passing through the dialysis membrane by backfiltration includes stimulation of inflammation, decreased response to erythropoiesis-stimulating agents, and possible aggravation of atherosclerosis. Use of a polysulfone or polyamide filter in the dialysate line may be adequate to remove endotoxins, but smaller molecules including bacterial DNA fragments may pass through the dialyzer and stimulate immune cells. In the absence of routine hot water disinfection of the machine and the connections to the water loop, the only way that endotoxin concentration can be kept low is by frequent measurement and disinfection of the entire system when concentration exceeds accepted standards.

Composition of Dialysates for Bicarbonate Dialysis

Component	Concentration	
	Range	Typical
Electrolytes (mmol/l)		
Sodium	135-145	140
Potassium	0-4.0	2.0
Calcium	0-2.0	1.25
Magnesium	0.5-1.0	0.75
Chloride	87-124	105
Buffers (mmol/l)		
Acetate	2-4	3
Bicarbonate	20-40	35
pH	7.1-7.3	7.2
P_{CO_2} (mm Hg)	40-100	
Glucose	0-11 (0-200 mg/dl)	5.5 (100 mg/dl)

Table 93-3 Composition of dialysates for bicarbonate dialysis.

Ultrapure water is recommended by international guidelines for use with high-flux dialyzers. Ultrapure water represents a basic prerequisite for convective dialysis modalities in which online production of substitution fluid is used (online hemofiltration or hemodiafiltration).

Liquid bicarbonate dialysis fluid concentrate distributed in a central distribution system may be a source of bacterial growth and should be replaced daily; acid concentrates in canisters and bicarbonate powder represent no bacterial growth risk.

Dialysis Solution

Dialysis fluid can be considered as a drug to be adjusted to the individual patient's needs (Table 93-3). In modern machines, dialysate is made by mixing two concentrate components, which may be provided as liquid or dry (powder) concentrates. The base concentrate contains sodium bicarbonate and sodium chloride; the conventional acid concentrate typically contains chloride salts of sodium, calcium, magnesium, and potassium, glucose monohydrate, and an organic acid. The organic acid can be in the form of acetic acid, citric acid, or lactic acid. The acid concentrate may also contain the salt of an organic acid, such as sodium acetate. The purpose of the acid is to lower the pH of the dialysate to below 7.3 so that calcium and magnesium do not precipitate as carbonate salts when bicarbonate is added. Base and acid components are mixed simultaneously with purified water to make the dialysate. Dialysate proportioning pumps ensure proper mixing. One typical mixing relationship is 1 : 1.72 : 42.28 (acid concentrate–base concentrate–water; also known as *45X preparation*). The relative amounts of water, bicarbonate, and acid component define the final dialysate composition. It is important to note that some dry acid concentrates contain sodium diacetate (8 mmol/l), which is made up of equal parts of acetic acid and sodium acetate. After mixing with bicarbonate, the final dialysate contains 8 mmol of sodium acetate per liter.[6] The addition of sodium acetate increases the total buffer load and may foster metabolic alkalosis. Dialysate composition can be further modified by small changes in the mixing ratio and by adding salt solutions; potential advantages and disadvantages of dialysate modifications are shown in Table 93-4.

Advantages and Disadvantages of Modifications of Dialysate Composition		
Component	**Advantage**	**Disadvantage**
Sodium		
Increased	Hemodynamic stability	Thirst; intradialytic weight gain; high blood pressure; sodium toxicity?
Decreased	Reduced osmotic stress in the presence of predialytic hyponatremia	Intradialytic hemodynamic instability
Potassium		
Increased	Fewer arrhythmias in digoxin intoxication with hypokalemia; may improve hemodynamic stability	Hyperkalemia
Decreased	Increased dietary potassium intake	Arrhythmias; risk of sudden death
Calcium		
Increased	Suppresses PTH, increased hemodynamic stability	Hypercalcemia, vascular calcification, adynamic bone disease resulting from PTH suppression
Decreased	Permits more liberal use of calcium-containing phosphate binders	Stimulation of PTH, reduced hemodynamic stability
Bicarbonate		
Increased	Acidosis control improved	Postdialytic alkalosis; increased mortality
Decreased	No postdialytic alkalosis	Promotes acidosis; increased mortality
Magnesium		
Increased	Hemodynamic stability, fewer arrhythmias, suppresses PTH	Altered nerve conduction, pruritus, renal bone disease
Decreased	Permits use of magnesium-containing phosphate binders; improved bone mineralization; less bone pain	Arrhythmias, muscle weakness and cramps, elevated PTH
Glucose		
Decreased	Avoidance of intradialytic hyperglycemia and hyperinsulinemia	Increased risk of disequilibrium (rare), hypoglycemia
Increased	Lower risk of disequilibrium	Intradialytic hyperglycemia and hyperinsulinism
Citrate	Heparin-sparing effect	High blood citrate levels in liver failure

Table 93-4 Advantages and disadvantages of modifications in the dialysate composition. *PTH,* Parathyroid hormone.

BIOCOMPATIBILITY

The contact of blood with some lines and membranes triggers an inflammatory response akin to that seen in infection. *Biocompatibility* is the property of a membrane that does not produce a toxic, injurious, or immunologic response on contact with blood. Although many components of the dialysis procedure contribute to the degree of biocompatibility, it is the membrane itself that is most important. Biocompatibility is of particular importance with the use of cellulose membranes, whereas synthetic membranes and reused membranes activate complement to a much lesser extent (Fig. 93-3). Activation of complement peaks at 15 minutes after the start of dialysis and lasts up to 90 minutes. RCA may improve biocompatibility because of reduced granulocyte degranulation.[7] Dialyzer reprocessing with appropriate antibacterial substances such as peracetic acid is also associated with improved biocompatibility, but also with reduced diffusion of larger molecules.

HEMOFILTRATION

Hemofiltration (HF) differs markedly from HD by the mechanisms by which the composition of the blood is modified (Fig. 93-4). HF is mainly used in the intensive care setting. In the simplest form of HF, blood under pressure passes down one side of a highly permeable membrane, allowing both water and substances up to a molecular weight of approximately 20 kd to pass across the membrane by convective flow, depending on membrane permeability. During HF, the filtrate is discarded and the patient receives a substitution fluid either before (predilution) or after (postdilution) the dialyzer. The substitution fluid contains the major crystalloid components of the plasma at physiologic levels. Both bicarbonate and lactate are used as buffers. The rate of fluid removal and substitution fluid infusion can be adapted to the patient's need. HF is particularly useful as a continuous renal replacement therapy in an intensive care setting.[8]

HEMODIAFILTRATION

Hemodiafiltration (HDF) combines the benefits of HD (high transport rate of low-molecular-weight solutes by diffusion) and HF (high convective transport of substances) (Fig. 93-5). HDF is used both as a continuous and an intermittent renal replacement therapy. HDF offers potential benefits with regard to anemia correction, inflammation, oxidative stress, lipid profiles, and calcium-phosphate product[9] and possibly the prevention of long-term complications such as dialysis (β_2-microglobulin) amyloidosis. Two randomized controlled trials (RCTs) did not show improved survival but suggested that higher substitution volumes would be beneficial. This notion was corroborated by a recently reported large RCT of high-efficiency postdilution on-line HDF in patients who all achieved a high substitution volume. This trial demonstrated that, compared with patients who continued on high-flux HD, those assigned to on-line HDF had a 30% lower risk of all-cause mortality, a 33% lower risk of cardiovascular mortality, and a 55% lower risk of infection-related mortality (see Chapter 94 for further discussion).[10]

DIALYSIS TIME AND FREQUENCY

Hemodialysis has conventionally been delivered in three treatment sessions per week. This developed as a practical compromise between the physiologic benefits of replacing renal function by HD ("the more, the better") and the practicalities of delivering HD, in terms of both patient tolerance and facility organization. There is good evidence that twice-weekly HD provides inferior outcomes to three times weekly, except in some patients with substantial residual renal function. Treatment times of 3 to 5 hours per session are now typical, but a growing number of centers also offer longer hours (up to 8 hours per session), originally necessary because of the relative inefficiency of the available HD techniques. It remains controversial whether the excellent long-term outcomes of patients receiving prolonged HD are related to selection bias rather than real advantages.

Two RCTs investigated the effect of increased HD frequency on changes in left ventricular mass, as measured by magnetic resonance

imaging, and quality of life including cognitive measures.[11,12] Frequent HD, as compared with conventional HD, was associated with positive results with respect to the composite outcomes of death or change in left ventricular mass and death or change in a physical health composite score. However, the number of access complications (but not access failures) increased with frequent HD.

ADDITIONAL DEVICES AND TECHNOLOGIES

Relative Blood Volume Monitoring

A decrease in blood volume because of ultrafiltration is one of the main causes of intradialytic hypotension. Blood volume monitors provide continuous noninvasive monitoring of relative changes in blood volume by continuous measurement of plasma protein concentration by ultrasound or hematocrit by optical scattering. Too rapid changes in blood volume from baseline indicate decreased plasma refilling rates and may precede intradialytic hypotension. Blood volume monitoring can be particularly useful for monitoring hemodynamically unstable dialysis patients. In some dialysis machines the rate of blood volume change is used to automatically adjust ultrafiltration rates or to warn of marked reduction in relative blood volume. This approach has been shown to reduce the frequency of symptomatic intradialytic hypotension.[13]

Ultrafiltration Profiling

The ultrafiltration rate is usually kept constant but can be changed during the dialysis session in a preprogrammed manner (ultrafiltration profiling). It may be advantageous to remove a large proportion, for example two thirds, of the ultrafiltration volume in the first half of the HD session. Because of a high initial plasma refilling rate, severely fluid-overloaded patients may tolerate a higher ultrafiltration rate in the early stages and normal fluid status may be reached more easily. In some machines, predefined ultrafiltration profiles are incorporated. The clinical benefits of ultrafiltration profiling have not been adequately evaluated.

Sodium Profiling

Normally the dialysate sodium concentration is kept constant throughout the dialysis treatment. The variable sodium option allows dynamic changes of the dialysate sodium concentration during the treatment (sodium profiling). Some patients with hemodynamic instability may benefit from this option if the initial sodium concentration is kept high and then the concentration is slowly reduced to avoid residual sodium loading. In the absence of appropriate reductions in dialysate sodium concentrations, the ensuing thirst may increase intradialytic weight gain.

Online Clearance Monitoring

Sodium and urea clearances are identical for practical purposes. Because the conductivity of the dialysate is largely a function of the dialysate sodium concentration, online clearance monitors can use this feature to compute the urea clearance *(K)* of a dialyzer during a dialysis treatment. Changes in inflow dialysate sodium concentration are related to the respective changes of conductivity in the dialysate outflow. The conductivity clearance is equivalent to urea clearance, and *Kt,* the product of *K* and treatment time *(t),* is easily calculated. Together with estimates of *V* (total body water), *Kt/V* can be determined during each treatment.

Blood Temperature Monitoring

During standard HD, the core body temperature usually increases. Because the thermoregulatory response to rising core temperature (dilation of thermoregulatory vessels) may offset the vascular response to hypovolemia (vasoconstriction), this increase in internal heat production might be in part responsible for the intradialytic hemodynamic instability. Cool dialysate has been shown to improve vascular stability during dialysis. The core temperature can be controlled by a blood temperature monitor, which adapts the dialysate temperature according to the desired core temperature. When no blood temperature monitor is available, the dialysate temperature can be set initially to the patient's core temperature. If this is well tolerated and intradialytic hypotension still occurs, the dialysate temperature may be reduced up to 0.5° C below the patient's core temperature, unless cold discomfort occurs. A meta-analysis of 22 studies concluded that intradialytic hypotension occurred seven times less frequently with cool dialysis[14] without reduction in urea clearance.

Bioimpedance

Bioimpedance devices are increasingly used to determine fluid status in HD patients. A recent RCT in 156 chronic HD patients indicated that assessment of fluid overload with whole body bioimpedance spectroscopy provides better management of fluid status, leading to regression of left ventricular mass index, decrease in blood pressure, and improvement in arterial stiffness compared with standard care.[15] Calf bioimpedance spectroscopy (cBIS) methods have been developed to identify normal fluid status in HD patients, and a recent study shows that cBIS compares favorably with whole-body bioimpedance methods.[16]

Sorbents, Nanotechnology, Wearable Artificial Kidney

Use of sorbents to absorb nondialyzable molecules will allow testing of the relevance of uremic toxins and of many protein-derived substances that accumulate in the plasma of uremic patients. Nanotechnologic approaches to dialysis therapy are under intensive investigation. A recent study reported the successful short-term use of a wearable artificial kidney.[17]

CHAPTER 94

Hemodialysis: Outcomes and Adequacy

Martin K. Kuhlmann, Peter Kotanko, and Nathan W. Levin

From an idealistic clinical perspective, an adequately treated hemodialysis (HD) patient is physically active, well nourished, euvolemic, and normotensive with a maintained good quality of life and a life expectancy that is not inferior to that of healthy patients. Despite these optimistic goals, outcomes for dialysis patients expressed in terms of mortality, hospitalization, and quality of life regrettably remain comparable to those observed in patients with solid organ cancer. The mean life expectancy of an average 60-year-old HD patient currently can be estimated at 5 to 7 years, with an annual mortality rate of 13% to 20% (www.usrds.org). Mortality in HD patients differs by gender and race; for example, in the United States there is lower mortality in African Americans compared with Caucasians, in Hispanics compared with non-Hispanics, and in Asians compared with any other racial group. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) suggest that variations in practice patterns, such as prescribed dialysis treatment time, average erythropoietin dose, preferred vascular access type, and number of patients with central venous catheters, may account for some of these differences. Outcomes are also directly related to comorbid factors occurring during evolution of chronic kidney disease (CKD), such as atherosclerotic vascular disease, diabetes, and arterial hypertension, and to background cardiovascular mortality of the respective general population.[1] Indeed, the majority of CKD patients die mainly of cardiovascular causes before reaching end-stage renal disease (ESRD). In addition to cardiovascular disease (discussed further in Chapter 82), other major factors influencing outcome that are common to all patients with ESRD include anemia (see Chapter 83) and control of bone and mineral metabolism (see Chapter 85).

In this chapter, we discuss dialysis-related factors influencing outcome in patients receiving maintenance HD and measures to influence these factors clinically (see summary in Table 94-1). A key factor influencing outcome is "adequacy" of dialysis, a term which was originally used exclusively to describe dialysis dosage measured by small solute removal, but now has a broader meaning encompassing all aspects of the replacement of excretory and endocrine functions of the kidney that affect outcome.

ADEQUACY OF DIALYSIS DOSE

Uremic Toxins

The retention in the body of compounds that normally are metabolized by healthy kidneys or filtered and secreted into the urine results in the uremic syndrome. These retained compounds are called *uremic retention solutes* or *uremic toxins* when they interact negatively with biologic functions. Uremic toxins include a small group of inorganic compounds, such as water, potassium, phosphate, and trace elements, and a much larger group of organic compounds that are further subdivided into small water-soluble solutes (<500 d), middle molecules (>500 d), and protein-bound solutes (Table 94-2).

A continuously updated list of uremic toxins is provided at www.uremic-toxins.org. The catalogue of uremic toxins is long, and a growing number of compounds have been associated with outcomes. Mortality has repeatedly been shown to be associated with reduced clearance of urea. Of commonly measured middle molecular size substances, serum concentrations of β_2-microglobulin have been associated with mortality, as have concentrations of *p*-cresyl sulfate among protein-bound uremic solutes.[2] Although it is evident that uremic toxicity is more than the retention of urea or water-soluble compounds alone, current dialysis and dialysis-related treatments do not remove any significant quantity of substances larger than 10 to 15 kd. Future means of removing higher-molecular-weight toxins or protein-bound substances may include the use of sorbents in addition to traditional diffusive and convective dialysis strategies.

Urea as a Surrogate Marker of Uremic Toxicity

Among all potential uremic toxins, only urea, a 60-dalton small water-soluble compound, is established as a marker of uremic solute retention and removal. Urea, which itself shows little toxicity, is a metabolite of amino acid metabolism; urea generation therefore depends on protein intake and the balance between protein anabolism and catabolism. The removal of urea was originally considered to be representative for the removal of other water-soluble solutes with a higher pathogenic impact, but it is now clear that urea removal does not closely parallel that of other small water-soluble compounds, protein-bound solutes, or middle molecules. This is because urea, in contrast to other uremic solutes, is freely diffusible through cell membranes, which allows rapid equilibration of urea concentration within whole body water after urea has been removed from the blood compartment. For other uremic toxins the intercompartmental transfer rate is much slower, leading to a protracted equilibration between the intravascular and other tissue compartments. Nevertheless, knowledge of urea kinetics is essential for the general understanding of the physics of solute removal during dialysis.[3]

Assessment of Dialysis Dose

Adequacy in terms of dialysis dose refers to delivery of a treatment dose that is considered sufficient to promote optimal long-term outcome. The delivered dose of dialysis is conventionally assessed by the removal of urea and expressed either by the urea reduction ratio (URR) or by the treatment index *Kt/V* (see later for detailed explanation). Simply following predialysis blood urea nitrogen (BUN) or serum urea concentration is misleading; low serum urea may much more reflect malnutrition from inadequate protein intake than adequate dialysis urea removal. If urea removal is inadequate, then dialysis is inadequate, regardless of the serum urea level.

Factors Related to Dialysis Outcome	
Factors	**Ways to Address These Factors**
Patient Characteristics	
Age	None
Gender	None
Race/ethnicity	None
Body size	Target BMI above 23 kg/m^2; treat malnutrition if BMI is falling
Social status	Social and family support
Dialysis vintage	Early renal transplantation
Comorbidities	
Diabetes mellitus	Prevent hypoglycemia, target HbA1c below 7.5%
Arterial hypertension	Optimize target weight, decrease dietary salt intake, avoid intradialytic positive sodium balance
Congestive heart failure	Optimize fluid status by gradual postdialysis target reduction, decrease dietary salt intake, avoid intradialytic positive sodium balance
Depression	Treat medically
Peripheral vascular disease	Aspirin, lipid-lowering substances, management of hyperphosphatemia
Transplant eligibility	Living donor transplantation
Frailty	Nephrologic rehabilitation program, exercise during dialysis to avoid falls and fractures
Physical activity	Nephrologic rehabilitation program, exercise during dialysis; avoid immobilization
Arrhythmias	Avoid hypokalemia and prevent hyperkalemia; do not use zero-K^+ dialysate bath
Obstructive sleep apnea	Optimize fluid status; use CPAP if indicated
Anemia	
Hemoglobin concentration	Target Hb level 10-11 g/dl
EPO resistance	Surveillance of iron status; target transferrin saturation >25%; identify and treat sources of inflammation
CKD-MBD	
PTH	Lower phosphate levels toward normal range, use vitamin D and calcimimetics
FGF-23	Lower phosphate levels toward normal range
Hyperphosphatemia	Optimize dialysis phosphate elimination; phosphate binder therapy, dietary phosphate restriction
Nutrition and Inflammation	
Inflammation	Ultrapure dialysate, avoid central venous catheters and graft access
Low serum albumin	Ultrapure dialysate, avoid central venous catheters and graft access
Protein-energy malnutrition	Nutritional counseling, enteral supplements
Fluid overload	Define post-HD target weight, bioimpedance?
Vascular access	Avoid central venous catheters and graft access
β_2-Microglobulin	Increase middle molecule clearance, HDF
Dialysis Treatment Factors	
Session length	Session length more important than urea clearance once minimum *Kt/V* has been achieved; minimum session length 4 h?
Frequency	Four to seven sessions per week; short daily in-center HD, daily or every-other-day nocturnal home HD
Long interdialytic interval	Every-other-day dialysis or four sessions per week
Dialysis dose	Target *Kt/V* >1.3; URR >65% per treatment
Dialysis modality	High efficiency on-line HDF; target convective volume >22 l per treatment
Hemodialysis membrane biocompatibility	Biocompatible membranes
Hemodialysis membrane type	High-flux membranes
Dialysate quality	Ultrapure dialysate
Dialysate composition (acidosis, hyperkalemia)	Individualized dialysate bicarbonate, potassium, calcium, and sodium concentration
Acidosis	Target pre-HD HCO_3^- >22 mmol/l, avoid severe post-HD alkalosis

Table 94-1 Factors related to dialysis outcome and ways to address these factors. *BMI,* Body mass index; *CKD-MBD,* chronic kidney disease–mineral and bone disorder; *CPAP,* continuous positive airway pressure; *EPO,* erythropoietin; *FGF-23,* fibroblast growth factor 23; *Hb,* hemoglobin; *HbA1c,* hemoglobin A1c; *HD,* hemodialysis; *HDF,* hemodiafiltration; *Kt/V,* dialysis treatment index; *PTH,* parathyroid hormone; *UFR,* ultrafiltration rate; *URR,* urea reduction ratio.

Factors Related to Dialysis Outcome	
Factors	**Ways to Address These Factors**
Hyperkalemia	Nutritional counseling, oral bicarbonate supplementation
Timing of dialysis initiation	Avoid early dialysis initiation without clinical symptoms of uremia
Intradialytic hemodynamic stability	Thermoneutral dialysis, avoid high UFR
Residual renal function	Avoid intradialytic hypotension, volume depletion, and high UFR

Table 94-1 Factors related to dialysis outcome and ways to address these factors—cont'd

Organic Uremic Solutes

Intradialytic Urea Kinetics

Dialyzers are highly efficient at removal of urea from the blood, reducing the urea concentration during one passage by 80% to 90%. Intradialytic serum urea kinetics were originally described by single-compartment (single-pool) models, assuming that full equilibration between blood and tissue compartments occurs immediately and without time delay. In such models, the change in serum urea follows first-order kinetics, with a linear decline and no urea rebound (Fig. 94-1, *dashed line*). *In vivo,* however, intercompartmental urea redistribution is somewhat delayed, and therefore the intradialytic urea concentration in the blood compartment is always lower than in tissue compartments. Full equilibration among all compartments is reached within 30 to 60 minutes after the end of a dialysis treatment. These features of urea kinetics are more accurately described by double-pool models that take into account the intercompartmental urea redistribution rate and postdialysis urea rebound (Fig. 94-1, *solid line*).

Current methods for assessment of dialysis dose are based on the predialysis and postdialysis difference in serum urea and include URR, single-pool *Kt/V (spKt/V),* equilibrated *Kt/V (eKt/V),* and weekly standard *Kt/V (std-Kt/V).*

Urea Reduction Ratio

Urea reduction ratio refers to the treatment-related reduction of serum urea concentration and is computed as follows:

$$\text{URR}\,(\%) = (1 - C_t/C_0) \times 100\%$$

where C_t is postdialysis and C_0 is predialysis serum urea concentration.

Urea reduction ratio is a simple but rather imprecise way to quantify dialysis dose because it does not take into account intradialytic urea generation and convective urea removal by ultrafiltration. Despite these limitations, URR correlates well with dialysis outcome

and is an accepted method for assessment of dialysis adequacy. A minimum URR of 65% to 70% is recommended for adequate HD.

Single-Pool *Kt/V (spKt/V)*

The treatment index *Kt/V* is the most widely used parameter to assess dialysis dose. *Kt/V* is a dimensionless number representing the total plasma volume cleared ($K \times t$, in liters) divided by volume of distribution (V, in liters). The concept of *Kt/V* may be applied to any substance but in clinical practice is used almost exclusively for urea, where K is the dialyzer blood water urea clearance (liters per hour), t is dialysis session length (hours), and V is the distribution volume of urea (liters), which equates closely to total body water. A delivered *Kt/V* of 1.0 implies that the volume of plasma cleared of urea ($K \times t$) during a dialysis session is equal to urea distribution volume *(V)*.

In daily clinical practice *spKt/V* may be computed according to the classic Daugirdas equation, which is based on URR and accounts for intradialytic urea generation and ultrafiltration volume.[4] The Daugirdas equation is validated for a *Kt/V* range of 0.8 to 2.0 and is widely used because of its simplicity and accuracy.

$$\text{spKt/V} = -\ln(\text{R} - 0.008 \times \text{t}) + (4 - 3.5 \times \text{R}) \times \text{UF/W}$$

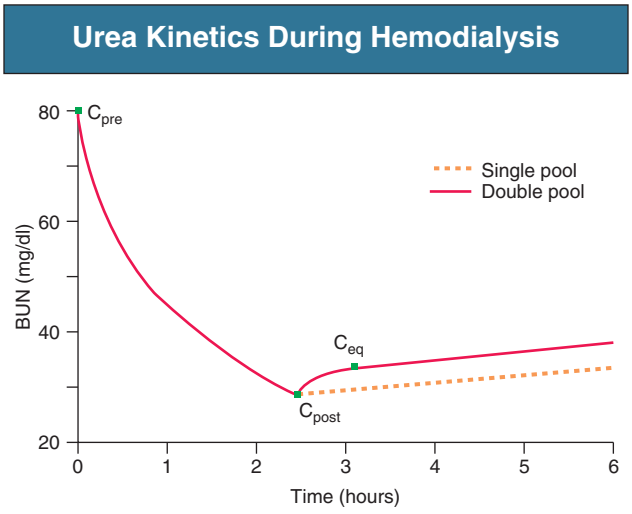

Figure 94-1 Urea kinetics during hemodialysis. Urea kinetics is determined by the difference between predialysis *(C_{pre})* and postdialysis *(C_{post})* blood urea nitrogen *(BUN)*. The single pool Kt/V model assumes no relevant change in BUN concentration after termination of dialysis except for a slow constant increase due to BUN generation *(yellow dashed line)*. The double pool *Kt/V* model *(red line)* more accurately describes the *in vivo* situation, where intercompartmental urea redistribution leads to a urea rebound until full equilibration between blood and tissue compartments is reached. Equilibrated postdialysis BUN concentration (C_{eq}) can be mathematically predicted from postdialysis BUN (C_{post}).

where ln is the natural logarithm, R is the postdialysis-predialysis serum urea ratio, t is treatment time (hours), *UF* is ultrafiltration volume (liters), and W is the patient's postdialysis body weight (kilograms).

The most accurate method for prescription and assessment of dialysis dose is formal urea kinetic modeling (UKM), where *spKt/V* is modeled from prescribed dialyzer clearance *(K)*, blood and dialysate flow rates, ultrafiltration volume, treatment time, and assumed urea distribution volume. Through comparison of modeled *Kt/V* with delivered *Kt/V*, problems in the accuracy of the delivery of dialysis dose, such as vascular access recirculation, can be identified. Because of its mathematical complexity, UKM requires advanced computer support.

Single-pool *Kt/V* regularly overestimates the delivered dialysis dose because nonequilibrated post-HD urea concentration is used for computation. A more accurate estimate of delivered dialysis dose can be achieved by taking into account the equilibrated post-HD urea concentrations. The difference between equilibrated and nonequilibrated urea concentration depends on the intensity of dialysis; the shorter and more intense a treatment, the higher the rebound. Simple equations can be applied for computation of *eKt/V* from *spKt/V*. Because nonequilibrated post-HD serum urea concentrations are lower than equilibrated concentrations, results for *eKt/V* will always be lower than for *spKt/V*. Typical results of *spKt/V* and *eKt/V* for identical treatment characteristics are shown in Table 94-3.

Computation of *spKt/V* requires accurate timing of blood collections. Predialysis blood samples must be collected right at the start of the treatment, and postdialysis samples immediately at the end of the treatment after the blood flow rate is slowed to reduce any potential effect of recirculation. Blood sampling procedures should be standardized in each center (for recommendations, see the Kidney Disease Outcomes Quality Initiative [KDOQI] clinical practice guidelines for HD adequacy, update 2006[5]). URR, *spKt/V*, or *eKt/V* should be assessed monthly, and dialysis prescription adjusted accordingly. In large cross-sectional studies, mortality increased when *spKt/V* fell below 1.2, and a target *spKt/V* of 1.3 is recommended for conventional thrice-weekly dialysis schedules.[5] Dose comparisons with more frequent dialysis schedules or peritoneal dialysis can be made by computation of a weekly dialysis dose.

Weekly Standard *Kt/V (std-Kt/V)*

The weekly HD dose is not equivalent to the product of session *Kt/V* and the number of treatments per week because the total urea mass removed per time unit decreases with increasing dialysis treatment time and dose as a result of lowering of serum urea concentration over time. This is exemplified by looking at a doubling of *Kt/V* from 1.0 to 2.0 per session, when the total mass of urea removed is not doubled but only increased by about 24% (Fig. 94-2). With the weekly *std-Kt/V* concept, the intermittently provided dialysis urea

Computation of Dialysis Dose: Results Derived from Different Model Equations

Formula	Result	Comment
$\text{URR} = (1 - C_t/C_0) \times 100\%$	67%	Urea rebound, urea generation, and ultrafiltration not taken into account
$\text{Kt/V} = \ln(C_0/C_t)$	1.10	Urea rebound, urea generation, and ultrafiltration not taken into account
$\text{spKt/V} = -\ln(\text{R} - 0.008 \times \text{t}) + (4 - 3.5\,\text{R}) \times \text{UF/W}$	1.33	Single-pool model; urea rebound not taken into account
$\text{eKt/V} = \text{spKt/V} - 0.6 \times \text{spKt/V/t} + 0.03$	1.16	Double-pool model for arteriovenous access including urea rebound
$\text{eKt/V} = \text{spKt/V} - 0.47 \times \text{spKt/V/t} + 0.02$	1.20	Double-pool model for central venous access including urea rebound

Table 94-3 Computation of dialysis dose: results derived from different model equations. Calculations based on dialysis duration *(t)* = 4 hours; predialysis blood urea nitrogen (BUN) (C_0) = 90 mg/dl; nonequilibrated postdialysis BUN (C_t) = 30 mg/dl; ultrafiltration volume *(UF)* = 3 liters; postdialysis body weight *(W)* = 72 kg; $R = C_t/C_0$. *URR,* Urea reduction ratio.

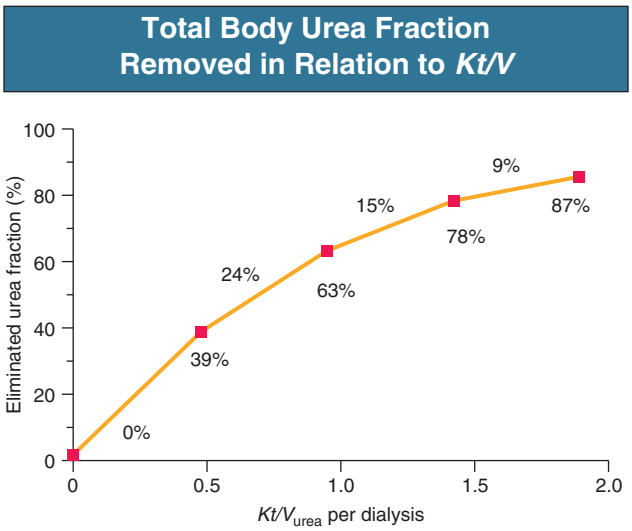

Figure 94-2 Total body urea fraction removed in relation to *Kt/V*. In this example, 63% of total body urea fraction is removed with *Kt/V* of 1.0; doubling of *Kt/V* to 2.0 increases the removed urea fraction by an additional 24%.

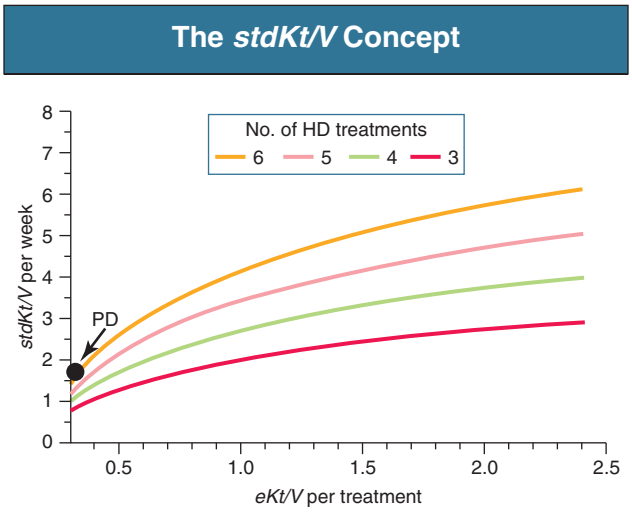

Figure 94-3 The weekly *std-Kt/V* concept. The weekly *std-Kt/V* for any hemodialysis *(HD)* frequency is derived by plotting *eKt/V* of a representative dialysis session onto the respective frequency curve. *CAPD,* Continuous ambulatory peritoneal dialysis.

clearance during 1 week is converted to an equivalent continuous "extracorporeal" urea clearance (in milliliters per minute), then multiplied by 10,080 (minutes per week) and divided by urea distribution volume *V* (in milliliters).[6] The resulting dimensionless *std-Kt/V* value is directly compatible with peritoneal dialysis weekly *Kt/V* and with native residual renal *Kt/V.* Weekly *std-Kt/V* can be derived graphically by plotting *eKt/V* of a representative dialysis session onto the respective frequency curve (Fig. 94-3). A maximum *std-Kt/V* of approximately 3.0/wk can be achieved with conventional thrice-weekly dialysis. To further increase the weekly dose, dialysis frequency needs to be altered. Residual renal function (RRF) expressed as weekly renal *Kt/V* is added to dialysis *std-Kt/V.* Independent of the treatment schedule, a minimum target *std-Kt/V* of 2.0/wk including renal *Kt/V* is recommended for all patients. This is exactly the value that is achieved with an *spKt/V* of 1.2 or *eKt/V* of 1.0 given three times per week in anuric patients.

Prescription of Dialysis Dose

Delivered dialysis dose depends on dialysate and blood flow rates, dialyzer efficiency (K_oA), session length *(t),* and the distribution volume *(V)* of the uremic toxin studied. As mentioned earlier, urea is distributed in total body water volume; but for other small-molecular-weight compounds, *V* may be substantially different. A standard dialysis prescription should include a minimum treatment time of 4 hours, a blood flow rate of at least 250 ml/min, and a dialysate flow rate of 500 to 800 ml/min. In a new dialysis patient, *V* is unknown and needs to be estimated (men, 58% of body weight; women, 55% of body weight).

Example

Male, body weight 76 kg; *V* = 58% of body weight = 44 liters
Target blood flow rate, 300 ml/min; effective dialyzer urea clearance (K_d) = 240 ml/min; target *spKt/V* = 1.3
Required treatment time (min): 1.3 × *V* (ml)/ K_d (ml/min) = 238 min

Once dialysis is delivered and *Kt/V* has been measured, the prescription is adjusted to meet the *Kt/V* target. In severe and longstanding uremia, the target dose is approached slowly during the course of several sessions to avoid the dialysis disequilibrium syndrome.

Is *V* the Adequate Denominator for *Kt/V*?

Patients with small urea *V,* typically women, tend to do poorly relative to larger people. Because total body water is much more closely related to muscle mass than to body weight, small urea *V* is a good indicator for low muscle mass. It is interesting to note that in the Hemodialysis (HEMO) study, a beneficial effect of higher *Kt/V* was reported for women but not for men. This implies that individuals with low muscle mass may require a higher clearance in relation to *V* and therefore raises the question of whether *V* is the appropriate denominator for dialysis dose. Native renal clearances, in contrast, are commonly related to body surface area (BSA), not to total body water. By analogy, it has been proposed to relate dialysis clearances to BSA. The ratio of BSA to urea *V* is generally higher in women than in men and decreases with an increment in *V.* Prescribing dialysis dose in relation to BSA ($K \times t$/BSA) would result in more dialysis for smaller patients of either gender and for women of any size. Rescaling dose of dialysis to BSA in the HEMO population supported this hypothesis by showing that the delivered dose in women was substantially lower than in men, which may explain some of the outcome differences observed in the trial.[7] Although not yet fully validated, a higher target dose of dialysis may be recommended for subpopulations with low muscle mass and associated high mortality risk.

Factors Affecting Delivered *Kt/V*

The effective dialyzer urea clearance K_d depends on the flow rates within the blood and dialysate compartments, dialyzer K_oA, effective membrane surface area, hematocrit, anticoagulation, and recirculation. Treatment time *t* is important for reaching the *Kt/V* target. Effective treatment time can be substantially shorter than prescribed treatment time because of intermittent pump stops or patient demand. *V* does not substantially change during a single HD session but may change over time. Dialysis dose needs to be adjusted for an increase in *V.* On the contrary, if there is a loss in body mass, which is associated with a decrease in *V, Kt/V* should not be reduced but rather adjusted to the higher, ideal patient *V* or, as pointed out before, to BSA.

Confronted with an inadequate delivered URR or *Kt/V,* it is sensible to check whether the studied session was representative of an

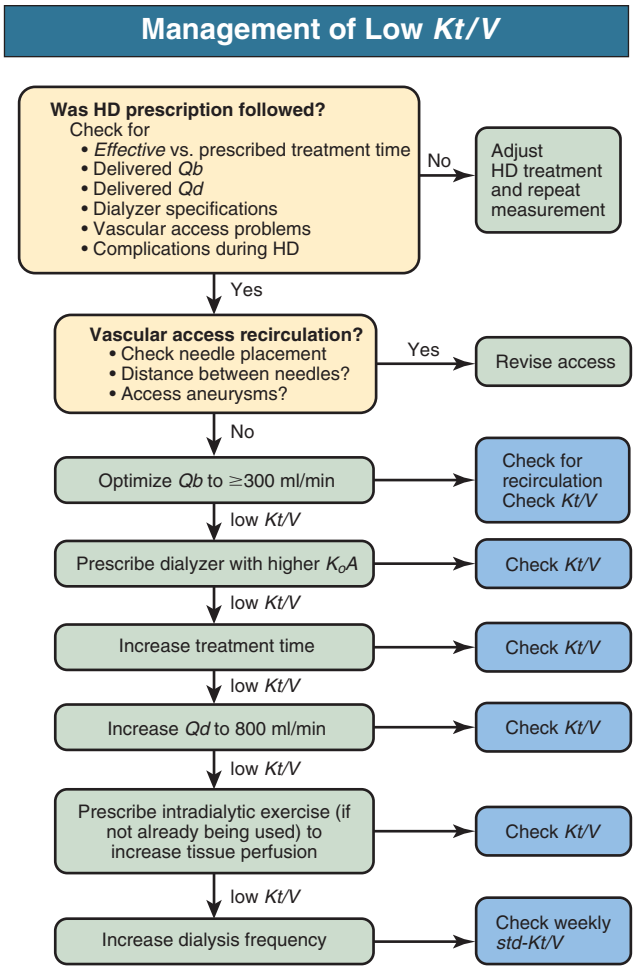

Figure 94-4 Management of low and inadequate *Kt/V*. *HD,* Hemodialysis; K_oA, the dialyzer urea mass transfer area coefficient; *Qb,* blood flow rate; *Qd,* dialysate flow rate.

average session because unusual problems may have occurred (e.g., shortened time, single-needle HD). Frequent causes of inadequately low delivered dialysis dose are vascular access problems leading to recirculation. Blood sampling errors should also be considered because delayed post-HD sampling will reduce *Kt/V* results. If a low *Kt/V* remains unexplained, treatment time should be increased and a more efficient dialyzer and higher blood and dialysate flow rates should be considered (Fig. 94-4). Active or passive muscle stimulation during dialysis improves *Kt/V* by increasing blood supply to poorly perfused muscle tissue and facilitates urea and phosphate removal.[8] Delivered *Kt/V* should be checked whenever the dialysis prescription has been modified substantially. Online clearance monitoring tools allow assessment of *Kt/V* during each single dialysis session without blood sampling.

Recommendations for Dialysis Dose Adequacy

Current European Best Practice Guideline recommendations[9] for dialysis strategies include the following:

- Dialysis should be delivered at least three times per week and the total duration should be at least 12 h/wk, unless supported by significant renal function.
- Delivered dialysis dose should be measured at least monthly.
- In anuric patients treated with three-times-per-week dialysis, the prescribed target *eKt/V* should be at least 1.2. Higher doses up to 1.4 should be considered in female patients and in patients with high comorbidity.
- For patients with renal function or those with dialysis schedules other than three times per week, weekly dialysis dose should be at least equivalent to an *std-Kt/V* of 2.0.

OTHER DIALYSIS FACTORS RELATED TO OUTCOMES

Middle Molecule Removal

It is widely held that retention solutes of middle molecular size may play an important role in the pathogenesis of the uremic state and contribute significantly to the high mortality of dialysis patients. Because of higher membrane porosity, high-flux dialyzers have the capacity to remove larger amounts of middle molecules than low-flux dialyzers do, and this may even be further increased by the use of convective dialysis strategies, such as hemodiafiltration (HDF). Because of slower intercompartmental equilibration rates, middle molecule removal is limited during conventional 4-hour dialysis sessions. Serum β_2-microglobulin, a surrogate for uremic middle molecules, can only be effectively removed by high-flux dialysis, and predialysis β_2-microglobulin levels were found to be related to mortality in patients treated randomly with high-flux or low-flux dialyzers.[10] Certain subgroups of dialysis patients, such as diabetics, and incident patients with serum albumin levels below 40 g/l, may benefit most from high-flux dialysis.[11,12] The European Best Practice Guidelines recommend the use of synthetic high-flux membranes to reduce the cardiovascular risk and to improve control of hyperphosphatemia and anemia.[9]

On-line HDF has the potential to provide the most extensive removal of the widest range of low and middle molecular size solutes. Documented advantages of on-line HDF include a higher removal rate for creatinine, phosphate, β_2-microglobulin, and some protein-bound uremic compounds. Three prospective randomized controlled studies have recently examined outcomes in on-line HDF compared with low- or high-flux HD. In two of these studies no statistically significant benefit was observed for on-line HDF in intention-to-treat analyses of the whole study populations.[13,14] However, in both studies *post hoc* on-treatment analyses revealed a significantly better outcome for subgroups of patients treated with a mean delivered convective volume of more than 18 to 22 liters per session. Results of a third randomized controlled trial from Spain (ESHOL trial)[15] confirmed these observations. Compared with patients who continued on HD, those assigned to high-efficiency on-line HDF with a mean delivered volume of 22 to 24 liters had a 30% lower risk of all-cause mortality, a 33% lower risk of cardiovascular mortality, and a 55% lower risk of infection-related mortality. Based on these three studies, high-efficiency HDF with a delivered substitution fluid volume exceeding 22 liters per session may well become a standard dialysis modality in the future.

Phosphate Removal

Hyperphosphatemia is a major problem in HD (see Chapter 85).[16] Management of hyperphosphatemia is based on phosphate removal by dialysis, dietary phosphate restriction, and intestinal phosphate binding with use of phosphate binder medication. Intradialytic phosphate kinetics differ significantly from urea kinetics, with serum phosphate levels steeply falling during the first 90 to 120 minutes into dialysis and stabilizing thereafter (Fig. 94-5). The intradialytic plateau is explained by phosphate mobilization from various compartments at a rate similar to that of dialyzer phosphate removal.

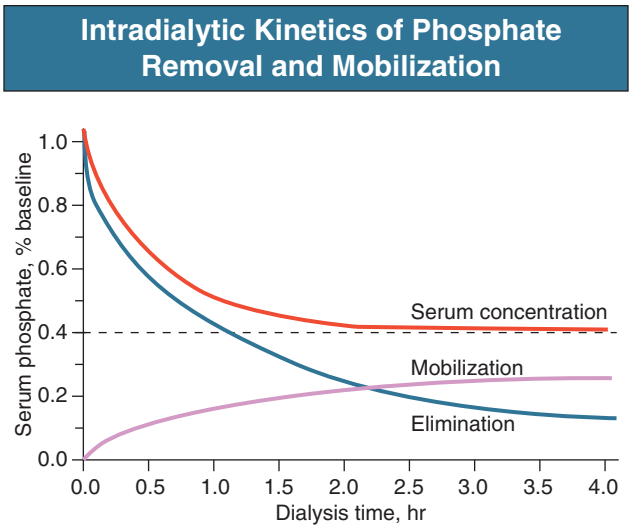

Figure 94-5 Intradialytic kinetics of phosphate removal and mobilization.

Phosphate removal can be improved by high-flux HD and HDF, by the use of a larger dialyzer surface area, and, most dramatically, by higher-frequency dialysis schedules, such as short daily or daily nocturnal HD. Long frequent dialysis schedules may even result in hypophosphatemia so that phosphate has to be added to the dialysate. In all patients, predialysis serum phosphate levels should be reduced toward the normal range.

Preservation of Residual Renal Function

Most patients starting dialysis still have considerable RRF; but by the end of the first year, the majority have lost RRF completely. Only 10% to 20% of patients still have RRF after more than 3 years of dialysis. RRF of 2 to 3 ml/min urea clearance contributes significantly to the elimination of uremic toxins.[17] This translates into lower serum β_2-microglobulin, phosphate, potassium, urea, creatinine, and uric acid levels, as well as maintained endocrine, metabolic, and antioxidative stress functions; higher hemoglobin concentration; enhanced nutritional status; better quality-of-life scores; and a reduced need for dietary and fluid restrictions. Loss of RRF, in contrast, is associated with left ventricular hypertrophy. To assess the relative contribution of RRF to total delivered dialysis dose, weekly dialysis dose should be expressed as *std-Kt/V*. For a patient with an estimated total body water of 40 liters, a residual urea clearance of 2 to 3 ml/min is equivalent to an *std-Kt/V* of 0.5 to 0.75/week. Risk factors for the loss of RRF include activation of the immune system by cellulose-based membranes and dialysate water impurities; intradialytic hypotension; use of angiotensin-converting enzyme inhibitors or nephrotoxic agents, such as radiocontrast media, aminoglycosides, and nonsteroidal anti-inflammatory drugs; and hypercalcemia. Loss of RRF may be delayed by adequate target post-HD weight prescription and prevention of intradialytic hypotensive episodes.

Dialysate Composition

During a standard treatment session, a patient's blood is exposed to 120 to 200 liters of dialysate. The several ingredients of dialysate should therefore be prescribed with great care.

Sodium

Sodium retention is a typical feature of ESRD and an important factor in the pathogenesis of hypertension in HD patients. Judicious control of sodium balance is effective in normalizing blood pressure, and dietary sodium intake should be restricted to 6 g salt or 100 mmol sodium per day. Sodium is mainly removed through ultrafiltration; but depending on the ratio of dialysate to plasma water sodium concentration, it will be additionally removed from or delivered to the patient by diffusion. For prevention of a positive sodium balance, either dialysate and serum sodium concentrations should be aligned or care should be taken that dialysate sodium does not exceed the patient's average predialysis serum sodium concentration by more than 2 to 3 mmol/l.

Potassium

Potassium removal during dialysis should ideally be equal to the amount accumulated during the interdialytic period. The dialysate potassium concentration has to be set at a level that avoids pre-HD hyperkalemia as well as intradialytic hypokalemia, which may provoke dialysis-induced arrhythmia. The typical dialysate potassium concentration is set to 2.0 to 4.0 mmol/l. Prescription of potassium dialysate concentrations below 2.0 mmol/l has been associated with an increased risk for tachyarrhythmia and sudden cardiac death and should therefore be avoided.[18]

Calcium

In light of the interdialytic positive calcium balance and accelerated vascular calcification as a major cardiovascular risk factor in ESRD, intradialytic calcium delivery to the patient should be avoided. In patients using calcium salts as phosphate binders, a negative intradialytic calcium mass balance is desirable.[19] A standard dialysate calcium concentration of 1.25 to 1.50 mmol/l is recommended by Kidney Disease: Improving Global Outcomes (KDIGO), but some patients will be in positive balance even at 1.25 mmol/l.[20] These and higher dialysate calcium concentrations may be associated with tissue calcium accumulation, whereas lower dialysate calcium will stimulate parathyroid hormone (PTH) secretion.

Bicarbonate

Chronic metabolic acidosis is associated with decreased protein synthesis and increased protein catabolism and contributes to mineral and bone disorders. Normalized pre-HD bicarbonate levels in the range of 20 to 23 mmol/l are associated with improved survival. Dialysate bicarbonate concentration is typically set at 35 to 40 mmol/l to generate a transmembrane concentration gradient favoring bicarbonate delivery to the patient. Data from DOPPS indicate that both high (>27 mmol/l) and low (<17 mmol/l) serum bicarbonate levels are associated with increased risk for mortality and hospitalization.[21]

Treatment Time

Conventional three-times-a week dialysis remains the standard of care in most countries; treatment time is typically governed by dialysis dose *(Kt/V),* with the consequence of longer dialysis in patients with higher urea distribution volumes. Acknowledging the difficulties in removing adequate amounts of low and middle molecular size uremic solutes during short dialysis sessions, a minimum treatment time of 4 hours per HD session is recommended in various countries, such as Germany. Even with similar *Kt/V,* longer treatment times are associated with higher mass removal of urea, creatinine, phosphate, and β_2-microglobulin compared with shorter treatment times.[22]

Weekly treatment time is the one factor with the potentially highest impact on dialysis dose and outcome. More frequent in-center dialysis and longer dialysis hours delivered by in-center or home nocturnal dialysis are increasingly used alternatives to

conventional thrice-weekly treatment. Both modalities offer the opportunity for improved solute clearance and complete removal of interdialytic weight gain with fewer problems because ultrafiltration rates are lower and hypotension is less likely. The randomized controlled Frequent Hemodialysis Network (FHN) study[23] demonstrated that short daily in-center HD is associated with a reduction in left ventricular mass and an improvement of the physical health score. Although it is assumed that this may translate into reduced mortality rates, survival advantages of daily HD over conventional HD still need to be demonstrated. Several retrospective epidemiologic studies in larger patient populations suggest a survival advantage for patients treated with extended time and/or frequency dialysis schedules, such as daily nocturnal or thrice-weekly nocturnal HD, over conventional HD.[24-26]

Fluid Status

Fluid overload, which is found in the majority of HD patients, is an established risk factor for the development of arterial hypertension, left ventricular hypertrophy, and cardiovascular mortality. It is the goal of an adequate HD treatment to normalize body water homeostasis and extracellular volume to a level comparable with that of patients of similar age and normal renal function. In clinical practice, this idealized postdialysis body weight is termed *dry weight,* and it may differ substantially from the target weight prescribed by the physician. Because of the difficulties in detecting fluid overload of 2 to 3 liters clinically from the presence of edema, high blood pressure, dyspnea, and increased jugular venous pressure, technical methods such as ultrasound (diameter of inferior vena cava), chest radiography, lung ultrasound, and whole-body bioimpedance should be applied regularly.[27] The prescribed post-HD target weight is achieved by ultrafiltration. Ultrafiltration rates above 1000 ml/h are associated with an increased risk of intradialytic hypotension, which in turn is associated with an increased long-term mortality risk. Transient myocardial ischemia appears to occur regularly during dialysis in relation to ultrafiltration rates exceeding 500 ml/h. Intradialytic hemodynamics can be stabilized by isothermic HD, in which the physiologic intradialytic rise in body core temperature, a key factor in the pathogenesis of intradialytic hypotension, is prevented through cooling of the dialysate.[28] In hemodynamically unstable patients, only low ultrafiltration rates and therefore longer dialysis treatment times can accomplish the goal of adequate fluid removal.

Dialysis patients are advised to limit daily fluid intake to 0.5 to 0.75 liter in excess of their average daily diuresis and to control dietary salt intake. A positive interdialytic and intradialytic sodium balance is a major factor governing thirst and interdialytic water intake. Dietary salt restriction to 6 g salt per day is recommended to prevent high interdialytic weight gain and the development of arterial hypertension and congestive heart failure. This often requires constant education including the family. A gradual reduction in interdialytic weight may reflect poorer appetite and diminished food intake and, together with a decrease in systolic blood pressure, serum albumin, and C-reactive protein, has been identified as a marker of imminent death within 1 year.[29]

Nutritional Status

Hemodialysis patients are at risk of malnutrition from protein-energy wasting, decreased appetite, infection, intercurrent illnesses, hospital admissions, and missed meals after dialysis.[30] The recommended daily intake of 1.0 to 1.2 g protein per kilogram of ideal body weight and 35 kcal/kg ideal body weight is often not met. The nutritional status of dialysis patients should be assessed regularly by clinical and biochemical means, including measurement of protein nitrogen appearance (see Chapter 87).

Vascular Access

The choice of vascular access strongly affects outcome in dialysis patients. A functioning vascular access is a major precondition for adequate dialysis treatment. Native fistulas should always be the first-line vascular access. In patients in whom a native fistula cannot be created, a vascular graft may be an alternative. Central venous catheters may be used for bridging until a vascular access can be used for dialysis. Only when a native fistula or a graft is not available and conversion to peritoneal dialysis appears not feasible should subcutaneous tunneled central venous catheters be used as permanent access. Worldwide, there are large differences in the fraction of patients with central venous catheters used as permanent access. Long-term catheter use is associated with a higher rate of chronic inflammation and acute infection, lower serum albumin levels, impaired response to erythropoietin, and higher hospitalization and mortality rates, mainly because of infection (see Chapter 91). The quality of the vascular access should be assessed regularly by clinical means, such as inspection, palpation, and auscultation, as well as by technical means, including intradialytic measurement of recirculation or access flow rate and Doppler ultrasound technology.

Quality of Life

Quality-of-life measures may be among the most sensitive indicators of the efficacy of dialysis therapies. Measures of physical and mental aspects of quality of life are recognized to assess the physical and psychological disturbances that can accompany the uremic state and can be modified by renal replacement therapy.[31] Various standardized quality of life tests are now routinely used in clinical trials involving HD patients. In addition to dialysis adequacy, quality of life may also be significantly affected by factors related to organizational issues—for example, travel delays, waiting time at the dialysis facility for treatment to start, time of dialysis in relationship to work or educational needs, and lack of exercise.

Depression is one of the major mental aspects affecting quality of life and may be assessed separately by validated standardized questionnaires, such as the Beck Depression Inventory.[32] Depression is frequently associated with biochemical evidence of inflammation or infection and may improve with appropriate treatment. One potential way to make some impact on some of these issues is to modify the "assembly line" character of many dialysis centers with variations including physical exercise and occupational therapy programs and opportunities for the patients to have regular meetings with staff to discuss their questions.

CHAPTER 95

Acute Complications During Hemodialysis

Kevan R. Polkinghorne and Peter G. Kerr

Although technical advances in hemodialysis (HD) have made the procedure increasingly safe and well tolerated, there are still important acute complications that will be encountered by physicians responsible for patients receiving HD in both acute and chronic clinical settings. These complications with their causes and management are discussed in this chapter.

CARDIOVASCULAR COMPLICATIONS

Intradialytic Hypotension

Intradialytic hypotension, which occurs in 10% to 30% of treatments, ranges from asymptomatic episodes to marked compromise of organ perfusion resulting in myocardial ischemia, cardiac arrhythmias, vascular thrombosis, loss of consciousness, seizures, or death.[1] Furthermore, in patients with acute kidney injury, intradialytic hypotension may induce more renal ischemia and retard recovery of renal function. Intradialytic hypotension and postdialysis orthostatic hypotension have been shown to be independent risk factors for mortality.[2] The pathogenesis of intradialytic hypotension is complex[3] and is summarized in Figure 95-1. Most commonly, however, intradialytic hypotension results from the need to deal with excessive fluid weight gain between dialysis treatments. The subsequent rate of fluid removal required exceeds the achievable rate of intravascular filling, resulting in relative intravascular volume depletion.

The immediate treatment is to restore the circulating blood volume by placing the patient in the Trendelenburg position, reducing or stopping ultrafiltration, and infusing boluses of 0.9% isotonic saline (100 ml or more, as necessary). Salt-poor albumin and other hypertonic solutions offer no advantage over isotonic saline and cost more. Blood flow rate should not be routinely reduced to manage hypotension, because this has not been shown to be beneficial. If the blood pump rate is reduced transiently, particular attention should be paid to minimizing underdialysis from such a practice. Of course, in the setting of excessive weight gain, the administration of boluses of saline makes achieving the target dry weight more difficult. Because cardiac factors can precipitate intradialytic hypotension, the clinician should maintain a high index of suspicion for cardiac ischemia, especially if hypotension is accompanied by chest pain or dyspnea, and an electrocardiogram and serum troponins should be obtained. Similarly, recurrent and unexplained episodes of hypotension might warrant echocardiography to rule out pericarditis or pericardial effusion.

Preventive strategies include correction of anemia and hypoalbuminemia and treatment of congestive heart failure or arrhythmias, avoidance of antihypertensive drugs before dialysis, and avoidance of food before and during dialysis. Patients should be counseled to avoid excessive interdialytic weight gain, and accurate assessment of the patient's dry weight is required. Particular attention should be given to ensuring minimal salt intake. Midodrine, an oral selective α_1-agonist, 5 to 10 mg predialysis, is a useful preventive therapy.[4]

Preventive strategies through modification of the dialysis procedure include in the first instance use of bicarbonate dialysate, volumetric control of ultrafiltration, and sodium modeling. Subsequently, reducing the ultrafiltration rate by increasing either the number of hours or the frequency of dialysis can be tried.[5] I On-line blood volume monitoring and biofeedback techniques have been developed in an attempt to improve intradialytic cardiovascular stability.[6] Although on-line blood volume devices have been shown to decrease the incidence of intradialytic hypotension in an at-risk population, there is limited evidence that blood volume monitoring can predict intradialytic hypotension in individual patients or produce a long-term morbidity and mortality benefit, especially in the wider HD population.[7] Cooling of dialysate to 35.5°C to 36°C (95.9°F to 96.8°F), a measure that induces release of catecholamines, resulting in vasoconstriction or at least preventing vasodilation, may lessen hypotension. A systematic review of the randomized controlled trials using biofeedback modulating dialysate temperature demonstrated significant reductions in the incidence of intradialytic hypotension compared with conventional dialysis.[8] Modulation of dialysate temperature is achieved by measuring the blood temperature in the arterial and venous circuits and feeding back the information to the arterial and venous thermostats in the dialysis machine. The machine can be programmed to allow either a constant body temperature and a negative overall energy transfer, so-called *isothermic hemodialysis,* or thermoneutral hemodialysis, which aims to prevent energy transfer between the dialysate and extracorporeal blood. Both isothermic and thermoneutral HD have been shown to reduce intradialytic hypotension in randomized trials compared with conventional HD.

Intradialytic Hypertension

Intradialytic hypertension occurs in 8% to 30% of treatments.[9] Hypertension during or immediately after HD constitutes an important risk factor for cardiovascular mortality. Moreover, an intradialytic increase in systolic blood pressure is associated with an increased risk of hospitalization or death.[10]

In most circumstances, an intradialytic elevation of blood pressure indicates significant volume overload. However, in a number of patients, blood pressure remains elevated despite fluid removal, a syndrome called *dialysis-refractory hypertension.* These patients are usually young with preexisting hypertension and have excessive interdialytic weight gain and a hyperactive renin-angiotensin system in response to fluid removal.[11] In these patients the hypertension is still mediated by the previous volume expansion, but there is often a lag of days to 2 or more weeks before the blood pressure becomes normal (known as the dialysis "lag phenomenon"). Often patients can discontinue most of their antihypertensive agents once this occurs.

Erythropoietin (EPO) and other erythropoiesis-stimulating agents have been associated with a 20% to 30% incidence of new onset or exacerbation of hypertension. Furthermore, among patients

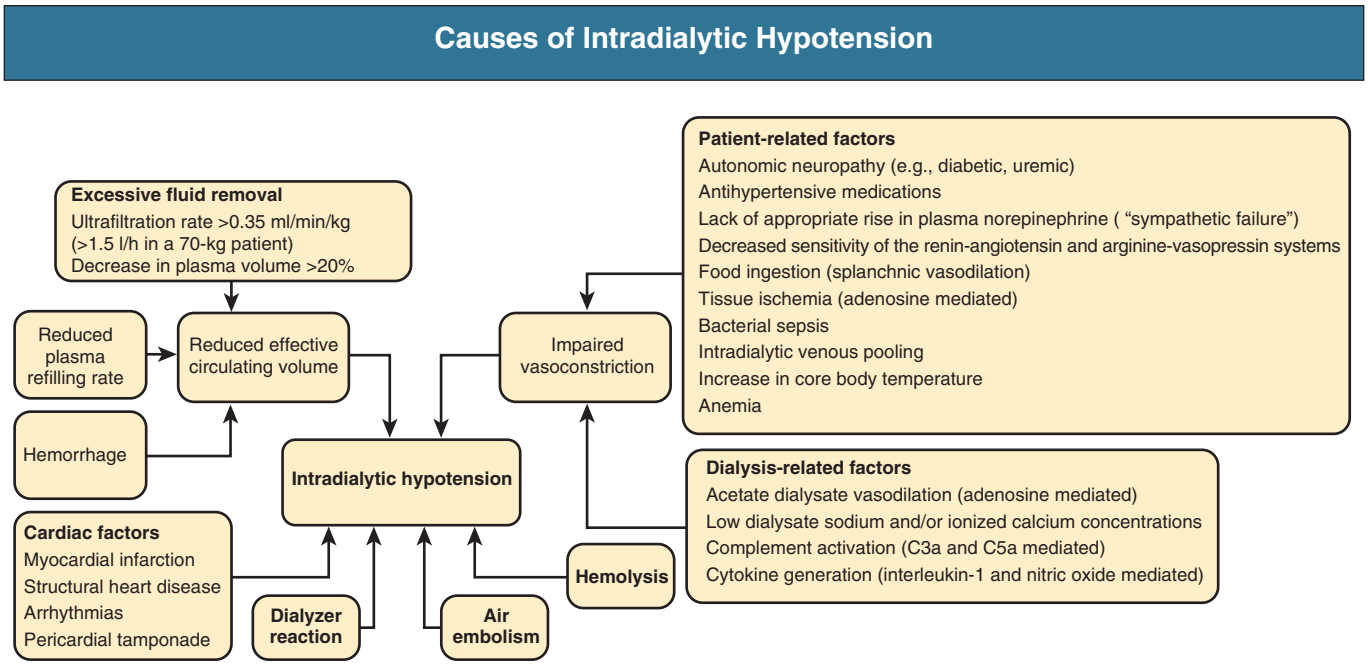

Figure 95-1 Pathogenesis and causes of intradialytic hypotension.

receiving intravenous (not subcutaneous) EPO, elevated levels of endothelin-1 (a potent vasoconstrictor) have been shown to correlate with increased blood pressure. Predominantly, such EPO-induced rises in blood pressure are associated with a rapid rise in hemoglobin and can be avoided by a more conservative approach to correcting the hemoglobin.

Intradialytic hypertension can be precipitated by the use of high sodium dialysate, which is intended to mitigate the intradialytic decrease in serum osmolality that occurs with the diffusive removal of urea and sodium.[12] Although this approach stabilizes blood pressure during dialysis by improving intravascular filling, high sodium dialysate results in a positive intradialytic sodium balance and is associated with increased postdialysis thirst, resulting in significant weight gain in the interdialytic period. To circumvent these problems, sodium modeling has been adopted as an approach that uses variable sodium concentrations in the dialysate, generally with sodium reduced in a continuous or stepwise manner from an initial level of 150 to 154 mmol/l to 138 to 142 mmol/l. Although sodium modeling has been widely promoted, randomized trial evidence for definite benefits of this approach is lacking.[13] Other hypothesized mechanisms of intradialytic hypertension include hyperactivity of the sympathetic nervous system[14] and increased cardiac output resulting from fluid removal, particularly among patients with cardiomyopathy.[15] Clinicians should also be aware of possible dialytic removal of certain antihypertensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and beta blockers.

Increasing hypertension during a dialysis session requires intervention if systolic blood pressure is greater than 180 mm Hg. This is best treated with a centrally acting agent such as clonidine or a short-acting ACE inhibitor such as captopril. Successful treatment of hypertension for a longer period requires an accurate determination of the patient's dry weight and its achievement by gradual ultrafiltration during several weeks of dialysis. Once dry weight is achieved, optimization of antihypertensive drug therapy is warranted, including the use of minimally dialyzable or nondialyzable medications such as angiotensin receptor blockers, calcium channel blockers, clonidine, and carvedilol. However, it should be remembered that use of antihypertensive agents may make achievement of dry weight difficult because of induced intradialytic hypotension. Evidence from the Dry-Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) trial[16] would suggest that optimal control of blood pressure in HD patients is via volume control, not the use of antihypertensive agents. One common error in management is to treat dialysis hypertension with increasing blood pressure medications as opposed to opting to achieve dry weight. The use of vasodilator drugs (hydralazine, minoxidil) can lead to increased fluid retention that worsens hypertension and volume overload. Minoxidil can also be associated with the development of pleural and pericardial effusions.

Cardiac Arrhythmias

Intradialytic arrhythmias are common and are often multifactorial in origin.[17,18] Left ventricular hypertrophy, congestive cardiomyopathy, uremic pericarditis, silent myocardial ischemia, and conduction system calcification are frequently encountered in adult dialysis patients. In addition, polypharmacy coupled with the constant alterations in fluid, electrolyte, and acid-base homeostasis may precipitate intradialytic arrhythmias. The range of electrocardiographic abnormalities that may be encountered in renal failure is shown in Table 95-1. QTc dispersion, the difference between maximum and minimum QTc interval on a standard 12-lead electrocardiogram, is prolonged after HD and has been proposed as a prognostic indicator of cardiac complications in dialysis patients.[19]

Preventive measures include the use of bicarbonate dialysate and careful attention to dialysate potassium and calcium levels. There are very few trials of the most appropriate dialysate potassium level, although recent observational evidence suggests that dialysate potassium levels below 2 mmol/l should be avoided in most patients.[20] Zero potassium dialysate should be avoided because of its arrhythmogenic potential, particularly in patients receiving digoxin, should serum potassium concentration decrease to less than 3.5 mmol/l. Serum digoxin levels should be regularly monitored and the need for the drug regularly reassessed.

Electrocardiographic Abnormalities in Renal Failure

Function	Abnormality Seen in Renal Failure
PR interval	Usually normal; prolongation in long-term hemodialysis Calcification of mitral valve annulus may involve His bundle, resulting in complete heart block
QRS interval	
Amplitude	Increases during ultrafiltration (correlates with reduction in left ventricular [LV] dimensions) LV hypertrophy (LVH) on voltage criteria found in up to 50%
Duration	Prolonged (within normal range) by hemodialysis Late potentials increased only in patients with preexisting coronary heart disease Prolonged in hyperkalemia
ST segment	Depression during hemodialysis does not predict coronary artery disease Depression or elevation may occur in hyperkalemia Depression during ambulatory monitoring poorly predictive of coronary artery disease
QTc interval	Increases during hemodialysis (correlates with reduction in K^+ and Mg^{2+}) Increased QT dispersion reported in patients on dialysis
T wave	Peaking or inversion may occur in hyperkalemia Inversion in anterolateral leads in LVH with strain pattern
Rhythm	High incidence of atrial and ventricular arrhythmias during hemodialysis

Table 95-1 Electrocardiographic abnormalities in renal failure. Risk factors include LV dysfunction, wall motion abnormalities, known coronary artery disease, abnormal perfusion scans (even without coronary artery disease), use of cardiac glycosides, and low dialysate potassium concentration.

Sudden Death

Cardiac arrest occurs at a rate of 7 per 100,000 HD sessions and is more common in the elderly, patients with diabetes, and patients using central venous catheters.[21] Some 80% of sudden deaths during dialysis are caused by ventricular fibrillation, more frequently observed after the long interdialytic interval on thrice-weekly dialysis, presumably because of more marked fluid and solute accumulation.[22-24] Consistent with this hypothesis, both peritoneal dialysis patients and patients undergoing long-duration HD do not show this high event rate on a particular day of the week.[24] Although coronary heart disease increases the risk of sudden death, other catastrophic intradialytic events need to be ruled out. The prompt recognition and treatment of hyperkalemia, often encountered in young, noncompliant patients, is imperative. Profound generalized muscle weakness may be a warning sign of imminent life-threatening hyperkalemia.

When cardiopulmonary arrest occurs during dialysis, an immediate decision must be made as to whether the collapse is the result of an intrinsic disease or technical errors, such as air embolism, unsafe dialysate composition, overheated dialysate, line disconnection, or sterilant in the dialyzer. Air in the dialysate, grossly hemolyzed blood, and hemorrhage caused by line disconnection can be easily detected. However, if no obvious cause is identifiable, blood should not be returned to the patient, particularly if the arrest occurred immediately on initiation of dialysis. A patient exposed to formaldehyde may have complained earlier of burning at the access site; fortunately this agent is rarely used today. If the possibility of a problem with dialysate composition is remote, blood may be returned to the patient. However, blood and dialysate samples should be immediately sent for electrolyte analysis, the dialyzer and blood lines saved for later analysis, and the dialysis machine replaced until all its safety features have been thoroughly evaluated for possible malfunction. It should be a standard practice to have defibrillators in dialysis units. The management of cardiopulmonary arrest during dialysis should follow the standard principles of cardiopulmonary resuscitation; the diagnosis and management of technical errors are discussed later.

Prevention of sudden cardiac death in HD patients, including the role of implantable defibrillators, is further discussed in Chapter 82.

Dialysis-Associated Vascular Steal Syndrome

Clinical Presentations (Symptoms Often Aggravated on Dialysis)
- Hand numbness, pain, or weakness
- Coolness of distal arm
- Diminished pulses
- Acrocyanosis, gangrene

Differential Diagnosis
- Dialysis-associated cramp
- Polyneuropathy—diabetes, uremia
- Entrapment neuropathy—$A\beta_2M$ amyloid
- Reflex sympathetic dystrophy
- Calciphylaxis

Evaluation of Steal Severity
- Pulse oximetry
- Plethysmography
- Doppler flow
- Angiography

Treatment Options (Depending on Severity)
- Symptomatic (e.g., gloves)
- Surgical, with preservation of vascular access: banding to reduce flow, distal revascularization–interval ligation (DRIL) procedure (see Fig. 91-6)
- Surgical, with loss of vascular access: ligation

Box 95-1 Dialysis-associated vascular steal syndrome.

Pericarditis

The management of pericarditis in dialysis patients is discussed in Chapter 82.

Dialysis-Associated Steal Syndrome

The construction of an arteriovenous fistula or graft frequently results in reduction of blood flow to the hand. Although clinically significant ischemia does not usually result, symptoms are by no means rare, particularly in diabetic or elderly patients with peripheral vascular disease. Dialysis-associated steal syndrome is more common in upper arm arteriovenous fistulas (about 4%) compared with both arteriovenous grafts and forearm arteriovenous fistulas (about 1%). The clinical presentation, differential diagnosis, and evaluation of dialysis-associated steal syndrome are summarized in Box 95-1 and are discussed further in Chapter 91.[25,26]

Treatment depends on the clinical severity of ischemia and vascular access anatomy.[26] Severe ischemia can cause irreparable injury to nerves within hours and must be considered a surgical emergency. Mild ischemia, manifested by mild pain during HD, subjective coldness and paresthesias, and objective reduction in skin temperature

but with no loss of sensation or motion, is common and generally improves with time.[27] Patients with mild ischemia should undergo symptom-specific therapy (e.g., wearing a glove) and frequent physical examination, with special attention to subtle neurologic changes and muscle wasting.[28] Failure to improve may necessitate surgical or radiologic intervention (see Chapter 91). Persistence of symptoms after an apparently successful correction of the vascular access flow should alert the clinician to other unrelated causes.

NEUROMUSCULAR COMPLICATIONS

Muscle Cramps

Muscle cramps occur in 5% to 20% of patients late during dialysis and frequently involve the legs. They account for 15% of premature discontinuations of dialysis.[30] Electromyography shows increased tonic muscle electrical activity throughout dialysis, and serum creatine kinase may be elevated.

Although the pathogenesis is unknown, dialysis-induced volume contraction and hypo-osmolality are common predisposing factors. Indeed, the onset of muscle cramps may give an indication that the target weight has been reached. However, hypomagnesemia and carnitine deficiency may also play a role.

The acute management is directed at increasing plasma osmolality. Cessation of ultrafiltration is not useful. Parenteral infusion of 23.5% hypertonic saline (15 to 20 ml), 25% mannitol (50 to 100 ml), or 50% dextrose in water (25 to 50 ml) is equally effective. However, hypertonic saline may result in postdialytic thirst, and both hypertonic saline and mannitol cause transient warmth and flushing during the infusion. Furthermore, large and repetitive infusions of mannitol may lead to increased thirst, interdialytic weight gain, and fluid overload. Overall, dextrose in water is preferred, particularly in nondiabetics.

Preventive measures include dietary counseling about excessive interdialytic weight gain. In patients without clinical signs of fluid overload, it is reasonable to increase the dry weight by 0.5 kg and to observe the clinical response. Quinine sulfate (250 to 300 mg) or oxazepam (5 to 10 mg) given 2 hours before dialysis may also be effective. Although the U.S. Food and Drug Administration regards quinine sulfate as both unsafe and ineffective for the prevention of cramps, this drug works well in some patients, and it is used freely in most parts of the world. Some reports also promote the use of vitamin E in this role.[31] The use of sodium gradient during dialysis may have some benefit as well. Proposed strategies include starting with a dialysate sodium concentration of 145 to 155 mmol/l and a linear decrease to 135 to 140 mmol/l by the completion of the treatment. A comparison of sodium modeling with an exponential, linear, or step program has yielded similar results.[32] In anecdotal reports, 5 mg of enalapril twice weekly may be effective, presumably by inhibiting angiotensin II–mediated thirst. Stretching exercises, magnesium, creatine monohydrate (12 mg before dialysis),[33] and L-carnitine supplementation (20 mg/kg per dialysis session) may also be beneficial.[34] An intradialytic blood volume biofeedback control system has been shown to reduce the incidence of muscle cramps.[35]

Restless Legs Syndrome

Restless legs syndrome is common in dialysis patients. The typical complaint is of crawling sensations in the legs that occur with inactivity, and symptoms may worsen during dialysis. The etiology, prevention, and management of restless legs syndrome are discussed in Chapter 86.

Dialysis Disequilibrium Syndrome

Despite a decline in its incidence, dialysis disequilibrium syndrome (DDS) is still observed sporadically in patients who are initiated on HD on high-flux dialyzers with large surface areas and short dialysis time. Risk factors include young age, severe uremia, rapid and marked intradialytic falls in urea at dialysis initiation, low dialysate sodium concentration, and preexisting neurologic disorders (see Chapter 86).

Dialysis disequilibrium syndrome commonly presents with restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, disorientation, tremor, and hypertension. More severe manifestations include obtundation, seizures, and coma. DDS usually develops toward the end of dialysis but may be delayed for up to 24 hours. Although cerebral edema is a consistent finding on computed tomographic scanning, DDS remains a clinical diagnosis because laboratory tests, including electroencephalography, are nonspecific. It is usually self-limited, but full recovery may take several days.

The pathogenesis of DDS is still a subject of debate. The reverse urea effect theory, which proposes that a transient osmotic disequilibrium occurs during dialysis as a result of a more rapid removal of urea from blood than from cerebrospinal fluid, has been disputed.[36] In animals undergoing rapid dialysis, despite the correction of systemic acidosis, a paradoxical cerebrospinal fluid acidosis develops that is aborted by slower dialysis. An additional mechanism is the intracerebral accumulation of idiogenic osmoles, such as inositol, glutamine, and glutamate.

In high-risk patients, preventive measures include the use of volumetric-controlled machines, bicarbonate dialysate, sodium modeling, earlier recognition of uremic states, and stepped initiation of dialysis (short initial treatment times with lower blood pump speeds). In addition, short and more frequent dialysis treatments are recommended with use of small surface area dialyzers and reduced blood flow rates. The target reduction in blood urea should initially be limited to 30%. The prophylactic use of mannitol or anticonvulsants is not recommended.

An extension of this syndrome may be one that mimics osmotic demyelination syndrome—similar to that seen with rapid correction of hyponatremia. Several cases have been reported in association with dialysis initiation, with clinical manifestations similar to the locked-in pontine picture of central demyelination. The difference is that with the dialysis-related condition, the patients appear to recover over the ensuing 5 to 7 days and the condition seems to be related to edema rather than demyelination.[37]

Seizures

Intradialytic seizures occur in less than 10% of patients and tend to be generalized but easily controlled. However, focal or refractory seizures warrant evaluation for focal neurologic disease, particularly intracranial hemorrhage. Causes of seizures are summarized in Figure 95-2 and are discussed further in Chapter 86.

Treatment of established seizures requires cessation of dialysis, maintenance of airway patency, and investigation for metabolic abnormalities. Intravenous diazepam, alprazolam or clonazepam, and phenytoin may be required. Intravenous 50% dextrose in water should be administered promptly if hypoglycemia is suspected.

Headache

Dialysis headache is common and consists of a bifrontal discomfort that develops during dialysis and may become intense and

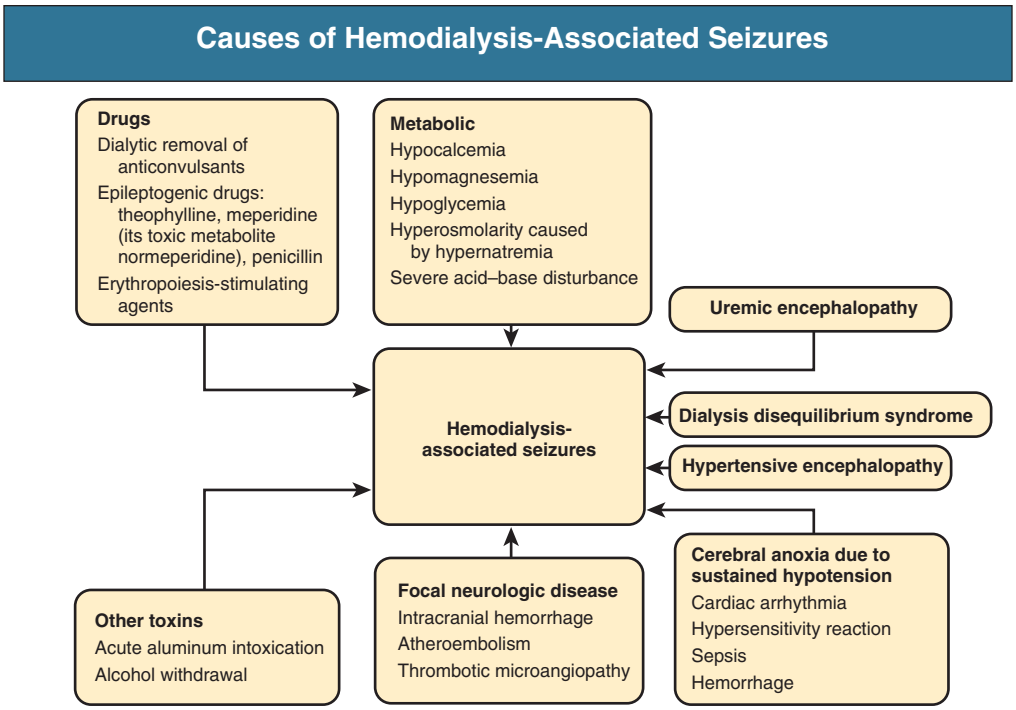

Figure 95-2 Causes of hemodialysis-associated seizures.

throbbing, accompanied by nausea and vomiting. It is usually aggravated by the supine position, but there are no visual disturbances.

Although its cause has not been elucidated, dialysis headache may be a subtle manifestation of DDS or may be related to the use of acetate, which is present in low concentrations (3 to 4 mmol/l) in almost all dialysate fluid. A role for nitric oxide has also been postulated.[38] Alternatively, it may be a manifestation of caffeine withdrawal caused by dialytic removal of caffeine.

Management consists of oral analgesics (e.g., acetaminophen [paracetamol]). Preventive measures include slow dialysis with reduced blood flow rates, change to bicarbonate dialysate, sodium and ultrafiltration modeling, coffee ingestion during dialysis, and use of reprocessed dialyzers. Attention should also be paid to adequate flushing of the lines and dialyzer before commencement of dialysis. Changing the dialysis membrane, especially to a synthetic membrane or an alternative synthetic membrane, sometimes is useful in patients with refractory cases.

HEMATOLOGIC COMPLICATIONS

Complement Activation and Dialysis-Associated Neutropenia

During dialysis with unsubstituted cellulose dialyzers, which are infrequently used, the free hydroxyl groups present on the membrane cause activation of the alternative pathway of complement.[39] This results in activation and increased adherence of circulating neutrophils to the endothelial capillary pulmonary vasculature, leading to transient neutropenia that reaches a nadir after 15 minutes of dialysis, followed by a rebound leukocytosis 1 hour later. Complement activation and neutropenia have also been detected with other more widely used dialyzer membranes, including cellulose acetate and polysulfone, but to a lesser degree. Although the long-term clinical relevance of this phenomenon remains speculative, its contribution to acute intradialytic morbidity is discussed later.

Intradialytic Hemolysis

Acute hemolysis can be caused by faulty dialysis equipment, chemicals, drugs, toxins, or patient-related factors (Fig. 95-3).[40] With the advent of better dialysis equipment and the widespread use of reverse osmosis and/or deionization systems and carbon filters, traumatic red blood cell fragmentation caused by poorly designed blood pumps and methemoglobinemia caused by water contamination with chloramine or copper are rarely seen today. However, nitrate or nitrite intoxication causing methemoglobinemia still occurs sporadically in patients on home HD who use well water that is contaminated with urine from domesticated animals. Furthermore, during dialyzer reprocessing, formaldehyde retention can result in hemolysis by inducing formation of cold agglutinins or inhibiting red cell metabolism.

The diagnosis of acute hemolysis is evident when grossly translucent hemolyzed blood is observed in the tubing. Patients with methemoglobinemia have nausea, vomiting, hypotension, and cyanosis, and oxygen therapy does not improve the black blood present in the extracorporeal circuit. Copper contamination should be suspected in the presence of skin flushing and abdominal pain or diarrhea.

Evaluation should include reticulocyte count, haptoglobin, lactate dehydrogenase, blood smear, Coombs test, and measurement of methemoglobin. Chromium 51 (^{51}Cr)–labeled red blood cell survival and bone marrow examination may occasionally be indicated if there is recurrent hemolysis. More important, analysis of tap water for chloramines and metal contaminants and thorough analysis of the dialysis equipment for clues of increased blood turbulence are recommended.

Hemorrhage

Bleeding complications are commonly related to the use of intradialytic anticoagulation, which further confounds the uremic bleeding diathesis (see Chapter 84).[41] In addition, dialysis patients are prone to spontaneous bleeding at specific sites, such as gastrointestinal

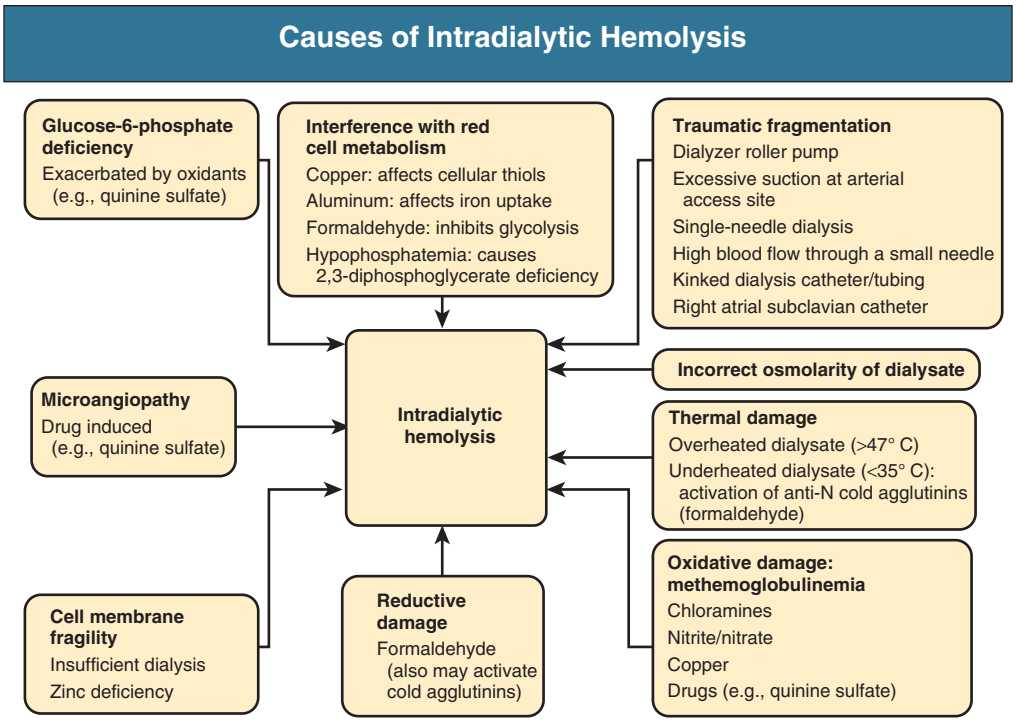

Figure 95-3 Causes of intradialytic hemolysis.

arteriovenous malformations; subdural, pericardial, pleural, retroperitoneal, and hepatic subcapsular spaces; and the ocular anterior chamber. Despite its limitations, the bleeding time remains the best indicator of hemorrhagic tendency.

In addition to specific measures directed to the site of hemorrhage, reversal of uremic platelet dysfunction is imperative. Strategies include the use of erythropoiesis-stimulating agents or red blood cell transfusions to achieve a hematocrit above 30% to improve rheologic platelet–vessel wall interactions, intravenous conjugated estrogens at 0.6 mg/kg per day for 5 consecutive days, intravenous or subcutaneous 1-deamino-8-D-arginine vasopressin (DDAVP) at 0.3 μg/kg administered over 15 to 30 minutes, and intravenous infusion of cryoprecipitate (see Box 84-2). For patients experiencing severe bleeding, it is advisable to consider heparin-free dialysis with use of normal saline flushes every 15 to 30 minutes with ultrafiltration adjustments. Other alternatives may include regional heparin or citrate anticoagulation, and in the long term the use of low-molecular-weight heparin, heparin modeling, or prostacyclin may be considered. More recently, the use of heparin-bound dialyzers (such as Hemophan or AN69ST) has been advocated in patients at risk of bleeding.[42] In patients scheduled for elective surgery or invasive procedures, cessation of aspirin should be considered a week earlier depending on the local protocols, the dose of anticoagulant reduced to a minimum, and the hematocrit maintained above 30%. In some patients, intravenous DDAVP to reverse the uremic platelet defect may also be required. Tranexamic acid, a potent fibrinolytic inhibitor, has occasionally been used as an adjuvant treatment to control hemorrhage in dialysis patients.[43]

Thrombocytopenia

An increasingly important cause of thrombocytopenia in dialysis patients is heparin-induced thrombocytopenia. The diagnosis and management, including alternative strategies for anticoagulation strategies for HD, are discussed in Chapter 84.

PULMONARY COMPLICATIONS

Dialysis-Associated Hypoxemia

In most patients, the arterial Pa_{O_2} decreases by 5 to 20 mm Hg (0.6 to 4 kPa) during dialysis, reaching a nadir at 30 to 60 minutes, and resolves within 60 to 120 minutes after discontinuation of dialysis. This decrease is usually of no clinical significance to patients unless there is preexisting chronic cardiopulmonary disease.

Hypoventilation is the main implicated factor and is primarily central in origin as a result of a decrease in carbon dioxide production after acetate metabolism (specific to acetate dialysate), loss of carbon dioxide in the dialyzer (with both acetate and bicarbonate dialysate), and rapid alkalinization of body fluids (particularly with large surface area dialyzers).[44] In addition, acetate-induced respiratory muscle fatigue can lead to hypoventilation, especially in acutely ill patients. Furthermore, a commonly observed ventilation-perfusion mismatch may be caused by pulmonary leukocyte agglutination (in part resulting from complement activation) or impaired cardiac output (resulting from acetate-induced myocardial depression).

In high-risk patients with fluid overload, preventive measures consist of using intradialytic oxygen supplementation, conventional bicarbonate dialysate, and biocompatible membranes. Optimizing hematocrit values and performing sequential ultrafiltration followed by HD may further reduce the likelihood of hypoxemia.

TECHNICAL MALFUNCTIONS

Air Embolism

The most vulnerable source of air entry into the extracorporeal circuit is the prepump tubing segment, where significant subatmospheric pressures prevail. However, other sources need to be considered, including intravenous infusion circuits especially with glass bottles, air bubbles from the dialysate, and (especially uncuffed)

dialysis catheters. High blood flow rates may allow rapid entry of large volumes of air despite small leaks.

Clinical manifestations depend on the volume of air introduced, the site of introduction, the patient's position, and the speed at which air is introduced.[45] In the sitting position, air entry through a peripheral vein bypasses the heart and causes venous emboli in the cerebral circulation. The acute onset of seizures and coma in the absence of precedent symptoms such as chest pain and dyspnea is highly suggestive of air embolism. In the supine position, air introduced through a central venous line will be trapped in the right ventricle, where it forms foam, interferes with cardiac output, and, if it is large enough, leads to obstructive shock. Dissemination of microemboli to the pulmonary vasculature results in dyspnea, dry cough, chest tightness, or respiratory arrest. Furthermore, passage of air across the pulmonary capillary bed can lead to cerebral or coronary artery embolism. In the left Trendelenburg position, air emboli migrate to the lower extremity venous circulation, resulting in ischemia as a result of increased outflow resistance. Foam may be visible in the extracorporeal tubing, and cardiac auscultation may reveal a peculiar churning sound.

The immediate management of clinically suspected air embolism is summarized in Figure 95-4. Prevention depends primarily on dialysis machines that are equipped with venous air bubble traps and foam detectors located just distal to the dialyzer and a venous pressure monitor at the venous end. The detector is attached to a relay switch that simultaneously activates an alarm, shuts off the blood pump, and clamps the venous blood line if air is detected. Therefore, dialysis should never be performed in the presence of an inoperative air detection alarm system. Glass bottles should be avoided because they create vacuum effects that can permit air entry into the extracorporeal system. Dialysis catheters should be aspirated and flushed with saline before connection. Dialyzer rinsing, before use, should expand all compartments to remove residual air bubbles.

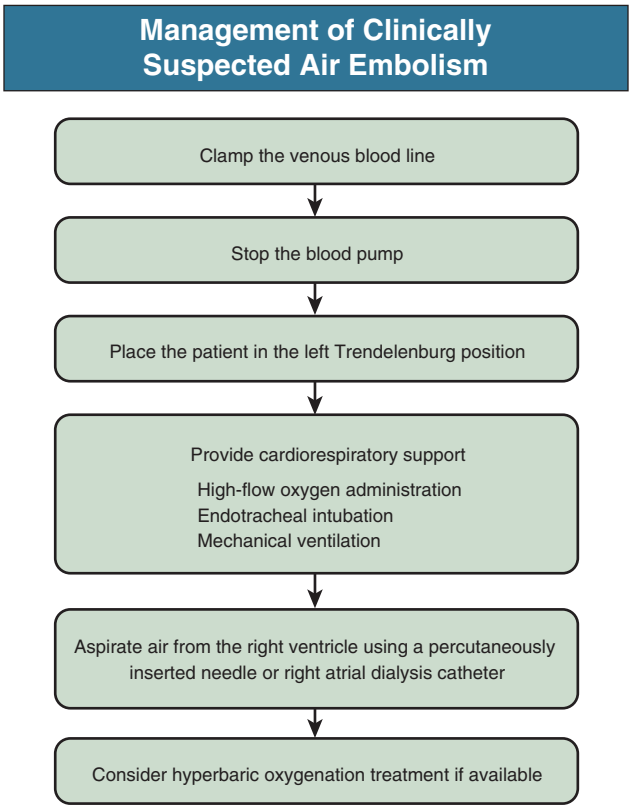

Figure 95-4 **Management of clinically suspected air embolism.**

Incorrect Dialysate Composition

Incorrect dialysate composition results from technical or human errors. Because the primary solutes constituting the dialysate are electrolytes, the dialysate concentration will be reflected by its electrical conductivity. Therefore, proper proportioning of concentrate to water can be achieved by the use of a meter that continuously measures the conductivity of the dialysate solution as it is being fed to the dialyzer. Life-threatening electrolyte and acid-base abnormalities are avoidable if the conductivity alarm is functioning properly and the alarm limits are set correctly. However, in dialysis machines that are equipped with conductivity-controlled mixing systems, the system automatically changes the mixing ratio of the concentrates until the dialysate solution conductivity falls within the set limits. This may inadvertently lead to dialysate without any bicarbonate, with apparently acceptable conductivity. Therefore, if conductivity-controlled systems are used, it is safer to also check the dialysate pH before dialysis. Conductivity monitors can fail or can be improperly adjusted by human error. Therefore, it is important to add human monitoring of dialysate composition before every treatment, whenever a machine has been sterilized or moved about, or whenever a new concentrate is used. Furthermore, many nonstandardized solutions are available, some of which may be used with an inappropriate proportioning system. Therefore, it is also essential that the supplies match the machine-proportioning ratio for which they were prepared for the appropriate final dialysate composition to be obtained. Double checking of concentrate variations (e.g., potassium and calcium concentration) should be practiced, as it is for intravenous drug administration.

Hypernatremia

Hypernatremia occurs when concentrate or the ratio of concentrate to water is incorrect and the conductivity monitors or the alarms are not functioning properly. Hyperosmolality results in intracellular water depletion. Clinical manifestations include thirst, headache, nausea, vomiting, seizures, coma, and death. Aggressive treatment is mandatory and includes cessation of dialysis, hospitalization, and infusion of 5% dextrose in water. Dialysis should be resumed with a different machine; the dialysate sodium level should be 2 mmol/l lower than the plasma level, and isotonic saline should be concurrently infused. Dialysis against a sodium level 3 to 5 mmol/l lower than the serum level may increase the risk of disequilibrium. Ultrafiltration with equal volume replacement with normal saline is another option.

Hyponatremia

Failure to add concentrate, inadequate concentrate-water ratio, or conductivity monitor or alarm malfunction can cause hyponatremia. Hyponatremia can also occur during the course of dialysis with a proportioning system if the concentrate container runs dry and the conductivity set limits are inappropriate. Acute hypo-osmolality causes hemolysis with hyperkalemia and hemodilution of all plasma constituents. Symptoms include restlessness, anxiety, pain in the vein injected with the hypotonic hemolyzed blood, chest pain, headache, nausea, and occasional severe abdominal or lumbar cramps. Pallor, vomiting, and seizures may be observed. Treatment consists of clamping the blood lines and discarding the hemolyzed blood in the extracorporeal circuit. High-flow oxygen and cardiac monitoring are

imperative because of hyperkalemia and potential myocardial injury. Dialysis should be restarted with a new dialysate batch containing low potassium, and high transmembrane pressure should be applied to remove excess water. Correction of serum sodium concentration should be achieved by no more than 1 to 2 mmol/l/h. Anticonvulsants are indicated for seizures and blood transfusions for severe anemia. Successful correction of severe hyponatremia has been reported in a single 3-hour HD session with a dialysate sodium concentration of 135 mmol/l without any adverse neurologic consequences despite a serum sodium correction rate of 3 mmol/l/h.[46] This suggests that elevated blood urea levels might protect uremic patients from the development of demyelinating syndromes when hyponatremia is rapidly corrected.

Metabolic Acidosis

Although acute intradialytic metabolic acidosis can be a manifestation of improper mixing of concentrates or failure of pH monitors, other causes need to be ruled out, including diabetic or alcoholic ketoacidosis, lactic acidosis, toxic ingestions, and dilutional acidosis.[47] The diagnosis is usually suggested by the acute onset of hyperventilation during HD and confirmed by laboratory evaluation. In most circumstances, correction of the underlying cause and use of bicarbonate dialysate at the appropriate concentration (32 to 35 mmol/l) are adequate measures.

Metabolic Alkalosis

Severe intradialytic metabolic alkalosis is rare and may be caused by error in dialysate concentrates, reversed connection of bicarbonate and acid concentrate containers to the entry ports of the dialysis machine, pH monitor malfunction, or use of regional citrate anticoagulation. The most common cause, however, is hydrochloric acid loss as a result of vomiting or nasogastric suction. Attention should also be directed to identification of sources of added alkali.[48] Furthermore, the combination of sodium polystyrene sulfonate and aluminum hydroxide can lead to absorption of alkali that is normally neutralized in the small intestine.

Acute treatment is rarely necessary unless a technical error has occurred. Removal of the alkali source is usually sufficient, and H_2 antagonists or proton pump inhibitors may be successful if there is gastric acid loss. The administration of sodium chloride to anephric patients with chloride-sensitive alkalosis will not repair the alkalosis. If a more rapid reduction in serum bicarbonate is desired, modification of the dialysate bath by replacement of alkali with chloride, substitution of bicarbonate with acetate dialysate, use of acid dialysate, and infusion of hydrochloric acid are effective but cumbersome measures. The use of conventional or low-bicarbonate (25 to 30 mmol/l) dialysate is probably as effective.

Temperature Monitor Malfunction

Malfunction of the thermostat in the dialysis machine can result in the production of excessively cool or hot dialysate. Whereas cool dialysate is not dangerous and may have beneficial hemodynamic effects (see discussion regarding intradialytic hypotension), overheated dialysate can cause immediate hemolysis and life-threatening hyperkalemia, particularly if the dialysate temperature increases to more than 51°C. In such an event, dialysis must be stopped immediately and blood in the system discarded. The patient should be monitored for hemolysis and hyperkalemia. Dialysis should be resumed to cool the patient by use of a dialysate temperature of 34°C to treat hyperkalemia and to allow blood transfusions if necessary. Visual and audible alarms are mandatory to prevent this complication.

Blood Loss

Intradialytic blood loss can result from arterial or venous needle disengagement from the access, separation of the venous or arterial line connections, femoral or central line dialysis catheter perforation or dislodgment, or rupture of a dialysis membrane with or without malfunction of the blood leak detector. Clinical findings include hypotension, loss of consciousness, and cardiac arrest. In addition, after traumatic insertion of a dialysis catheter, blood loss can result in pain or mass from a rapidly expanding hematoma; chest, shoulder, or neck pain from intrapericardial blood loss; back, flank, groin, or lower abdominal pain or distention from retroperitoneal bleeding; or hemoptysis from pulmonary bleeding. Acute management includes the discontinuation of HD, pressure application for local hemostasis, reversal of anticoagulation (e.g., protamine sulfate for heparin), hemodynamic support, oxygen administration, and surgical intervention if needed.

Clotting of Dialysis Circuit

Clotting of the extracorporeal circuit during dialysis is a common practical problem, has many underlying causes, and warrants a thorough investigation. Technical factors include an inadequate or poor priming technique, resulting in retention of air in the dialyzer, and lack of or inadequate priming of the heparin infusion line. Such operator-induced errors are corrected through ongoing staff education and competency assessment. Incorrect heparin loading dose, insufficient time lapse after loading dose of heparin for systemic anticoagulation to occur, incorrect pump setting for constant heparin infusion, delayed start of the heparin pump, and failure to release the heparin line clamp are important correctible causes of clotting that should also be considered. Low-molecular-weight heparin is often used as a single bolus at the commencement of dialysis but may not maintain anticoagulation for extended hours of treatment (e.g., nocturnal dialysis). Vascular access–related problems from inadequate blood flow caused by needle or catheter positioning or clotting, excessive access recirculation, and frequent interruption of blood flow resulting from inadequate delivery or machine alarm situations are additional causes that can result in clotting. Immediate management requires prompt recognition of the underlying cause and implementation of corrective actions, including ongoing heparin dose adjustment and, if indicated, vascular access revision.

DIALYSIS REACTIONS

During HD, blood is exposed to surface components of the extracorporeal circuit, including the dialyzer, tubing, sterilization processes, and other foreign substances related to the manufacturing and reprocessing procedures. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions (Fig. 95-5).[49]

Anaphylactic and Anaphylactoid Reactions

Clinical Presentation

Anaphylaxis is the result of an IgE-mediated acute allergic reaction in a sensitized patient, whereas anaphylactoid reactions result from the direct release of mediators by host cells. The onset of symptoms usually occurs within the first 5 minutes of initiation of dialysis,

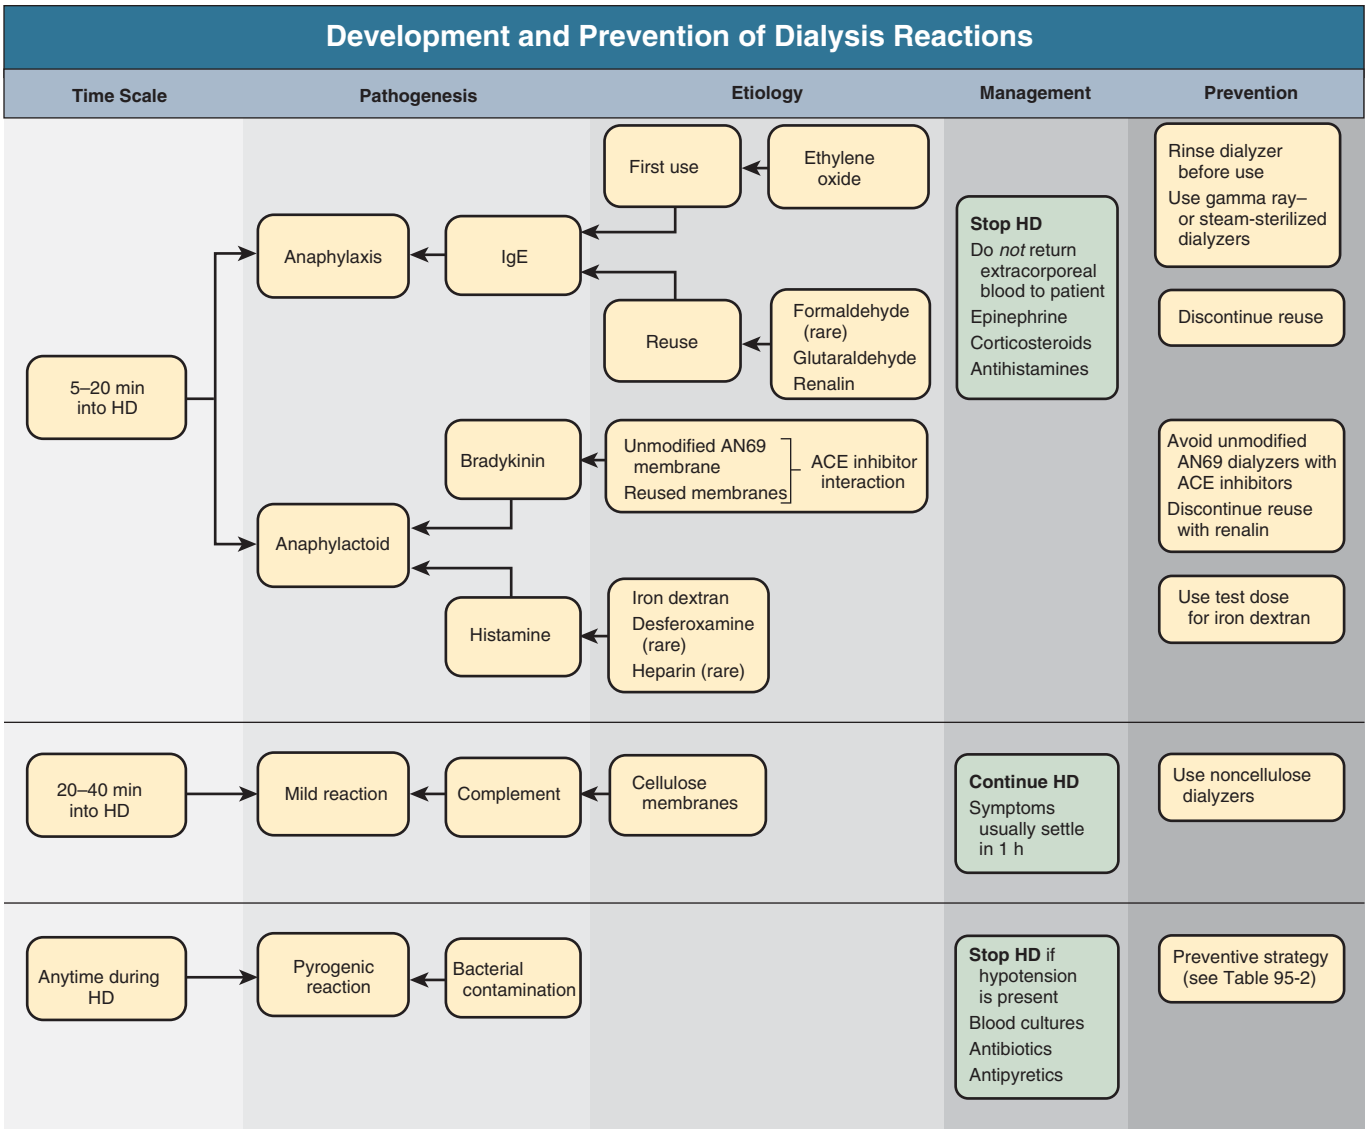

Figure 95-5 Development and prevention of dialysis reactions. *ACE,* Angiotensin-converting enzyme; *HD,* hemodialysis.

although a delay of up to 20 minutes is possible. Symptoms vary from subtle to severe and include burning or heat throughout the body or at the access site; dyspnea, chest tightness, and angioedema or laryngeal edema; paresthesias involving the fingers, toes, lips, or tongue; rhinorrhea, lacrimation, sneezing, or coughing; skin flushing; pruritus; nausea or vomiting; abdominal cramps; and diarrhea. Predisposing factors include a history of atopy, elevated total serum IgE, eosinophilia, and the use of ACE inhibitors. The etiology of dialysis reactions is diverse, and a thorough investigation is required.

First-Use Reactions

The majority of first-use reactions were ascribed to the manufacturer's dialyzer sterilant ethylene oxide (ETO), which is now rarely used. The potting compound that anchors the hollow fibers in the dialyzer housing acts as a reservoir for ETO and may impede its washout from the dialyzer, leading to sensitization. When it is conjugated to human serum albumin (HSA), ETO acts as an allergen. By use of a radioallergosorbent test (RAST), specific IgE antibodies against ETO-HSA are detected in two thirds of patients with such reactions. However, 10% of patients with no history of dialysis reactions have a positive RAST result.

Reuse Reactions

Because most residual ETO is washed out of the dialyzer during first use, reuse reactions are likely to be a result of the disinfectants used for dialyzer reprocessing. These agents include formaldehyde, glutaraldehyde, and peracetic acid–hydrogen peroxide (Renalin); in allergic patients, specific IgE antibodies against formaldehyde are occasionally detectable.

Bradykinin-Mediated Reactions

In the early 1990s, anaphylactoid reactions appeared in Europe among patients dialyzed with modified acrylonitrile (AN69) dialyzers who were also taking ACE inhibitors. Investigation of these incidents revealed that binding of factor XII to this sulfonate-containing, negatively charged membrane resulted in the formation of kallikrein and release of bradykinin, which in turn led to the production of prostaglandin and histamine, with subsequent vasodilation and

increased vascular permeability. ACE inactivates bradykinin, and therefore ACE inhibitors can prolong the biologic activities of bradykinin.[50] These membranes have since been chemically modified, thereby reducing this risk.

Anaphylactoid reactions have also been observed in patients taking ACE inhibitors who were dialyzed with membranes that had been reprocessed. Renalin was the sterilant used, and the reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors. It has been speculated that Renalin may oxidize cysteine-containing proteins that are adsorbed on the dialyzer membrane, leading to the formation of cysteine sulfonate and contact activation of factor XII.

Drug-Induced Reactions

Anaphylactoid reactions to parenteral iron dextran occur in 0.6% to 1% of HD patients. Significantly higher rates of anaphylactoid reactions have been observed among users of higher molecular weight compared with lower molecular weight iron dextran.[51] *In vitro,* dextran produces a dose-dependent basophil histamine release. In light of hypersensitivity reactions, the National Kidney Foundation's Clinical Practice Guidelines recommend that resuscitative medication and personnel trained to evaluate and to resuscitate anaphylaxis should be available whenever a dose of iron dextran is administered.[52] There are now alternative preparations of iron that provoke fewer anaphylactoid reactions than iron dextran. These are discussed further in Chapter 83.

Hypersensitivity to heparin formulations is rare and usually responds to substitution of beef with pork heparin, or vice versa. An alternative is to substitute low-molecular-weight heparin. A recent nationwide outbreak in the United States of severe adverse reactions in HD patients was attributed to vials of heparin contaminated with oversulfated chondroitin sulfate.[56]

Treatment and Prevention

Treatment of anaphylactic and anaphylactoid reaction requires the immediate cessation of HD without returning the extracorporeal blood to the patient. Epinephrine, antihistamines, corticosteroids, and respiratory support should be provided, if needed. Specific preventive measures include rinsing the dialyzer immediately before first use, substituting ETO- with gamma ray– or steam-sterilized dialyzers, avoiding unmodified AN69 membranes in patients taking ACE inhibitors, and discontinuing reprocessing procedures in selected patients.

Mild Reactions

Mild reactions particularly occur 20 to 40 minutes after initiation of dialysis, predominantly with unsubstituted cellulosic dialyzers, and consist of chest or back pain. Dialysis can be continued because symptoms usually abate after the first hour, suggesting a relation to the degree of complement activation. Indeed, these reactions decrease with the use of substituted and reprocessed unsubstituted cellulose membranes. Oxygen therapy and analgesics are usually sufficient. Preventive measures include automated cleansing of new dialyzers and use of noncellulose dialyzers.

Fever and Pyrogenic Reactions

Fever during dialysis can be the result of either a localized or a systemic infection or excessive microbial contamination of the dialysis apparatus. The latter, known as *pyrogenic reaction,* is usually a diagnosis of exclusion. Several factors during dialysis place patients at risk of exposure to bacterial products, including contaminated water or bicarbonate dialysate, improperly sterilized dialyzers, use of central venous dialysis catheters, and cannulation of infected arteriovenous grafts or fistulas.[49] Soluble bacterial products such as endotoxin fragments can diffuse across the dialyzer into the blood, resulting in cytokine production and, consequently, pyrogenic reactions. Whereas high-flux dialyzers have larger pores that may potentially allow larger fragments to cross from the dialysate to the patient, the synthetic high-flux membranes have a thick wall that tends to be very adsorptive for endotoxin fragments, thus mostly preventing this phenomenon.[57] Strategies for the prevention of pyrogenic reactions are summarized in Table 95-2.[58]

When fever develops during HD, the first step is to address hemodynamic stability. If the patient is hypotensive, administration of fluids, cessation of ultrafiltration, and discontinuation of dialysis are often required, and refractory hypotension suggesting severe sepsis should trigger hospitalization.

The next step is to identify a potential source of infection. The dialysis vascular access should be carefully examined. If a non–vascular access–related infectious source is identified, specific therapy should be instituted on the basis of the working diagnosis. Nontunneled and tunneled central venous dialysis catheters should always be suspected as a likely cause of infection, even in the absence

Strategies to Prevent Bacterial Contamination

Strict Adherence to AAMI Standards		
Type of Fluid	**Microbial Count**	**Endotoxin**
Water products	<200 cfu/ml	<2 EU
Dialysate	<200 cfu/ml	No standard
Reprocessed dialyzers	No growth	—
Use appropriate germicide: 4% formaldehyde* 1% formaldehyde heated to 40°C*† Glutaraldehyde† Hydrogen peroxide–peracetic acid mixture (Renalin)*† Heat sterilization (105°C for 20 hours) for reprocessing of polysulfone membranes†		
Wash and rinse the vascular access arm with soap and water.		
Before cannulation, inspect vascular access for local signs of inflammation.		
Scrub the skin with povidone-iodine or chlorhexidine and allow to dry for 5 minutes before cannulation.		
Record temperature before and after dialysis.		
When central delivery system is used: Clean and disinfect connecting pipes regularly. Remove residual bacteria or endotoxin by additional filtration.		
When single-patient proportioning dialysis machine is used: Freshly prepare bicarbonate dialysate on a daily basis. Discard unused solutions at the end of each day. Rinse and disinfect containers with fluids that meet AAMI standards. Air dry containers before dialysate preparation.		
Follow manufacturer's guidelines for use of preservative-free medications.		

Table 95-2 Strategies to prevent bacterial contamination. *AAMI,* Association for the Advancement of Medical Instrumentation; *cfu,* colony-forming units; *EU,* endotoxin units. *A minimum of 11- or 24-hour exposure to peracetic acid or formaldehyde is required, respectively. †These germicides are equivalent or superior to 4% formaldehyde. The action level for the total viable microbial count in the product water and conventional dialysate is 50 cfu/ml, and the action level for the endotoxin concentration is 50% of the relevant standard.

of local signs of infection such as erythema and exit site drainage. Catheters with evident signs of infection at the insertion site should be removed and the tip cultured.

Antipyretics should be administered and blood culture specimens should be obtained before initiation of antibiotic therapy; this should include cultures from temporary access devices. The initial choice of antibiotics should include gram-positive and gram-negative bacterial coverage, and the regimen should be adjusted according to the culture results.[59]

In the presence of a dialysis catheter, paired blood culture specimens should be obtained from both a peripheral vein and the catheter lumen, and the aforementioned broad-spectrum antibiotic regimen should be initiated. Catheter lock solutions that use either antibiotics or sterilants such as calcium citrate have been demonstrated to significantly reduce the rate of catheter-related bacteremia.[60-62] In the case of catheter-related bacteremia, removal of the dialysis catheter is strongly indicated, as is transesophageal echocardiography to rule out endocarditis, particularly with staphylococcal sepsis. A regimen of at least 14 days of antibiotic therapy is also recommended.[59]

An outbreak of bacteremia among several dialysis patients involving a similar organism should prompt a thorough search for bacterial contaminants in the dialysis equipment.[49] Attention should also be paid to single-use vials that are punctured several times, such as vials of EPO, which has been linked to an outbreak of bloodstream infection.[63]

Investigation of a Dialysis Outbreak

Although causes of dialysis outbreaks are usually easily identifiable, often the reason for the outbreak is less clear, such as water contamination with bacterial toxins,[64] medication chemical impurities,[56] bacterial contaminants,[63] systemic embolization of degraded dialyzer membrane polymer after prolonged or improper storage,[65] and hemolysis from faulty blood tube sets.[66] Investigation of a dialysis outbreak requires a methodical approach including a critical review of the medical records and the various steps of the dialysis procedure (Box 95-2).

MISCELLANEOUS COMPLICATIONS

Postdialysis Fatigue

An ill-defined "washed out" feeling or malaise during or after HD is a common nonspecific symptom that is observed in about one third of patients[67] and has multifactorial origins. Reduced cardiac output, peripheral vascular disease, depression, poor conditioning, postdialysis hypotension, hypokalemia or hypoglycemia, mild uremic encephalopathy, myopathy caused by carnitine deficiency, and membrane bioincompatibility through cytokine production have all been incriminated. The use of bicarbonate dialysate with or without additional glucose (5 to 10 mmol/l) and L-carnitine supplementation (20 mg/kg/day) have been shown to improve postdialysis well-being. A trial of thrice-weekly L-carnitine at 20 mg/kg for 6 months resulted in a marked decrease in C-reactive protein level, which was paralleled by an increase in body mass index.[68] To date, however, there are insufficient data to support the use of L-carnitine to improve quality of life in unselected dialysis patients.[52]

Compared with thrice-weekly HD, more frequent dialysis, including short daily and nocturnal HD, has been associated with a marked shortening in the time it takes for patients to recover from a dialysis session and to resume their daily activities, which is a surrogate for postdialysis fatigue.[69]

Pruritus

Pruritus is common. The etiology is often multifactorial, including xerosis, hyperparathyroidism, neuropathy, derangements in the immune system, and inadequate dialysis. In many patients, pruritus is more severe during or after dialysis and may be a manifestation of an allergic reaction to heparin, ETO, formaldehyde, acetate, or the dialysis membrane. In this subgroup of patients, use of gamma ray–sterilized dialyzers, discontinuation of formaldehyde use, switching to bicarbonate dialysate, and use of low dialysate calcium and magnesium might result in cessation of itching. Eczematous reactions to antiseptic solutions, rubber gloves or puncture needle components, puncture needles, or adhesive tapes used to secure dialysis needles should also be considered.[70]

The management of uremic pruritus is discussed further in Chapter 88 (see Fig. 88-3).

Genitourinary Problems

Priapism occurs in less than 0.5% of male HD patients. It is not related to sexual activity and occurs while the patient is on dialysis. The patient is usually awakened from sleep by a painful erection. Although the majority of cases are idiopathic, secondary causes include heparin-induced hyperviscosity; high hematocrit from androgen or epoetin therapy; dialysis-induced hypoxemia and hypovolemia from excessive ultrafiltration, particularly in African American men with sickle cell disease; and use of α-blockers, such as prazosin, or an antidepressant, such as trazodone.[71]

Urgent urologic referral is mandatory. Acute treatment consists of corporal aspiration and irrigation. Although surgical bypass provides venous egress from the corpora cavernosa, secondary impotence commonly develops but may be effectively treated by a penile prosthesis.

An unusual case of testicular angina occurring during excessive ultrafiltration has also been described. The patient was diabetic and had extensive vascular calcification evident on imaging. He eventually required orchidectomy.[72] A similar mechanism for this type of "angina" has also been described for the mesentery and right colon.

Hearing and Visual Loss

Intradialytic hearing loss may be caused by bleeding in the inner ear as a consequence of anticoagulation or cochlear hair cell injury from edema.

Intradialytic visual loss is rare but can be caused by central retinal vein occlusion, retinal hemorrhage secondary to heparin exposure in diabetics, precipitation of acute glaucoma, ischemic optic neuropathy secondary to hypotension, or Purtscher-like retinopathy secondary to leukocyte embolization.

CHAPTER 96

Peritoneal Dialysis: Principles, Techniques, and Adequacy

Bengt Rippe

Peritoneal dialysis (PD) is presently used by approximately 180,000 end-stage renal disease (ESRD) patients worldwide, representing approximately 7% of the total dialysis population.[1] In PD the peritoneal cavity, which is the largest serosal space in the body, is used as a container for 2 to 2.5 L of sterile, usually glucose-containing dialysis fluid, which is exchanged four to five times daily via a permanently indwelling catheter. The dialysis fluid is provided in plastic bags. The peritoneal membrane, via the peritoneal capillaries, acts as an endogenous dialyzing membrane. Across this membrane waste products diffuse to the dialysate, and excess body fluid is removed by osmosis induced by the glucose or another osmotic agent in the dialysis fluid, usually denoted *ultrafiltration* (UF). PD is usually provided 24 h/day and 7 days/wk in the form of continuous ambulatory peritoneal dialysis (CAPD). Approximately one third of the patients in most centers are on automated peritoneal dialysis (APD; sometimes also referred to as continuous cycling peritoneal dialysis [CCPD]), in which nightly exchanges are delivered via an automatic PD-cycler. The use of PD as a modality for ESRD treatment varies widely among countries, mostly because of nonmedical factors such as the reimbursement policy. One study reported that 81% of all dialysis patients in Hong Kong were treated with CAPD or APD in 2006, followed by Mexico (71%) and New Zealand (39%), whereas in the United States, PD was used by only 7.5%, and in Germany by 4.8%.

ADVANTAGES AND LIMITATIONS OF PERITONEAL DIALYSIS

If patients or their care givers are competent to undertake PD, the only absolute contraindications are large diaphragmatic defects, excessive peritoneal adhesions, surgically uncorrectable abdominal hernias, or acute ischemic or infectious bowel disease. These and other relative contraindications are discussed further in Chapter 97. PD is best used for patients with some residual renal function, although anuric patients may also do very well. Most patients who start PD will eventually, after several years, transfer to other modalities of renal replacement therapy (RRT), such as hemodialysis (HD), if adequacy cannot be maintained or as a result of other complications, such as recurrent peritonitis or exit site or catheter problems. Only rarely do HD patients transfer to PD, most commonly because of failure to maintain adequate vascular access for HD.

Peritoneal dialysis offers a number of advantages over HD, at least during the first 2 or 3 years of treatment. First, PD represents a slow, continuous, physiologic mode of removal of small solutes and of excess body water, associated with relatively stable blood chemistry and body hydration status. Second, there is no need for vascular access. The absence of vascular access and the absence of the blood-membrane contact of HD make catabolic stimuli less prominent in PD than in HD. Furthermore, residual renal function is somewhat better preserved in PD patients than in HD patients. Because of its continuous nature, PD provides a standardized weekly *Kt/V* similar to that of thrice-weekly HD despite less efficient small-solute clearance.

Peritoneal dialysis is a home-based therapy, and most patients are trained to do the bag exchanges themselves. In general, home dialysis patients have a better quality of life than those on other types of dialysis. The number of hospital visits is reduced, and the ability to travel is increased. There is also some evidence that PD patients may be better candidates for transplantation than HD patients; several studies have shown a lower incidence and severity of delayed graft function in PD patients after transplantation.[2] In children, PD (usually APD) is the preferred dialysis modality because it is noninvasive and socially acceptable, reducing hospital visits and allowing the child to attend school. Advocates of PD often recommend that RRT should ideally begin with PD according to the patient's choice and then proceed, as required when residual renal function declines, to HD or transplantation. PD should thus be regarded as part of an integrated RRT program, together with HD and transplantation.[3] Factors influencing the choice of dialysis modality between PD and HD as well as global variations in the use of PD are discussed further in Chapter 90.

PRINCIPLES OF PERITONEAL DIALYSIS

Three-Pore Model

The major principles governing solute and fluid transport across the peritoneal membrane are diffusion, driven by concentration gradients, and convection (filtration or UF), driven by osmotic or hydrostatic pressure gradients. The barrier separating the plasma in the peritoneal capillaries from the fluid in the peritoneal cavity is represented by the capillary wall and the interstitium. The interstitium can be regarded as a barrier coupled in series with that of the capillary wall; the mesothelium lining the peritoneal cavity is of much less significance as a transport hindrance. For the transport of fluid (UF) and of large solutes, the capillary wall is by far the dominating transport barrier. However, for small-solute diffusion the interstitium accounts for approximately one third of the transport (diffusion) resistance. The permeability of the capillary wall can be described by a three-pore model of membrane transport (Fig. 96-1).[4,5] In the capillary wall the major route for small-solute and fluid exchange between the plasma and the peritoneal cavity is the space between individual endothelial cells, the so-called interendothelial clefts. The functional radius of the permeable pathways in these clefts, denoted *small pores,* is 40 to 50 Å, slightly larger than the radius of albumin (36 Å). The size of these pores markedly impedes the transit of albumin and completely prevents the passage of larger molecules

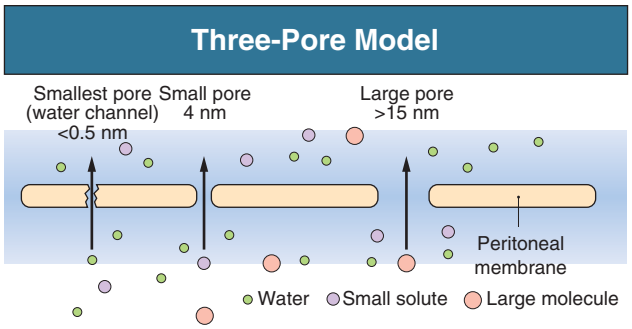

Figure 96-1 Three-pore model. The small pores in the middle represent the major pathway across the peritoneum through which small solutes move by diffusion and water by convection driven by hydrostatic, colloid osmotic, and crystalloid osmotic pressure differences. Across large pores *(to the right),* macromolecules move out slowly by convection from plasma to the peritoneal cavity. The smallest pores *(to the left)* are represented by aquaporins permeable to water, but impermeable to solutes. Water moves here exclusively by crystalloid osmotic pressure.

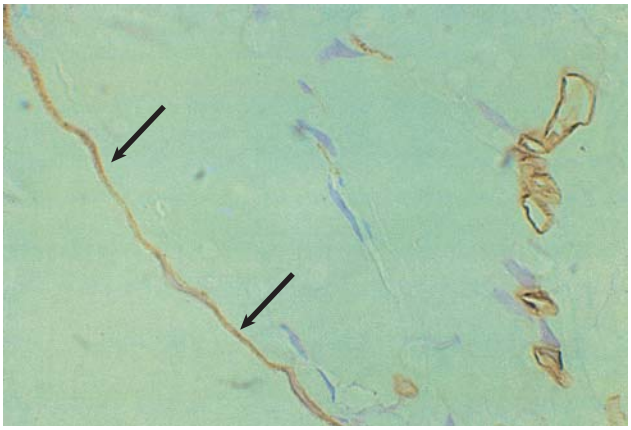

Figure 96-2 Light microscopic section of a peritoneal membrane with capillaries and venules *(to the right)* in an "amorphous" interstitium. The peritoneum is lined by a thin layer of mesothelium *(to the left).* Capillaries and venules, as well as the mesothelium, are immunocytochemically stained for aquaporin-1 (AQP-1) *(brownish in color). (From reference 55.)*

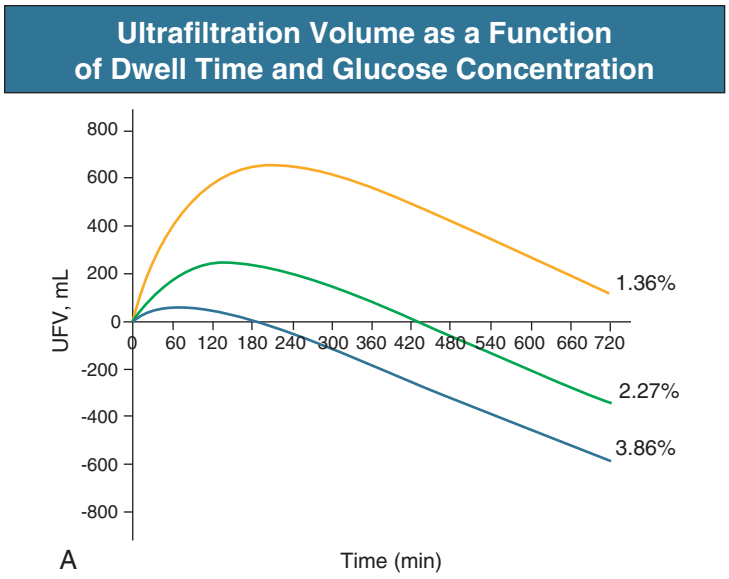
(e.g., immunoglobulins and α_2-macroglobulin). However, larger proteins can transit via very rare large pores (radius approximately 250 Å) in capillaries and postcapillary venules. The large pores constitute only 0.01% of the total number of capillary pores, and the transport across them occurs by hydrostatic pressure–driven unidirectional filtration from the plasma to the peritoneal cavity. In addition, the capillary wall has a high permeability to osmotic water transport via aquaporin-1 (AQP-1) channels in the endothelial cell membranes (Fig. 96-2).[6]

Fluid Kinetics

Under normal (non-PD) conditions most transport occurs via the small pores. Only 2% of peritoneal water transport occurs via AQP-1. In PD, fluid removal is markedly enhanced by infusion of a hyperosmolar dialysate into the peritoneal cavity. The type of osmotic agent used markedly affects the mechanism of osmosis. Glucose will induce fluid flow through both AQP-1 (approximately 45%) and small pores (approximately 55%), whereas large molecules, such as polyglucose (icodextrin) will remove fluid mainly via small pores (approximately 90%). Thus glucose osmosis will result in a rapid



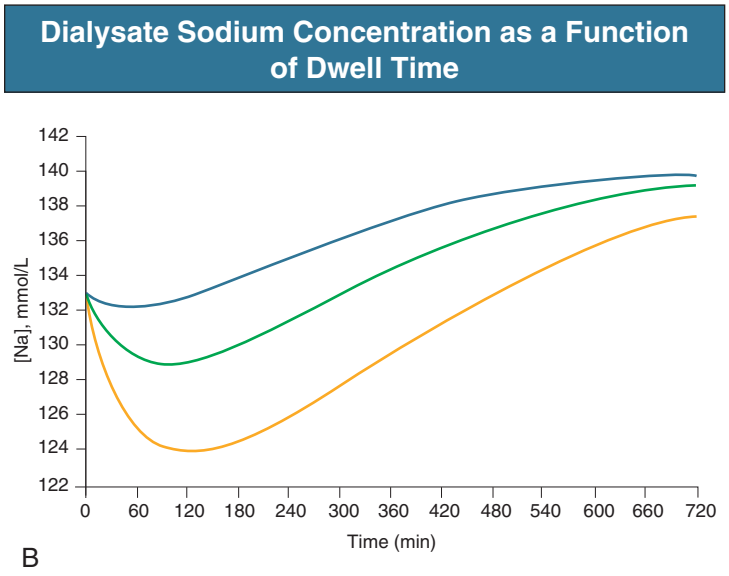


Figure 96-3 A, Ultrafiltration as a function of dwell time. Net ultrafiltration volume *(UFV)* as a function of dwell time for 3.86% *(yellow line),* 2.27% *(green line),* and 1.36% *(blue line)* glucose, computer simulated using the three-pore model of peritoneal transport. **B, Dialysate sodium as a function of dwell time.** Dialysate sodium as a function of dwell time for 3.86% *(yellow line),* 2.27% *(green line),* and 1.36% *(blue line)* glucose, computer simulated according using the three-pore model of peritoneal transport.

dilution of the peritoneal dialysate, as reflected by a fall in sodium concentration *(sodium sieving)* during the first 2 hours of the dialysate dwell, caused by relatively large transport via the water-only AQP-1 channels; this tends to correct later as diffusion across the small pores eventually increases the sodium concentration to that in the plasma.

Glucose, the commonly used osmotic agent, is usually available at three concentrations: 1.36%, 2.27%, and 3.86%. Figure 96-3, *A*, demonstrates the intraperitoneal fluid kinetics, computer simulated using the three-pore model, over 12 hours of dwell time with these three solutions. Glucose is an intermediate-size osmolyte with a low osmotic efficiency (osmotic reflection coefficient [σ] = 0.03) across small pores, whereas glucose is 100% efficient as an osmotic agent across AQP-1 (σ = 1). For that reason, glucose will markedly (30-fold) boost the transport of fluid through AQPs and thus redistribute

fluid transport away from the small pores toward AQP-1, resulting in significant sodium sieving. For example, for 3.86% glucose in the PD solution, the dialysate Na^+ concentration will drop from 132 mmol/l to 123 mmol/l in 60 to 100 min, which later increases toward serum Na^+ concentration (Fig. 96-3, *B*). On the other hand, icodextrin, with an average molecular weight of 17 kd, has a high osmotic efficiency (σ approximately 0.5) across small pores and in relative terms is rather inefficient across AQPs. Hence, during icodextrin-induced osmosis only a very minor fraction of the UF will occur through AQP-1, producing insignificant sodium sieving (see Fig. 96-7, *B*).

In addition to the size of the osmotic agent, the degree of sodium sieving is dependent on the presence and quantity of AQP-1, and also on the total rate of net UF (which is mainly determined by the glucose concentration), and the diffusion capacity of Na^+. A high rate of small-solute transport, and thereby of sodium diffusion, in so-called fast transporters will manifest as rapid equilibration of small solutes (creatinine and glucose) in the peritoneal equilibration test (PET; see later) and will also reduce sodium sieving.

In the absence of an osmotic agent in the PD fluid, the dialysate would be reabsorbed into the plasma within a few hours, mainly driven by the difference in colloid osmotic pressure between plasma and the peritoneum. This absorption will to a major extent occur via small pores, whereas approximately 30% of the peritoneal fluid will be removed by lymphatic absorption. The partial fluid flows in the peritoneal membrane modeled across different fluid conductive pathways in the three-pore model (for 3.86% glucose) are shown in Figure 96-4. It is the presence of relatively high concentrations of glucose in the peritoneal fluid that prevents the reabsorption of fluid into the plasma during the first few hours of the dwell.

Patients who have a high rate of sodium diffusion (fast transporters) also have rapid transport of glucose out of the peritoneal cavity. Therefore the glucose gradient favoring UF dissipates more rapidly, and it is harder to achieve effective fluid removal compared with "slow transporters." In fast transporters the maximum UF volume is reduced and UF occurs earlier. There is usually also a more rapid reabsorption of fluid in the late phase of the dwell. The issue of fluid loss from the peritoneum is, however, very controversial, because some authors claim that the peritoneal fluid loss occurring in the late phase of the PD dwell is dominated by lymphatic absorption.[7]

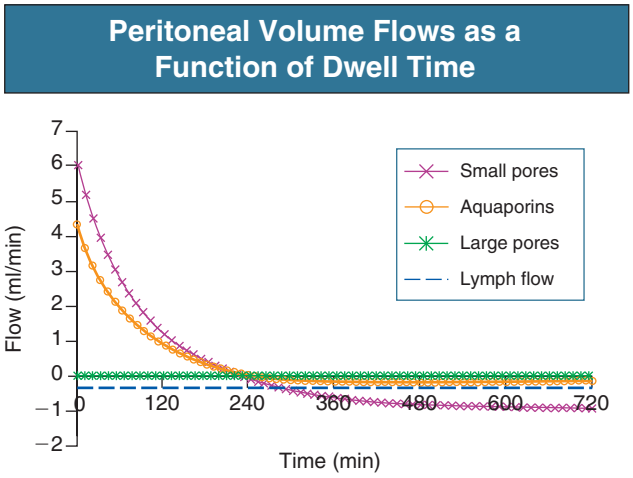

Figure 96-4 Peritoneal volume flows as a function of dwell time. Peritoneal volume flows as a function of dwell time for 3.86% glucose partitioned among aquaporins, small pores, large pores, and lymphatic absorption. The small-pore volume flow is initially approximately 60% of total volume flow and becomes negative after peak time (220 min). The aquaporin-mediated water flow becomes slightly negative after approximately 250 min. The large-pore volume flow is negligible and remains constant throughout the dwell, as does lymphatic absorption (0.3 ml/min). *(Modified from reference 56.)*

Effective Peritoneal (Vascular) Surface Area

The functional surface area of the peritoneum reflects the effective surface area of the peritoneal capillaries.[8] The transport of small solutes, such as urea, creatinine and glucose, is partly limited by the degree of perfusion of these capillaries—the effective peritoneal membrane blood flow. Furthermore, as mentioned earlier, some of the diffusion resistance for the smallest solutes (urea and creatinine) is located in the interstitium. The number of effectively perfused capillaries is increased by arteriolar vasodilation and reduced by vasoconstriction. These alterations often occur without large changes in the fluid permeability (hydraulic conductance [L_pS]) of the peritoneum. Thus, during vasodilation or vasoconstriction there is usually a dissociation between changes in the permeability–surface area product (PS) for small solutes and in the L_pS of the membrane. Vasodilation, with recruitment of capillary surface area, occurs early in the dwell when glucose is used as the osmotic agent, causing early, transient increases in PS.[9]

Peritonitis is also associated with marked vasodilation, again leading to increases in small-solute PS, in the absence of large changes in L_pS, during the first 60 to 100 minutes of the dwell. However, in some patients with peritonitis, an increase in L_pS will result in relative increased fluid transport across the small pores. Furthermore, there is usually an opening of large pores in the capillaries (and postcapillary venules), resulting in enhanced leakage of macromolecules (e.g., albumin and immunoglobulins) from plasma to peritoneum. Peritonitis may thus result in relative difficulty in removing fluid (because of rapid dissipation of intraperitoneal glucose), a reduced sodium sieving (because of the reduced UF and increased Na^+ diffusion), and a markedly increased leakage of proteins to the dialysate.

The contact area between the dialysate and the peritoneal tissue varies as a result of posture and fill volume. Adult patients usually tolerate 2 to 2.5 liters of instilled volume. An intraperitoneal hydrostatic pressure (IPP) of less than 18 cm H_2O (supine position) is usually tolerated.[10] At higher pressures (>18 cm H_2O) the patient usually feels some discomfort. At intraperitoneal volumes of less than 2 liters there is a reduction in small-solute PS, whereas PS is only moderately increased at high fill volumes. Overall, an increased fill volume implies a more efficient exchange with regard to both small-solute exchange and UF, the latter being much more pronounced for hypertonic solutions.[11] For a long time it was thought that increased fill volumes would directly affect peritoneal fluid reabsorption by the hydrostatic pressure effect (increases in IPP). However, because 80% of any increase in IPP is transmitted via vein compression back to the capillaries, the actual changes in the transcapillary hydrostatic pressure gradient, which governs UF, will be rather small.[12] Thus the impact of IPP on fluid absorption is moderate.[13]

PERITONEAL ACCESS

The key to successful chronic PD is a safe and permanent access to the peritoneal cavity (Fig. 96-5). Despite improvements in catheter survival over the past few years, catheter-related complications still occur, causing significant morbidity and sometimes forcing the removal of the catheter. Catheter-related problems are a cause of permanent transfer to HD in up to 20% of all patients. Most catheters

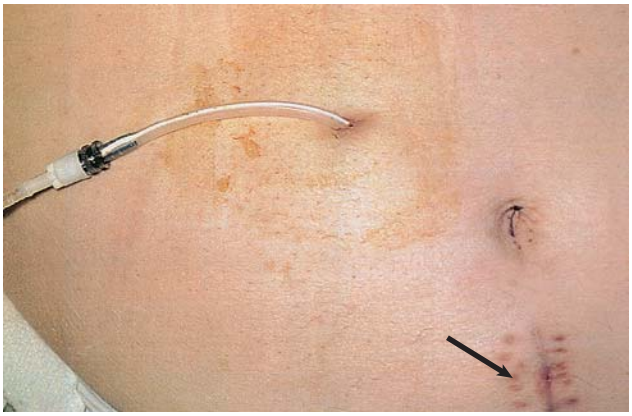

Figure 96-5 A recently implanted peritoneal dialysis catheter *in situ*. Note the subumbilical midline scar where the catheter enters the peritoneal cavity *(arrow)*.

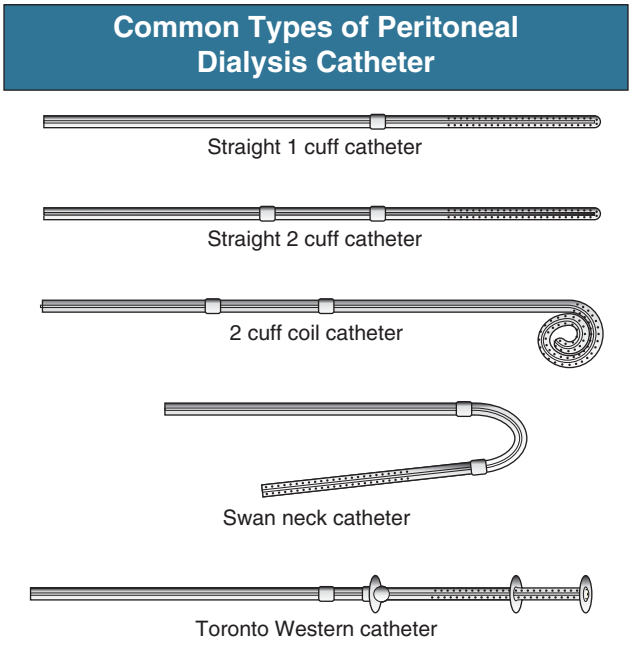

Figure 96-6 Common types of peritoneal dialysis catheter.

are derived from that originally devised by Tenckhoff and Schechter.[14] The Tenckhoff catheter is a Silastic tube with side holes along its intraperitoneal portion. There are usually one or two Dacron cuffs, allowing tissue ingrowth, which secures the catheter in place and prevents pericatheter leakage and infection. The Tenckhoff catheter is straight, having one cuff lying on the peritoneum with the catheter tip pointing in the caudal direction; the outer cuff is close to the skin exit. Several centimeters of the catheter is thus located transcutaneously. Intraperitoneal and transcutaneous catheter modifications continue to appear, indicating that no single design is perfect (Fig. 96-6). Although a number of studies report less frequent catheter drainage failures with use of the arcuate "swan neck" catheter (see Fig. 96-6) compared with straight catheters, there is no hard evidence that any of the modified catheters on the market are actually superior to the original (one- or two-cuff) Tenckhoff catheter.[15]

Ideally, catheter insertion should be undertaken under operating room sterile conditions by an experienced operator, either a surgeon or a nephrologist trained in interventional nephrology techniques. Presurgical assessment for the presence of herniation or any weakness of the abdominal wall is essential. If present, it may be possible to correct these at the time of catheter insertion. Before the operation, eradication of nasal carriage of *Staphylococcus aureus* with locally applied antibacterials (such as mupirocin) significantly reduces exit site infection rates. A single preoperative intravenous dose of a first- or second-generation cephalosporin is also recommended. To avoid development of vancomycin-resistant enterococcus, vancomycin should not be used as a prophylactic agent. Several placement techniques have been described and practiced: surgical mini-laparotomy and dissection, blind placement using the Tenckhoff trocar, blind placement using a guidewire (Seldinger technique), mini-trocar peritoneoscopy placement, and laparoscopy. These techniques are discussed further in Chapter 92.

TECHNIQUES OF PERITONEAL DIALYSIS

In CAPD, 2 to 2.5 liters of dialysis fluid is instilled into the peritoneal cavity four or five times daily. In 4 to 5 hours there is 95% equilibration of urea and approximately 65% equilibration of creatinine, whereas the glucose gradient has dissipated to approximately 40% of the initial value. For glucose as an osmotic agent, 4 to 5 hours is a suitable dwell time. For night dwell exchanges, longer dwell times can be accepted (8 to 10 hours), although this increases the quantity of glucose and therefore calorie absorption. Furthermore, there is room for individual exchange schedules that can be adjusted to suit individual patient convenience. Dwell times shorter than 4 to 5 hours can be performed with use of a machine (cycler). This technique can be used to maintain adequate dialysis when more frequent lower-volume exchanges are needed—for example, to minimize leakage in conjunction with catheter insertion, hernia repair, or abdominal operations. Rapid exchanges may also be required during treatment for peritonitis, or in patients with fluid overload when the patient's hydration status needs to be corrected rapidly.

Today, double-bag systems (so-called Y systems) are in general use according to the principle "flush before fill." The double-bag system contains the unused dialysis fluid connected to an empty sterile drain bag via a Y-set tubing system. After the patient has connected the system and flushed the connection (for 2 to 3 seconds), a frangible (breakable) pin to the drain bag is opened, and the peritoneal cavity is drained over 10 to 15 minutes to fill the drain bag. Then this bag is clamped and the fresh bag opened, so as to fill the peritoneal cavity over another 10 to 15 minutes. The time for exchange (instillation and drainage), if the catheter is in good order, should not exceed a total of 30 minutes. Usually the first 1.6 to 1.8 liters will drain rapidly (at ≥200 ml/min), whereas the last 200 to 300 ml will drain much more slowly. The breakpoint between the rapid and the slow phase may vary markedly from individual to individual.

Automated peritoneal dialysis is usually performed with use of a cycler overnight (8 to 10 hours), during which large volumes (10 to 20 liters) can be exchanged. During the daytime the APD patient usually has a so-called wet day—that is, a long dwell, usually with icodextrin as the osmotic agent in the dialysis fluid. Some patients with nightly APD perform one daily exchange so that there are two long (6- to 8-hour) daily dwells. Most cyclers can be programmed to vary inflow volume, inflow time, dwell time, and drain time. Cyclers usually warm the fluid before inflow, and they also monitor outflow volume and the excess drainage (UF volume). Current APD machines have alarms for inflow failure, overheating, and poor drainage. Some cyclers interrupt drainage at the breakpoint between the fast and slow phases to make the exchange more efficient. Another way to

accelerate exchanges is to allow a considerable sump volume in the peritoneal cavity by not letting all the fluid drain; subsequent inflow volumes are proportionally reduced, and after a number of cycles complete drainage occurs. This technique is called *tidal peritoneal dialysis* (TPD).

The exchange volume should be adjusted according to the patient's size. Adult patients weighing less than 60 kg should start with 1.5-liter bags. The average patient (60 to 80 kg) should receive 2-liter exchanges, and for patients weighing more than 80 kg, 2.5 liters should be used. If pressure monitoring systems are available, the IPP may inform the choice of exchange volume. In the supine position most patients have an IPP of 12 cm H_2O.

PERITONEAL DIALYSIS FLUIDS

The majority of PD fluids used today have the composition of a lactate-buffered, balanced salt solution devoid of potassium, with glucose (1.36%, 2.27%, or 3.86%) as the osmotic agent. The K^+ concentration in current PD fluids is zero to aid control of potassium balance.

Lactate is used as a buffer instead of bicarbonate, because bicarbonate and Ca^{2+} may precipitate (to form calcium carbonate) during storage. With the advent of newer multichambered PD delivery systems, it is possible to replace lactate with bicarbonate and to make a number of other solution modifications that previously were not feasible. However, the higher cost of a number of the newer more physiologic fluid formulations should be borne in mind.

Electrolyte Concentration

In current PD fluids the concentrations of Na^+, Cl^-, Ca^{2+}, and Mg^{2+} are selected to be close to the serum concentration. The removal of these ions across the peritoneum is therefore a result of the low diffusion gradient, more or less completely dependent on convection. For every deciliter of fluid removed in a 4-hour dwell, approximately 10 mmol of Na^+[16] and 0.1 mmol of Ca^{2+} are removed, provided that serum Na^+ and Ca^{2+} are within the reference ranges.[12]

The frequent use of calcium-containing phosphate binders requires an understanding of Ca^{2+} kinetics for various types of dialysis fluids to avoid hypercalcemia. The calcium concentration of current PD solutions is usually 1.25 to 1.75 mmol/l. However, because Ca^{2+}, like Na^+ and Mg^{2+}, has a UF-dominated transport, 1.25 mmol/l may be considered appropriate only for 1.36% glucose, to achieve a zero (neutral) peritoneal calcium removal. To reach the same objective for 3.86% glucose, the dialysis fluid Ca^{2+} would have to be increased to 2.3 mmol/l to prevent (UF-driven) Ca^{2+} loss during a 4-hour dwell. With use of a three-compartment system for the PD bags, it would be possible to adapt the dialysis fluid Ca^{2+} concentration to obtain net zero peritoneal Ca^{2+} transport across the peritoneum, or to reach a preset calcium removal target, for each PD fluid glucose concentration used.[17] However, in currently available PD solutions, Ca^{2+} concentration is not variable as a function of glucose concentration; therefore 1.25 mmol/l Ca^{2+} is recommended when patients use calcium-containing phosphate binders. However, it should be noted that net peritoneal calcium removal with 1.25 mmol/l Ca^{2+} level can be achieved only by PD fluids containing 2.27% or 3.86% glucose.

The Mg^{2+} concentration commonly used in current PD solutions is 0.25 to 0.75 mmol/l. For 1.36% glucose, 0.25 mmol/l would be appropriate for zero Mg^{2+} transport during the dwell, whereas for higher dialysis fluid glucose concentrations there will be net Mg^{2+} losses.

Osmotic Agents

Glucose is the principal osmotic agent used for fluid removal (UF) in PD. Alternative commercially available osmotic agents are amino acids and icodextrin. Icodextrin is a polydisperse glucose polymer with an average molecular weight of 17 kd.[18] However, because of the polydispersity of icodextrin, approximately 70% of the molecules have a molecular weight of 3 kd or less.[11] Icodextrin is available as a 7.5% solution with essentially the same electrolyte composition as glucose-based dialysates. The osmolality of the glucose polymer solution, unlike that of 1.36% glucose (osmolality 350 mOsm/kg) dialysis fluid, is within the same range, or actually slightly lower, than that of normal serum. The presence of larger molecules in the icodextrin solution, compared with those in glucose-based solutions, improves the osmotic efficiency markedly across the small pores ($\sigma = 0.5$) and also reduces the dissipation of the osmotic gradient over time. This yields a sustained UF over 8 to 12 hours (Fig. 96-7, *A*). Therefore, icodextrin is preferably used for long dwell exchanges, for example, overnight, and particularly for patients who tend to absorb glucose rapidly (fast transporters, see later). Icodextrin is slowly absorbed into serum and degraded (circulating α-amylase) to oligosaccharides, such as maltose, which may give false-positive results for glucose, leading to erroneous measures of hyperglycemia and to inappropriate use of glucose-lowering agents.[19]

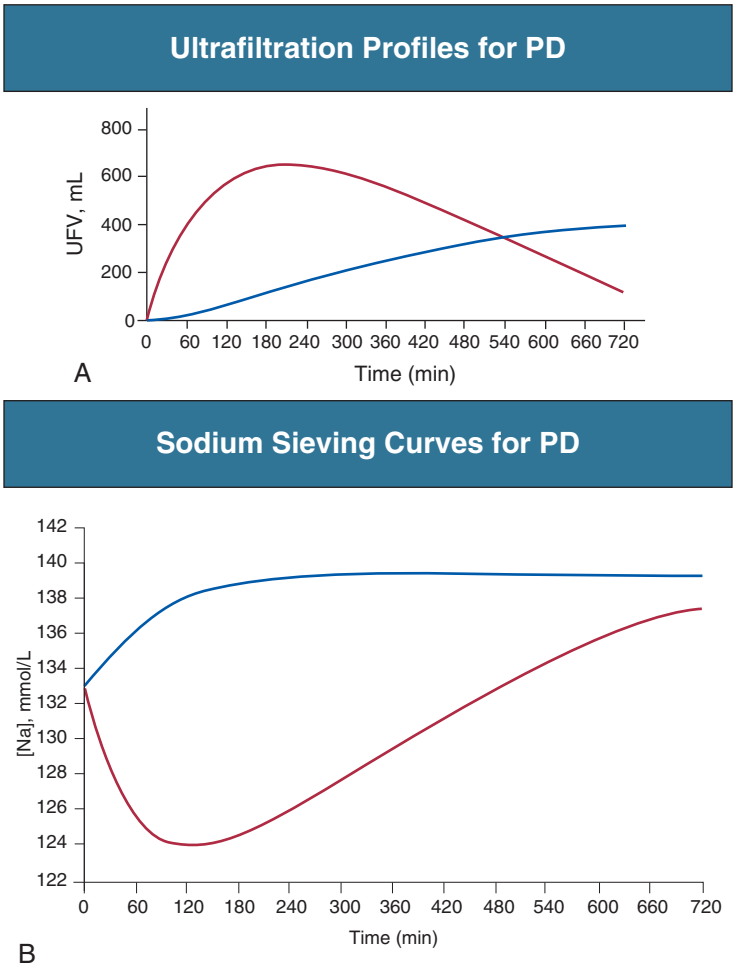

Figure 96-7 A, Ultrafiltration (UF) profiles for peritoneal dialysis *(PD).* Ultrafiltration profile for 7.5% icodextrin *(blue line),* computer simulated according to the three-pore model in an average patient who is not naive to icodextrin, in comparison with the computer simulated UF curve for 3.86% glucose *(red line). UFV,* ultrafiltration volume. **B, Sodium sieving curves for PD.** Sodium-sieving curves for 7.5% icodextrin *(blue line)* and 3.86% glucose *(red line)* (see Fig. 96-3). *Na,* sodium. *(A from reference 11.)*

Another alternative osmotic agent that is commercially available is a 1.1% amino acid mixture having the same osmolality as 1.36% glucose.[20] According to some studies, regular use of this dialysate may increase certain nutritional indices, although there is also some evidence that amino acid solutions increase acidosis and raise plasma urea. Both icodextrin-based and amino acid–based solutions may be used to reduce the glucose exposure of the peritoneal membrane and the total glucose load to the patient.

Until recently, conventional PD solutions have had a low pH and a high concentration of glucose degradation products (GDPs). GDPs are reactive carbonyl compounds that form during heat sterilization and/or storage of glucose-based solutions. GDPs are toxic to a variety of cells *in vitro* and also potentially toxic *in vivo*.[21] By the use of multicompartment systems it has been possible to compose new solutions with much lower concentrations of GDPs and a neutral pH, and also to use bicarbonate or bicarbonate-lactate mixtures as buffers.[22-24] Solutions using bicarbonate or bicarbonate-lactate mixtures result in significantly less infusion pain and are as effective as lactate at correcting acidosis, when used at the same total buffer ion concentration.[25] In prospective, randomized studies these fluids have been associated with improvement in dialysate effluent markers of peritoneal membrane integrity, particularly cancer antigen 125 (CA-125), a measure of peritoneal mesothelial cell mass.[22-24] There have also been some indications of improved residual renal function in patients with PD solutions low in GDPs,[24] although this was not confirmed in recent prospective, randomized studies.[26,27] One of those studies, however, the balANZ study,[27] suggested that biocompatible PD solutions may delay the onset of anuria and reduce the incidence of peritonitis compared with conventional solutions.

Pyruvate is an alternative buffer to lactate (or bicarbonate) but is not yet clinically available. Finally, certain additives may help to preserve the peritoneal membrane, such as *N*-acetylglucosamine (NAG), hyaluronic acid (HA), citrate, and low-molecular-weight heparin (LMWH). LMWH, 4500 IU in every morning bag daily for 3 months, increased UF as a result of reduced glucose reabsorption during the dwell.[28] This effect was, however, not found in a subsequent randomized open multicenter study of the addition of daily self-administration of LMVH (3500 IU) to the long daily icodextrin-based dwell.[29] Conceivably, if LMVH actually increases UF, this action may be a result of reduction of the initial vasodilation that regularly occurs with intraperitoneal instillation of glucose-based PD solutions.[28] HA seems to reduce the reabsorption of fluid that occurs in the late phase of the dwell, possibly by producing a "filter cake" at the peritoneal surface.[30] None of the mentioned additives (NAG, HA, or LMWH) or buffers (pyruvate, citrate) can yet be recommended in routine clinical practice, and further trial data are awaited.

ASSESSMENTS OF PERITONEAL SOLUTE TRANSPORT AND ULTRAFILTRATION

Small-Solute Removal

The net removal of solutes and fluid during PD, in excess of residual renal excretion, can be measured by evaluating the drained dialysate. For this purpose the concentrations of urea and creatinine are measured in dialysate and plasma. The dialysate-plasma concentration ratios (D/P) of either of these solutes multiplied by the daily drain volume gives the 24-hour clearance. Weekly creatinine and urea clearances are obtained by multiplying these figures by 7. For comparison between patients, creatinine clearance is conventionally related to body standard surface area (1.73 m^2), and urea clearance (mostly for comparison with HD) is expressed as *Kt/V* (where *Kt* is the weekly clearance and *V* the volume of distribution of urea). In PD, routine assessment of *V* is imprecise, in contrast to the situation in HD, in which *V* can be mathematically derived directly from urea kinetics. *V* should preferably be determined by direct techniques, such as from the dilution of isotopic water (total body water); in practice, however, *V* is usually approximated from standard tables using BW and height as anthropometric parameters together with gender.[31] Criticism of the *Kt/V* concept in PD is based on the uncertainty of determining a correct value for *V*. In those who are markedly underweight or overweight the ideal body weight should be used for calculating *V*.[32]

Large-Solute Removal

For more insight into peritoneal transport, the clearance of larger solutes such as β_2-microglobulin, as well as markers for transport across the large pores, such as albumin, immunoglobulins and α_2-macroglobulin, can be measured. Although many centers assess the daily peritoneal removal of total protein and/or albumin, measurements of most other solutes are not made in routine clinical practice.

Ultrafiltration

Ultrafiltration can be assessed with a 24-hour collection. Even if done accurately, there is a considerable dwell-to-dwell and day-to-day variability in UF depending on drainage conditions, posture, and varying levels of residual (sump) intraperitoneal volume. Reasonably accurate estimations of daily UF volume can be obtained by averaging collections of all fluid during a period of several days. In clinical practice, the patient's own daily dialysis records should also be examined with respect to dwell-to-dwell UF volumes and the number of hypertonic bags used per day. For a 3.86% glucose dwell a UF volume less than 400 ml will indicate insufficient UF—that is, ultrafiltration failure (UFF). UF volume can also be determined by the PET as described later. In a routine 2.27% glucose PET, less than 200 mL of UF in 4 hours signals UFF. More accurate determination of intraperitoneal volume can be achieved as a function of time with use of a marker, such as iodine 125 (^{125}I)–human serum albumin or dextran 70. This is not required in routine clinical practice but as a research tool allows more precise UF volume estimations.

Peritoneal Membrane Function

Peritoneal Equilibration Test

The PET yields approximate estimations of the rate of peritoneal transport of small solutes and of UF capacity.[33] The rate of small-solute transport is dependent on the effective peritoneal surface area, which is essentially dependent on the number of effectively perfused capillaries available for exchange (and the blood flow). The volume ultrafiltrated in 4 hours is a function of the so-called osmotic conductance to glucose (OCg; the peritoneal UF coefficient times the reflection coefficient for glucose) as well as the rate of dissipation of the glucose osmotic gradient (the rate of small-solute transport). In general, when the rate of glucose disappearance is high, UF volume is low.

The PET procedure is summarized in Box 96-1. After an overnight dwell (8 to 12 hours) the dialysate fluid is drained, and a 2-liter 2.27% glucose bag is infused for 10 minutes with the patient in supine position (rolling from side to side every 2 minutes). After 10 minutes—that is, at completion of the infusion—200 ml is drained into the drainage bag and mixed, and a zero time dialysate sample taken. At the end of the 4-hour dwell period, dialysate is drained out

and measured. The net volume is noted. Concentrations of glucose and creatinine in the outflow and plasma are measured, as well as the concentration of glucose in the zero sample. The results are expressed as the dialysate-plasma (D/P) solute concentration ratio and as the dialysate glucose at 4 hours–dialysate glucose at time zero (D/D_0) concentration ratio. The higher the D/P ratio for creatinine, the faster the rate of transport for small solutes. According to D/P ratios for creatinine or D/D_0 for glucose, patients can be divided into slow, slow average, fast average, or fast transporters (Fig. 96-8).

It should, however, be emphasized that D/P measurements give only an approximate estimation of small-solute transport rate. Additional information can be obtained by variations including the modified PET (instilling a 3.86% solution and draining after 4 hours),[34] the mini-PET (instilling a 3.86% solution and draining after 1 hour), and the double-mini-PET (instilling sequentially a 1.36% solution and a 3.86% solution, draining each after 1 hour).

Mini–Peritoneal Equilibration Test

In the mini-PET, a 3.86% glucose solution is instilled and completely drained after 1 hour. The Na^+ concentration in the drained dialysate assesses the degree of sodium sieving and hence gives a measure of AQP-mediated ("free") water flow.[35,36] The fraction of "free" water transport can be evaluated in the early phase of the dwell from the 1-hour drained volume minus the 1-hour peritoneal Na^+ clearance (i.e., the drained Na^+ minus the instilled Na^+ divided by the serum Na^+ concentration). In the first hour when Na^+ diffusion is negligible, the peritoneal clearance of sodium (across small pores) will directly reflect the peritoneal small-pore fluid clearance (UF). This value is then subtracted from the total (1-hour) UF volume to yield an estimate of the free (AQP-mediated) water transport. Reductions in this parameter usually occur over time on PD, and marked reductions in free water transport are assumed to reflect peritoneal fibrosis.[37,38]

Double–Mini–Peritoneal Equilibration Test

The OCg can be measured with a double-mini-PET—that is, a 1-hour dwell with 1.36% glucose and also a 1-hour dwell with 3.86% glucose solution. The calculation of OCg is based on the difference in the 1-hour drained volume between the 3.86% and 1.36% glucose solutions.[39] In long-term PD, increases in D/P-creatinine and reductions in D/D_0-glucose are usually seen, eventually resulting in UFF. These changes are often combined with moderate reductions in OCg, the latter perhaps coupled with peritoneal fibrosis.[40] Marked reductions in OCg may signal imminent development of peritoneal sclerosis.

An overview of current techniques to clinically assess peritoneal membrane function has recently been published.[41]

Peritoneal Equilibration Test

1. The night bag (8 to 12 hours) must be 1.36% or 2.27% glucose, drained for 20 minutes with patient sitting.
2. Two liters (warm) 2.27% fluid instilled for 10 minutes with the patient supine and rolling from side to side every 2 minutes.
3. Exactly at 10 minutes after start of the infusion, 200 ml is drained into the bag. Draw 5 ml (discard); the next 5 ml taken for creatinine and glucose determination.
4. After 2 hours, new samples collected as in 3.
5. After 4 hours (exactly), drainage for 20 minutes. Note total bag weight. Subtract empty bag weight. Take samples (after mixing) for creatinine and glucose.
6. Glucose D/D_0 (the ratio of dialysate glucose at 4 hours and at time zero) and creatinine D/P (the ration of dialysate and serum creatinine at 4 hours) are plotted versus time (as shown in Figure 96-8). The drain volume is noted.

Box 96-1 **Peritoneal equilibration test.**

Residual Renal Function

In PD, residual renal function is of considerable importance for patient and technique survival. Residual renal function is somewhat better preserved over treatment time in PD than in HD.[42] Residual renal function can be assessed by collecting all urine during a day and by assessing the urine concentrations of urea and creatinine and total urine volume. Because renal creatinine clearance, as a result of tubular secretion, yields an overestimate of the glomerular filtration rate (GFR) (by 1 to 2 ml/min) when the GFR is 10 ml/min or lower, and renal urea clearance yields an underestimate of GFR (by 1 to 2 ml/min) in the same interval of (reduced) GFR, a good estimate of actual GFR can be calculated as the average of renal creatinine clearance and urea clearance. However, if the daily urine volume is

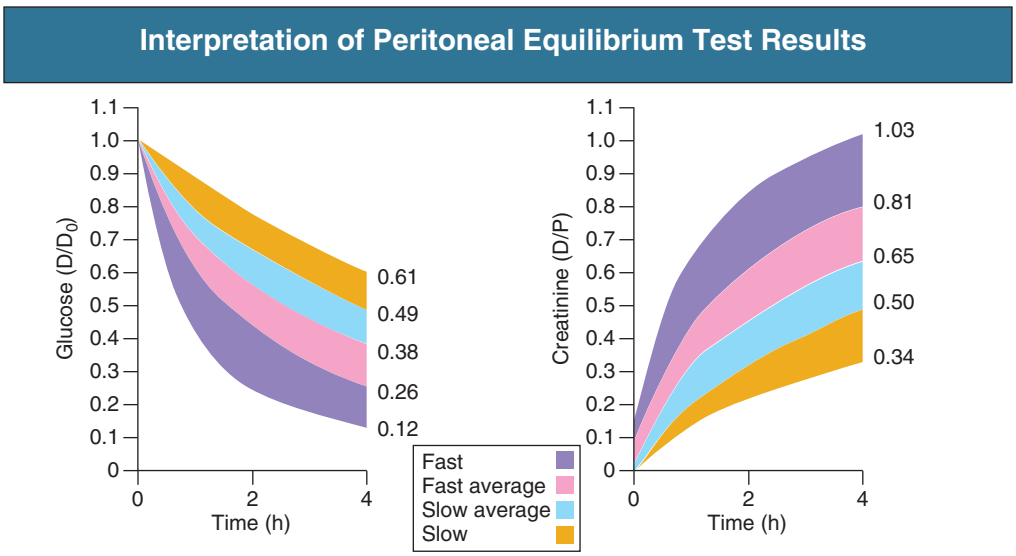

Figure 96-8 **Interpretation of the peritoneal equilibration test (PET) results.** Changes in solute concentration during a PET allow classification into different transport types. *(Modified from reference 33.)*

less than 200 ml, residual renal function will be too small to be measured accurately.

ADEQUACY

The most important measure of dialysis adequacy is the general clinical state of the patient, as manifested by a good nutritional status (maintained muscle mass) and the absence of anemia, edema, hypertension, electrolyte and acid-base disturbances, neurologic symptoms, pruritus, and insomnia. Management of anemia and bone disease in ESRD patients is discussed in Chapters 83 and 85 respectively. Some criteria for PD adequacy are given in Table 96-1.

Small-Solute Clearance

Few prospective randomized studies define adequate PD. From a clinical point of view it has been suggested that a weekly *Kt/V* above 1.7 and a weekly creatinine clearance above 50 l/1.73 m^2 would be (minimally) adequate for patients on CAPD. In a large prospective study in the United States and Canada, the CANUSA study, the outcome for a cohort of 680 patients starting CAPD was studied with an average follow-up of 2 years.[43] In this study, patients who maintained a high *Kt/V* or creatinine clearance over time did better than those who did not. An increase of 0.1 unit of *Kt/V* (peritoneal + renal) per week was associated with a 5% decrease in relative risk of death, and an increase of 5 l/1.73 m^2 of creatinine clearance per week (peritoneal + renal) was associated with a 7% decrease in the relative risk of death. Further analysis of the CANUSA study findings indicated that the survival advantage of patients with higher total small-solute clearance was entirely attributed to the residual renal function. For each increase of 250 ml of urine output per day, there was a 36% decrease in the relative risk of death. In the Adequacy of Peritoneal Dialysis in Mexico (ADEMEX) study,[44] a large randomized controlled clinical trial (RCT) designed to test the value of increasing peritoneal small-solute clearance in a Mexican PD cohort, there was no survival advantage of increasing the peritoneal clearance to obtain a total weekly creatinine clearance above 60 l/1.73 m^2 at an average peritoneal *Kt/V* of 2.12 (intervention group) compared with a clearance above 50 l/1.73 m^2 at an average peritoneal *Kt/V* of 1.56 (control group). However, although overall mortality, hospitalization, withdrawal, and technique survival were similar in the two groups, the causes of withdrawal were different. Relatively more patients in the control group withdrew because of uremia, hyperkalemia, and acidosis and died from congestive heart failure than in the intervention group.

From these studies it seems that renal and peritoneal clearance are not mutually comparable. High residual renal function is of greater survival advantage than high peritoneal solute transport capacity. The fact that the survival of PD patients is equal to or supersedes that of HD patients during the first 2 to 3 years of dialysis (see later), despite the fact that PD provides approximately 50% of the total *Kt/V* of HD, indicates that the benefit of PD goes beyond the clearance of small solutes. In a European multicenter study of APD, the European Automated Peritoneal Dialysis Outcomes Study (EAPOS), small-solute clearance did not correlate with survival in anuric patients.[45] On the contrary, total volume removal and hydration state were important factors. Still, there is reasonably good evidence that a weekly *Kt/V* above 1.7 and a weekly creatinine clearance above 50 l/1.73 m^2 are adequacy targets that should be reached and maintained in a majority of patients. Lower values of *Kt/V* and creatinine clearance have been found to be associated with more clinical problems and higher consumption of erythropoiesis-stimulating agents in a large RCT.[46]

Commercially available computer programs* can predict urea and creatinine clearances and peritoneal UF performance and provide suggestions for treatment options, based on drained volumes and on plasma and dialysate creatinine and urea values. These parameters are often obtained by PET or standardized schedules for specified dwell exchanges. Some of the programs yield an estimate of peritoneal albumin clearance, which to a great extent is dependent on the filtration occurring across large pores, being increased in "inflammation." Recommended dialysis schedules based on the categorization of the PET are given in Table 96-2.

Criteria for Peritoneal Dialysis Adequacy	
Clinical	Patient feels well and has stable lean body mass No symptoms of anorexia, asthenia, nausea, emesis, insomnia Stable nerve conductance velocity
Small-solute clearance	Weekly *Kt/V* urea >1.7 (renal + peritoneal) Weekly creatinine clearance >50 l/1.73 m^2
Large-solute clearance	Albumin clearance <0.15 ml/min
Fluid balance	No edema No hypertension No postural hypotension
Electrolyte balance	Serum potassium <5 mmol/l
Acid-base balance	Serum bicarbonate >24 mmol/l
Nutrition	Daily protein intake ≥1.2 g/kg Daily calorie intake >35 kcal/kg/day Serum albumin >3.5 g/l BMI 20-30 kg/m^2 Stable midarm muscle circumference

Table 96-1 Criteria for peritoneal dialysis adequacy. *BMI,* Body mass index.

Fluid Balance

As in all types of RRT, long-term maintenance of adequate fluid and electrolyte balance is of crucial importance for the survival of patients on PD. As already mentioned, the outcome of PD is directly related to residual renal function, particularly a high urine output. Furthermore, patients with fast transport in the PET (a more rapid absorption of glucose and a more rapid loss of the osmotic gradient) have a reduced technique survival. It seems evident that after 2 or 3 years of PD, when residual renal function is low, most patients in PD are fluid overloaded.[47,48] It is likely that volume overload not only aggravates hypertension but also leads to progression of left ventricular hypertrophy, often already present at the start of PD. However, during the first year of PD there is often a fall in blood pressure and a reduced need for antihypertensive agents. Unfortunately, with time on PD, blood pressure usually rises and the number of antihypertensive drugs needed usually again increases.[49] Therefore it is advisable to regularly assess fluid removal in the patients over time, at least every 6 months, with a modified PET (4-hour 3.86% glucose dwell, in conjunction with a standard 2.27% 4-hour PET.

Management of Fluid Overload

As total urinary water (and sodium) excretion and peritoneal UF volume decline, it is advisable to instruct patients to restrict salt and

>2.0	CAPD+, HD	APD+ 15-20 l	APD+* 15-20 l	APD+* 15-20 l

Table 96-2 Peritoneal dialysis regimens. Typical peritoneal dialysis regimens required to achieve adequate solute clearance according to patient size and membrane characteristics in anuric patients. The total volume of dialysate fluid required increases with body size, with use of 2.5- or even 3.0-liter exchanges. As solute transport increases, the use of automated peritoneal dialysis (APD) with shorter overnight exchanges is favored over continuous ambulatory peritoneal dialysis (CAPD). Both CAPD and APD may have to be augmented by the use of an additional exchange (denoted by +); this is given by way of an additional afternoon exchange in CAPD patients or by use of an exchange device that delivers a single additional exchange at night. *D/P,* Dialysate-plasma concentration ratios; *HD,* hemodialysis. *The use of glucose polymer (icodextrin) solution for the long exchange will enhance both solute clearance and ultrafiltration.

water intake. In view of the difficulty in compliance with salt restriction, the use of PD solutions with lower sodium concentration has been advocated. Preliminary studies of low-sodium PD solutions have been very promising with regard to reducing the need for blood pressure–lowering drugs to control hypertension[50]; however, low-sodium solutions are not yet commercially available. Loop diuretics such as furosemide 250 to 500 mg daily can be used to maintain urine volumes but do not maintain renal clearance. If salt and water restriction and diuretics are not effective in maintaining UF, it can be enhanced by increasing the dialysis glucose concentration. Patients with alterations in peritoneal membrane function, appearing over the first few years of PD, usually have an increased small-solute transport combined with only a moderate change in peritoneal UF capacity,[40] and there is an increased reabsorption of fluid in the late phase of the dwell. These patients can benefit from switching to APD and to the use of icodextrin for one of the (daily) exchanges. Randomized controlled trials using icodextrin for the long daytime dwell in APD have demonstrated an improved UF and a reduced extracellular fluid (ECF) volume.[51] Patients who have been on PD for several years may have a reduced UF capacity (reduced OCg).[39,40] These patients would (theoretically) benefit less from switching to icodextrin because of the reduced UF capacity.[11]

Nutrition

During their first year of treatment, CAPD patients typically have evidence of net anabolism; the average weight gain may exceed 5 kg without any clinical signs of fluid overload. Contributing to this weight gain is the peritoneal glucose reabsorption (on average 100 to 150 g daily), which adds 400 to 600 kcal of energy intake daily and results in metabolic syndrome in approximately 50% of prevalent PD patients.[52] As residual renal function declines, the nutritional and metabolic abnormalities in CAPD become increasingly manifest, with reductions in lean body mass. The main cause of protein-energy malnutrition and wasting, apart from poor food intake, is the impaired metabolism of protein and energy in uremia. Despite glucose absorption, many patients on long-term CAPD have signs of energy malnutrition, a major component of the uremic wasting syndrome. Contributing factors are (low-grade) inflammation associated with carbonyl and oxidative stress and with accelerated atherosclerosis, the so-called malnutrition inflammation atherosclerosis (MIA) syndrome.[53] It is important that CAPD patients be prescribed an adequate amount of protein (>1.2 g protein/kg/day) and energy (total energy intake >35 kcal/kg/day) and a sufficient dose of dialysis, enabling the patient to ingest this diet. It should be noted that the daily losses of protein to the dialysate are not negligible, but approximately 5 to 7 g daily, of which approximately 4 to 5 g is albumin. This actually compares with the losses occurring in nephrotic range proteinuria. The nutritional management of PD patients should include frequent assessments of their nutritional status, and if inadequate, referral for HD (or transplantation) should be considered. Nutrition in PD patients is discussed further in Chapter 87.

OUTCOME OF PERITONEAL DIALYSIS

Registry data have indicated a lower risk of death in patients treated with PD during the first 3 years of treatment compared with those treated with HD, although overall the mortality of patients on PD compared with HD is not significantly different.[1] Survival differences seem to vary substantially according to the underlying cause of ESRD, age, and baseline comorbidity. In a study based on U.S. Medicare registry data,[54] HD was associated with a higher risk of death among diabetic patients with no comorbidity and among younger patients (age 18 to 44), whereas PD was associated with a higher risk of death among older patients (age 45 to 64). In patients with mortality rates adjusted for comorbidity at start of dialysis, there were no differences between HD and PD among nondiabetic patients and among younger diabetic patients (age 18 to 44), but mortality was higher on PD for older diabetic patients with baseline comorbidity.

CHAPTER 97

Complications of Peritoneal Dialysis

Simon J. Davies and Martin E. Wilkie

Peritoneal dialysis (PD) is associated with a number of potential complications that affect technique and patient survival. Understanding their etiology, presentation, and management frequently enables their prevention, correction, or amelioration. These complications can be separated into mechanical aspects relating to the PD technique and the catheter itself, infections either at the exit site of the catheter or peritonitis, changes affecting the peritoneal membrane, and metabolic consequences that arise from components of the dialysis solutions—predominantly the glucose content. Mechanical or catheter-related problems are more likely to occur at the start or early in the treatment course, or when there is an increase made to the volume of the dialysate; infectious complications can occur at any stage during the course of treatment, whereas membrane and metabolic problems are more prominent after the patient has been on treatment for months or years.

CATHETER MALFUNCTION

Optimal Timing and Placement of the Peritoneal Dialysis Catheter

Catheter dysfunction adversely affects patient outcome by preventing commencement of the chosen dialysis modality, as well as by being disruptive to training schedules and increasing health care costs. Published literature does not give a strong indication that one insertion technique is better than another, although a recent meta-analysis suggested an advantage of the laparoscopic compared with the open surgical insertion technique[1] (techniques of catheter insertion are further discussed in Chapters 92 and 96). It is clear that the enthusiasm and experience of the operator are key determinants of catheter outcome,[2] and international guidelines describe the optimal conditions for catheter insertion.[3] Timing is also important: Patients randomized to the late start limb of the Initiating Dialysis Early and Late (IDEAL) study (estimated glomerular filtration rate [eGFR] 5 to 7 ml/min), as opposed to patients starting dialysis early (eGFR 10 to 14 ml/min), were less likely to start on PD despite it being their treatment of choice, probably because of delayed planning.[4] Early catheter problems are more difficult to manage in the absence of residual kidney function. For optimized catheter function it is necessary that each center audit its success with catheter placement against internationally agreed-on standards as part of local quality improvement cycles.[2,3]

Catheter Function: Inflow

A 2-liter bag of dialysate should take 15 minutes or less to run into the peritoneal cavity. If inflow is significantly slowed or even stopped completely, mechanical causes should be suspected. After a check to ensure that the tubing and catheter are not kinked, that all clamps or rollers are open to the inflow position, and that any frangible seal is fully broken, the catheter should be flushed vigorously with 20 ml of heparinized saline. If the catheter is cleared, then heparin should be added (500 U/l) to the next few cycles because the cause of the blockage is often a fibrin plug. Should the catheter remain blocked, a plain abdominal radiograph is required. If this shows that the catheter is in a satisfactory position in the pelvis, an attempt to restore patency should be made with a thrombolytic agent (urokinase, 100,000 U or tissue plasminogen activator [tPA], 2 mg in 40 ml of normal saline, either instilled for at least 1 hour)[5] diluted in normal saline, which can be instilled into the PD catheter for approximately 1 hour before being withdrawn. If inflow is restored, heparin should be added to the dialysate for the next few cycles. We would no longer recommend the use of an endoscopic brush because of safety concerns.

If the radiograph shows the catheter to be malpositioned, an attempt should be made to reposition the catheter tip into the pelvis (Fig. 97-1). This can be done under radiologic screening with a sterile catheter guide although this is not widely practiced. Alternatively, the catheter can be repositioned at laparotomy or with the laparoscope. Sometimes the catheter becomes wrapped in omentum, suggested usually by complete inflow and outflow failure. This requires a partial omentectomy or an omental hitch, a surgical procedure in which the omentum is temporarily held away from the catheter by a dissolvable suture. The value of laparoscopy in this context is that it can provide a diagnosis as to the cause of catheter flow failure and provide a solution—for example, by repositioning the catheter, removing an omental wrap, or performing a limited omentectomy.

Catheter Function: Outflow

The most common reason for outflow failure is constipation, although causes of inflow failure discussed previously should also be considered. Loading of the bowel with fecal material is often obvious on a plain radiograph, but treatment for constipation should be initiated without recourse to this investigation because it is so common. Constipation should be treated with oral laxatives or an enema. Subsequently, bowel action should be kept regular by increasing the fiber in the diet and, if necessary, adding a mild laxative. Slow outflow can be a problem in patients using automated peritoneal dialysis (APD), resulting in excessive machine alarms. This is can be managed by switching to tidal APD and using a relatively large residual volume, for example 25% to 50% of the fill volume.

Fibrin in the Dialysate

The mesothelial cells of the peritoneal membrane have a range of physiologic functions including the production of fibrinolytic agents such as tPA. This process is disrupted during peritonitis when the appearance of fibrin in the dialysate is common. If fibrin causes restriction of dialysate flow, heparin (500 U/l) should be added to each bag. A small number of patients have fibrin formation in the absence of peritonitis. Immediately on drainage the bag may appear

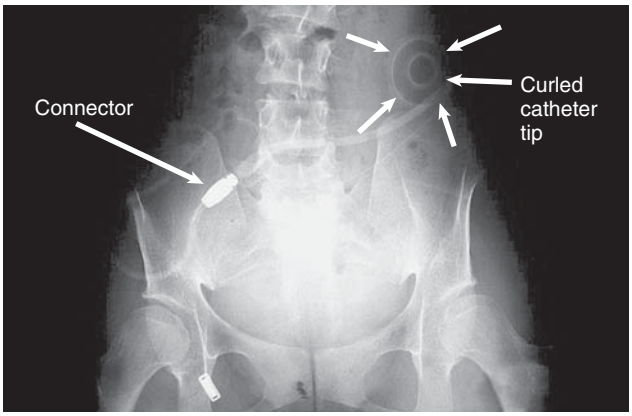

Figure 97-1 Catheter malposition. Plain radiograph of the abdomen with curled catheter *(arrows)* misplaced in the upper left abdomen.

cloudy, but on standing the fibrin will aggregate and the fluid becomes clear. The first time this happens, a sample must be sent to the microbiology laboratory to exclude infection. If the results of this testing prove negative, the patient can be reassured.

FLUID LEAKS

Fluid leaks occur whereby dialysate leaks out of the peritoneal cavity—which can be either visible externally or not. It is recommended that after PD catheter surgery, patients be allowed to heal sufficiently before use (2 weeks) to minimize this risk. If the catheter has to be used early, then low volumes should be used (start with 1 liter) in the supine position (e.g., APD with a dry day), with the patient instructed not to mobilize while dialysate is in the peritoneal cavity during the first 2 weeks after catheter insertion. Although PD catheters can be used as the primary approach to manage late-presenting patients or for acute kidney injury, the incidence of leaks is higher under these conditions.[6]

External Leaks

On occasion, fluid may leak from the exit site or even the incision used to insert the catheter into the peritoneal cavity. A leak of dialysate, which is confirmed by measuring glucose concentration in the leaking fluid, is a risk factor for infection. It is important that PD catheters be adequately immobilized if used for early start PD to reduce the risk of tugging and leak.

Internal Leaks

Isolated edema of the abdominal wall suggests an internal leak from the peritoneal cavity, either spontaneously or in association with a surgical hernia. In contrast, genital edema suggests an inguinal hernia or patent processus vaginalis. On occasion, both can be present. The site of the leak can be visualized on computed tomography (CT) scanning after intraperitoneal instillation of contrast material or on magnetic resonance imaging (MRI) without the use of contrast. It may be necessary for the patient to stand or to perform other maneuvers to increase intra-abdominal pressure before the leak is demonstrated (Fig. 97-2, *A*). An alternative diagnostic test is to perform scintigraphy after injection of a compound such as technetium Tc 99m–labeled diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA; Fig. 97-2, *B*). A surgical repair will be required if a major leak is visualized and should always be considered when there is a hernia.

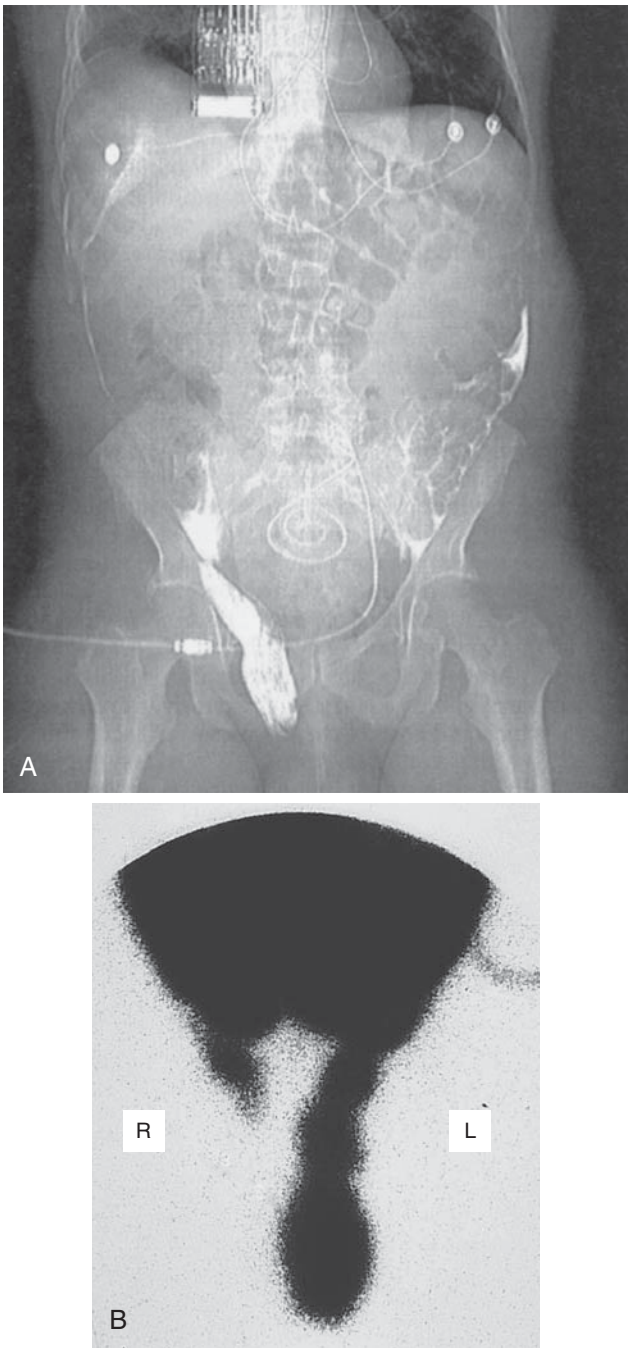

Figure 97-2 Inguinal hernia during peritoneal dialysis. A, CT scan after intraperitoneal injection of contrast material in a male patient showing dialysate flowing into a right inguinal hernia. **B,** Peritoneal scintigram of a male patient on peritoneal dialysis showing bilateral inguinal hernias. The left hernia extends into the scrotum; the right hernia is less extensive. (***A*** *from reference 34.*)

Most leaks, however, will heal after resting or with APD, using dry days, or temporary HD.

Hydrothorax

A pleural effusion can occur with generalized fluid overload or local lung disease, but it is occasionally caused by a leakage of dialysate through the diaphragm (Fig. 97-3, *A*). This occurs more commonly on the right side. A leak is most simply indicated by aspirating a sample of the effusion and demonstrating that its

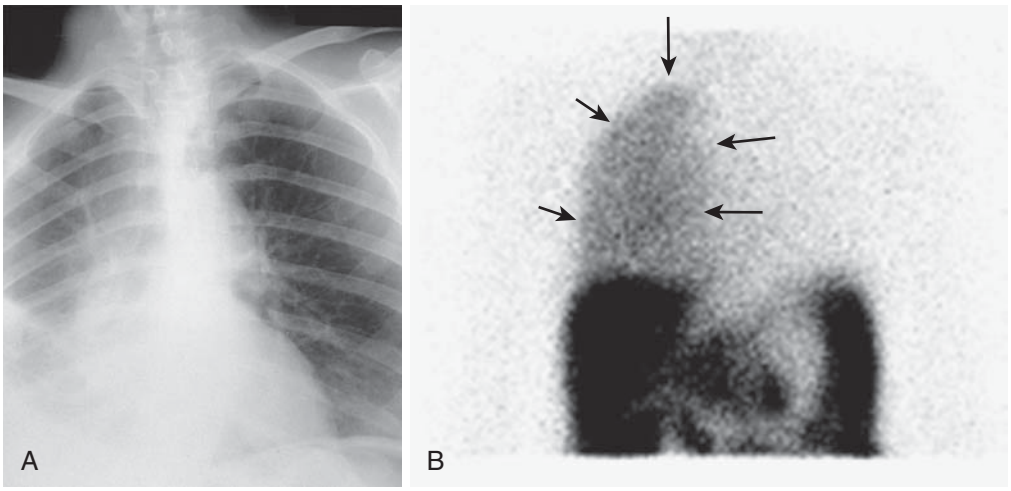

Figure 97-3 Hydrothorax in peritoneal dialysis. A, Chest radiograph showing a right-sided pleural effusion with partial collapse of the right lung caused by a diaphragmatic leak. **B,** Scintigram in a peritoneal dialysis patient showing isotope in the right hemithorax *(arrows)* confirming a right pleural effusion.

glucose concentration is higher than the patient's blood glucose concentration, and this can be confirmed by scintigraphy after intraperitoneal instillation of isotope, usually ^{99m}Tc-DTPA (Fig. 97-3, *B*). If one can be confident that the pleural effusion is not caused by the PD, then PD can be continued while the effusion is investigated and managed. Although there are reports that repairing pleural leaks allows subsequent PD, the best advice is to transfer the patient to HD unless there are very strong reasons not to.

PAIN RELATED TO PERITONEAL DIALYSIS

Inflow Pain

Soon after starting PD, patients may experience pain during fluid inflow, and occasionally pain affects the shoulders and is pleuritic in nature, possibly because of diaphragmatic irritation, which usually resolves over the following days. Slowing the rate of fluid inflow will often reduce the symptoms, and peritonitis should be excluded and treated. A small number of individuals have persistent inflow pain, and the use of bicarbonate-lactate–buffered dialysate at physiologic pH improves symptoms in such patients.[7]

Outflow Pain

Some patients have discomfort or even pain when the fluid is drained out, which can be experienced in the genital area or rectum, and is commonly a result of pelvic irritation related to the catheter tip. This emptying sensation is abolished when the next cycle runs in and is best treated by leaving a small residual volume of fluid in the peritoneal cavity at the end of the drain, for example by using tidal APD.

Blood-Stained Dialysate

Blood-stained dialysate is uncommon. It is rarely serious but causes considerable alarm to the patient. There is sometimes a clear history of trauma to the abdomen or of unexpected strain. A range of rare conditions are associated with this complication[8]; a few female patients relate the episode to their time of ovulation or menstruation. The treatment is to flush the abdomen with a few cycles of dialysate containing heparin (500 U/l) to minimize the chances of clotting in the catheter. The problem usually resolves spontaneously and often is visible only in one outflow. It is unusual for the blood-stained dialysate to be associated with infection, although it is wise to have the fluid cultured. Routine use of antibiotics is not necessary.

INFECTIOUS COMPLICATIONS

Peritonitis

There are wide variations in peritonitis rates both between and within countries. Reducing peritonitis rates requires a multifaceted, multidisciplinary approach based on the use of preventative measures around the time of catheter insertion, the use of modern disconnect systems, exit site management, and education of patients and health care professionals.[9] This should be supported by regular local audit of peritonitis rates including causative organisms and local sensitivities, which is increasingly important because of the emergence of resistant organisms, and the requirement to use antibiotics effectively. Root cause analysis should be performed after each episode of PD peritonitis, with retraining as appropriate. Guidelines for the diagnosis and management of PD peritonitis are published by the International Society for Peritoneal Dialysis (ISPD; www.ispd.org).[10] The spectrum of peritonitis and its management in children have also recently been described in detail.[11] The reader is directed to a detailed review on reducing peritonitis risk.[9]

Diagnosis of Peritonitis

The diagnosis of peritonitis should be suspected in any patient who develops a cloudy bag when PD fluid is drained or abdominal pain. Fever may also be present but is not a universal feature. Patients should be advised to contact their dialysis unit immediately if they observe a cloudy bag or develop persistent abdominal pain. Samples of the dialysate should be taken for cell count and microbiologic examination. The diagnosis is confirmed by finding more than 100 white blood cells/mm^3 (1×10^7 cells/l). A Gram stain of the spun deposit should also be performed to help identify the type of causative organism, although initial treatment will usually be empiric pending culture and sensitivity results. Various culture techniques have been proposed, but white cell lysis and inoculation into blood culture media is often helpful in increasing the yield of a positive growth.

The dialysate leukocyte count will be affected by dwell length, and this needs to be taken into account in APD patients. In short dwells, the count will be lower, and under these circumstances, if the proportion of cells that are neutrophils exceeds 50%, empiric treatment of peritonitis should be commenced. Conversely, if the patient has had a dry abdomen during the day, the initial drain on connection may be cloudy. This will clear within one or two cycles, and the majority of the cells found will be mononuclear leukocytes.

Treatment of Peritonitis

The empiric treatment of peritonitis will vary according to center and should be developed in close collaboration with the local microbiology service, taking into account sensitivity patterns and infection control policy. Initial regimens must cover both gram-positive and gram-negative organisms; the latest ISPD guidelines (www.ispd.org) give examples of appropriate antibiotics including vancomycin, cephalosporins, and aminoglycosides.[10,11] Dosage regimens will depend on whether the patient is on CAPD or APD. For CAPD, the antibiotic is administered as a loading dose in the first bag and then as a maintenance dose in subsequent bags. Although it was customary to transfer APD patients to CAPD for the purpose of treating peritonitis, this is no longer necessary. APD patients are now given large loading doses in dialysis fluid with a minimum 6-hour dwell (e.g., vancomycin 30 mg/kg) and then are given additional doses every 3 to 5 days according to checked blood levels. Once the culture result is available, the regimen should be modified accordingly (Table 97-1). If the organism is methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin will be continued as part of the regimen.

If the culture is negative, empiric therapy should be continued for 2 weeks, assuming there is a clinical response. If a gram-negative organism is identified, the subsequent management will depend on the sensitivity (Fig. 97-4). The isolation of multiple organisms including anaerobes strongly suggests perforation of the small or large intestine or biliary system. Metronidazole should be added to the regimen to cover anaerobic organisms, and consideration given to surgical intervention.

A wide variety of antibiotics other than those cited have been used with success. In particular, a commonly used strategy is to include an oral quinolone, such as ciprofloxacin. There is debate surrounding the role of aminoglycosides—advantages being simplicity of use and good gram-negative organisms coverage; however, there are concerns regarding ototoxicity and nephrotoxicity, the former of which is irreversible. Reports regarding the impact of these agents on residual renal function are not consistent, and it is clear that serious episodes of peritonitis in themselves have an adverse

Antibiotic Regimens for Bacterial PD Peritonitis

Culture	Antibiotic
Enterococci (including vancomycin-resistant enterococci)	Ampicillin
*Staphylococcus aureus** Methicillin resistant*	Cephalosporin-floxacillin (flucloxacillin) Vancomycin
Other gram-positive organism†	Cephalosporin-floxacillin
Gram-negative organisms (including *Pseudomonas* species)*	Cefazolin, quinolone, or aminoglycoside‡, depending on sensitivities and residual renal function
Multiple or anaerobic organisms*	Metronidazole ± laparotomy
Culture negative	Continue empiric treatment

Table 97-1 Antibiotic regimens for bacterial PD peritonitis. Suggested antibiotic regimens when dialysate fluid culture is available. Except for culture-negative episodes, empiric treatment is stopped once the sensitivities are known. All antibiotic regimens should be developed in consultation with local microbiology practices. *Three-week treatment. †Two-week treatment. ‡Avoid unnecessary use if there is residual function.

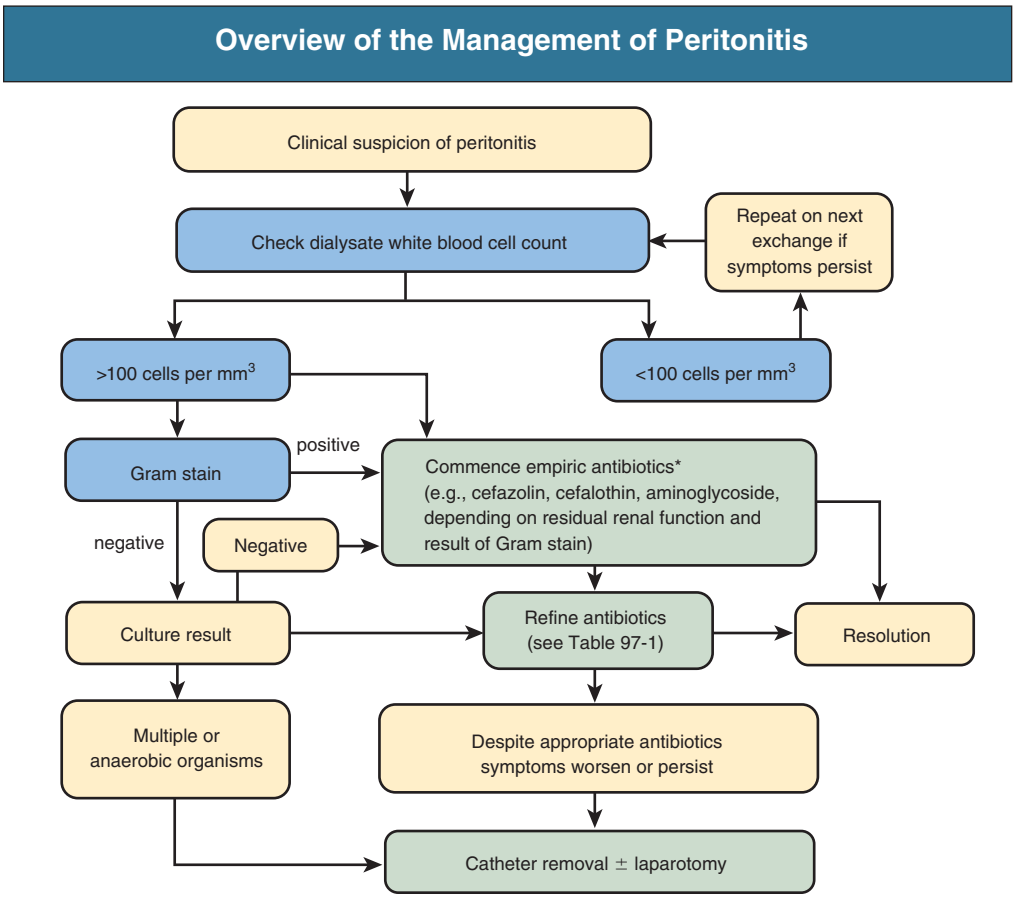

Figure 97-4 Overview of the management of peritonitis.

effect on residual renal function. It is, however, advisable to avoid recurrent courses of aminoglycosides; and if they are used, concomitant *N*-acetylcysteine should be considered to block the ototoxicity. Current recommendations are that for gram-positive organisms, therapy should be for 14 days except in the case of *S. aureus,* for which 21 days is suggested. For culture-negative episodes, 14 days of therapy should suffice. The same is true in the case of single-organism gram-negative peritonitis. For *Pseudomonas* species, *Xanthomonas* species, or multiple organisms, 21 days is recommended.

Many patients can be treated successfully as outpatients. It is extremely important, however, that they be followed up either in the clinic or by telephone. In most patients, clinical resolution, as judged by the clearing of the bags, starts within 48 hours. If there is no improvement within 96 hours despite use of the correct antibiotic, as judged by sensitivity tests, the fluid must be retested by cell count, Gram stain, and culture. The ISPD recommends that the catheter be removed if there is no improvement in 5 days; however, in a severe infection this should be done earlier, and in a more indolent case the period of observation can be longer. In addition, the possibility of intra-abdominal or gynecologic disease or the presence of unusual organisms such as mycobacteria should be considered. Under these circumstances, a mini-laparotomy should be performed to exclude intra-abdominal disease, and if mycobacterial infection is suspected, a peritoneal biopsy specimen should be obtained for culture.

Fungal Peritonitis

If peritonitis is caused by yeasts or fungi, the peritoneal catheter should always be removed. This should be combined with antifungal treatment with fluconazole, combined with intraperitoneal flucytosine until sensitivities are known, with care taken in view of its toxicity in renal failure. Oral antifungals should be continued for at least 10 days and up to 4 weeks after catheter removal, at which point catheter replacement can be considered.[10,11]

Relapsing Peritonitis

Relapsing peritonitis is defined as infection caused by the same organism as the original infection occurring within 4 weeks, whereas *recurrent peritonitis* is defined as a different organism within 4 weeks of completion of an appropriate course of antibiotics. In general, the advice is to treat as for a primary infection but to try to establish an underlying cause. For example, recurrence of *S. aureus* infection should trigger the search for pericatheter infection. If enterococci or gram-negative organisms are the cause of a relapse, the possibility of intra-abdominal disease or an abscess should be considered (although these organisms are frequently water-borne). If a patient has other gastrointestinal symptoms, such as change in bowel habit, appropriate investigation should be conducted. Some organisms (including coagulase-negative staphylococci) produce biofilm that can lead to a relapse of the infection. Consideration should be given to changing the PD catheter once the infection has been treated; of course, the catheter will need to be removed if the infection does not respond to treatment. Current practice in most units is to allow a period of up to 3 weeks before a new catheter is inserted.

Culture-Negative Peritonitis

The importance of culture-negative peritonitis is that it is associated with increased treatment failure. Commonly the cause relates to the sampling technique or the microbiologic approach; alternatively, concurrent antibiotic use may be responsible. It is important to be aware of the possibility of fastidious organisms (e.g., atypical mycobacteria or yeasts). In addition, other causes of peritoneal inflammation may responsible; these include the presence of an intra-abdominal malignancy or surgical pathology or eosinophilic reactions—for example, in the case of vancomycin allergy or some fungal infections. Chylous effluent is a rare finding in PD; the cause is often unclear, but if recurrent; conditions affecting lymphatic drainage should be considered.

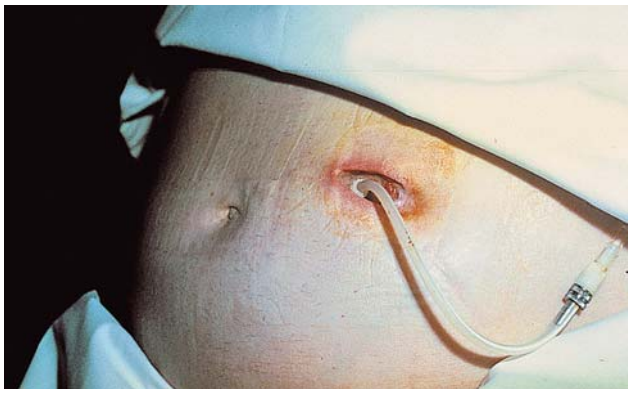

Figure 97-5 Exit site infection. A severe exit site infection that has exposed the outer cuff of the catheter.

Exit Site Infection

Exit site infection is an important complication of long-term PD. The diagnosis is suspected on clinical grounds, usually by the presence of marked erythema or discharge from the exit site (Fig. 97-5). A scoring system for exit sites has been developed to determine the likelihood of infection and to grade its severity, with points assigned for crusting, swelling, pain, and discharge according to severity; if the discharge is purulent, this mandates treatment.[10] Extension of the infection into the tunnel may be assessed either clinically or by ultrasound. The most common infecting organism is *S. aureus.* There is evidence for the use of prophylactic topical antibiotics at the exit site, the strongest being for mupirocin; a systematic review concluded that mupirocin prophylaxis was effective in prevention of exit site infection and peritonitis caused by *S. aureus.*[12] There is also evidence for the use of topical gentamicin; however, a number of case reports of gentamicin resistance following regular topical application has raised concerns regarding its use as a routine prophylactic agent.

All suspected infected exit sites should be swabbed; routine swabbing of healthy exit sites should be avoided, and incidental bacterial growths do not require treatment. Unless there is prior evidence that the patient carries MRSA or *Pseudomonas,* initial treatment should be with an antibiotic effective against *S. aureus*—for example, flucloxacillin (500 mg four times a day) or a cephalosporin if the patient is allergic to penicillin. In most patients, the drug can be given orally; but if the individual is systemically ill, the antibiotics should be administered intravenously until clinical improvement occurs. Hospitalization, parenteral antibiotics, and often urgent catheter removal are required if there is evidence of spread into the tunnel. If the infection is with MRSA, eradication therapy should be attempted with systemic vancomycin, as for peritonitis. Should the culture grow a gram-negative organism, ciprofloxacin (500 mg twice a day orally) will be effective empiric treatment in most patients.

Treatment is recommended for a minimum of 2 weeks. In gram-positive infections, if there is no improvement within 7 days, ultrasound of the catheter tunnel should be performed because a collection of fluid around the catheter signifies a tunnel infection. If complete healing does not take place after 4 weeks of therapy, further measures should be considered, such as exteriorizing and shaving the outer

cuff because it may be involved in the infection. If the infection persists or relapses, catheter removal must be considered because there is a high risk that the exit site infection will lead to peritonitis. It is important that the new exit site be formed in a different part of the anterior abdominal wall.

REDUCED ULTRAFILTRATION AND ULTRAFILTRATION FAILURE

Definition and Significance of Ultrafiltration Failure

There are two complementary approaches to defining ultrafiltration failure. The first is absolute and membrane based: With use of a standard 4-hour peritoneal equilibration test (PET), net ultrafiltration capacity below 400 ml with a hypertonic glucose exchange (3.86%) is indicative of an inadequate membrane,[13] bearing in mind that this may not be clinically relevant in a patient with well preserved residual renal function. If a middle-strength glucose solution is used (2.27%), then the equivalent value is 0 ml (excluding overfill). In both cases, in measuring the ultrafiltration capacity it is important that overfill of dialysis bags by the manufacturers, which can be as much as 200 ml, be taken into account. Although this definition is clear enough, the main limitation is that it relies on a single measurement of ultrafiltration capacity, which is subject to significant error (coefficient of variation is up to 25%). The second approach to defining ultrafiltration failure is more holistic in that it considers patient factors that affect fluid status (such as comorbid conditions) and an acceptable glucose exposure required to maintain adequate hydration. Many clinicians now take the view that regular the use of hypertonic solutions is not acceptable unless the life expectancy is shorter than the development of severe membrane failure and its complications.

Ultrafiltration failure is a significant cause of technique failure[14]; it results in low ultrafiltration, which in turn increases the risk of mortality in anuric patients[15,16]; and is also a risk factor for encapsulating peritoneal sclerosis (EPS).[17] Although it is impossible to set a precise overall fluid removal goal that applies to all patients, the European Automated Peritoneal Dialysis Outcomes Study (EAPOS), which preset an ultrafiltration target of more than 750 ml/day in anuric patients on PD, found that those who failed to reach this goal had higher mortality and less efficient membranes.[15] Patients who achieve less than a total fluid removal of 1 liter per day should have their membrane function assessed.

Establishing the Causes of Ultrafiltration Failure

Failure of the membrane to ultrafiltrate needs to be distinguished from other causes of inadequate peritoneal fluid removal such as catheter dysfunction, leak, or excessive fluid reabsorption.[18] The latter can occur if the intraperitoneal cavity pressure is too high, suspected if the ultrafiltration falls after an increase the dialysate volume. If doubt is present, a dialysate sodium concentration below 125 mmol/l 1 hour into a PET using 3.86% glucose suggests that ultrafiltration is preserved.

There are two main causes of ultrafiltration failure: fast peritoneal solute transport rate (fPSTR) and low membrane ultrafiltration efficiency caused by reduced osmotic conductance. Both can exist at the start of PD or can be acquired with time on therapy, although it is rare for a patient to develop reduced osmotic conductance without also having rapid transport.

Fast Peritoneal Solute Transport Rate–Related Ultrafiltration Failure: Diagnosis and Management

With the 4-hour PET, a dialysate–plasma creatinine ratio greater than average (0.64) could contribute to poor ultrafiltration. This is because the more rapid the diffusion of small solute across the membrane, the earlier the dissipation of the osmotic gradient driving ultrafiltration. Furthermore, once the gradient is lost, membranes with a larger diffusive area will reabsorb fluid more rapidly. In continuous ambulatory PD patients, fPSTR is associated with increased mortality,[19] whereas the converse is true when APD is used.[20] Thus both theoretically and empirically the short exchanges used in APD prescription are associated with better outcomes in fPSTR-associated poor ultrafiltration. Prevention of fluid reabsorption during the long day or night exchange is also required in these patients, and this can be achieved by use of icodextrin (polyglucose solution), which also improves the fluid status.[21] It is now known that the main determinant of fPSTR is increased intraperitoneal inflammation, which is independent of systemic inflammation. Only the latter is an independent predictor of mortality.

Low Osmotic Conductance–Related Ultrafiltration Failure: Diagnosis and Management

This problem should be suspected if despite adjustment of the prescription to accommodate the peritoneal solute transport rate (PSTR), ultrafiltration failure persists. Osmotic conductance is a measure of the efficiency of the peritoneal membrane to ultrafiltrate for a given osmotic agent—typically glucose. Osmotic conductance can be measured quite easily in the clinic with the double-mini-PET,[18] which requires back-to-back 1-hour exchanges using low (1.36%) and high (3.86%) glucose concentrations; a difference of less than 200 ml net ultrafiltration between the two exchanges indicates poor osmotic conductance. The two causes so far identified are reduced aquaporin function, possibly constitutive and thus present at the start of treatment, and progressive fibrosis of the membrane as a consequence of acquired membrane injury. There is no specific treatment, so clinical effort should focus on prevention (next section).

CHANGES IN PERITONEAL STRUCTURE AND FUNCTION

It is widely assumed that alterations in peritoneal function, a combination of an increased PSTR and loss of osmotic conductance, are related to structural changes in the peritoneal membrane.[22] There is accumulating evidence that continuous exposure to dialysis solution components and repeated episodes of bacterial peritonitis are the main drivers of this process (Fig. 97-6). Although the relationship between structure and function has not been fully defined, increased PSTR is likely to reflect a greater vascular surface area, whereas loss of osmotic conductance requires an additional mechanism that could be explained by the progressive fibrotic changes.

Studies that have quantified these changes within the submesothelial collagenous zone suggest a progressive increase in thickness with time on PD (Figs. 97-7 and 97-8). Changes within the peritoneal vascular bed have also been identified. These include progressive changes to the structure of small venules ranging from subtle thickening of the subendothelial matrix to complete obliteration of vessels (Fig. 97-9).[23] In one study the extent of these changes in a small group of patients correlated with the loss of ultrafiltration.[24] Thus there is accumulating evidence that changes occur in both the

interstitial and vascular compartments of the dialyzed peritoneal membrane.

Preventing Membrane Injury

The main clinical factors associated with more rapid and severe membrane injury are early loss of residual renal function, recurrent or severe peritonitis, and the earlier use of higher glucose-containing solutions (often associated with loss of diuresis but an independent risk factor).[25] Hypertonic solutions may induce injury because of direct glucose toxicity, glucose degradation products (GDPs) present as a result of the sterilization process, or both. The prevention of membrane injury should focus on all of these drivers and include the following: preservation of residual renal function by avoiding volume depletion and using angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs); use of loop diuretics to maintain urine volume and delay use of hypertonic exchanges; use of icodextrin in the long exchange; avoidance of peritonitis; and use of low-GDP neutral pH solutions.[25] The balANZ study shows that the increase in PSTR over the first 2 years of PD is

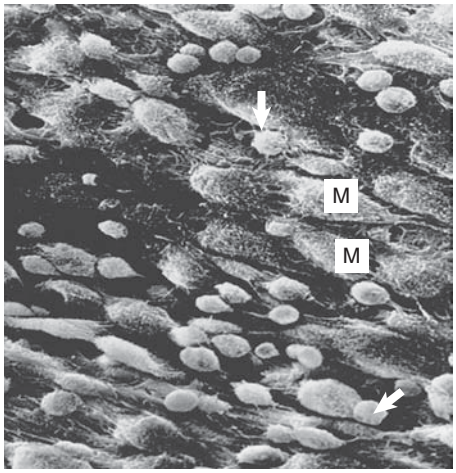

Figure 97-6 Peritonitis. Scanning electron micrograph of the peritoneum from a patient receiving peritoneal dialysis who has peritonitis. The small round cells *(arrows)* are phagocytes, which are widely distributed among the mesothelial cells *(M).* (Magnification ×1800.)

Peritoneal Membrane Thickening in Peritoneal Dialysis

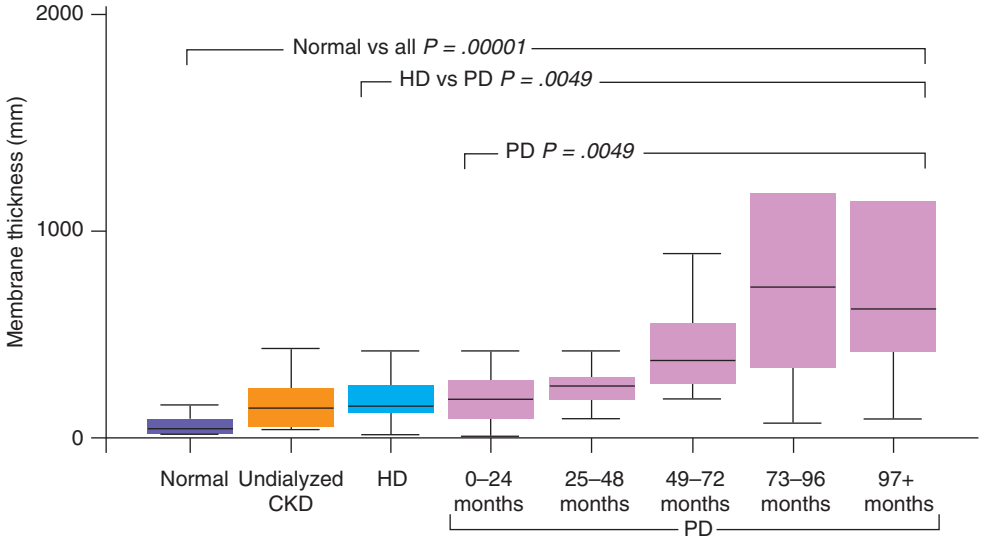

Figure 97-7 Peritoneal membrane thickening in peritoneal dialysis *(PD).* The thickness of the submesothelial collagenous zone of the peritoneal membrane in normal individuals, in undialyzed patients with advanced CKD, patients with uremia, in patients receiving hemodialysis *(HD),* and in those who have received PD for different periods. Membrane thickness is significantly increased in all uremic and dialysis patients compared with normal individuals. Membrane thickness increases significantly with duration of PD and is increased in PD patients as a group compared with HD patients.

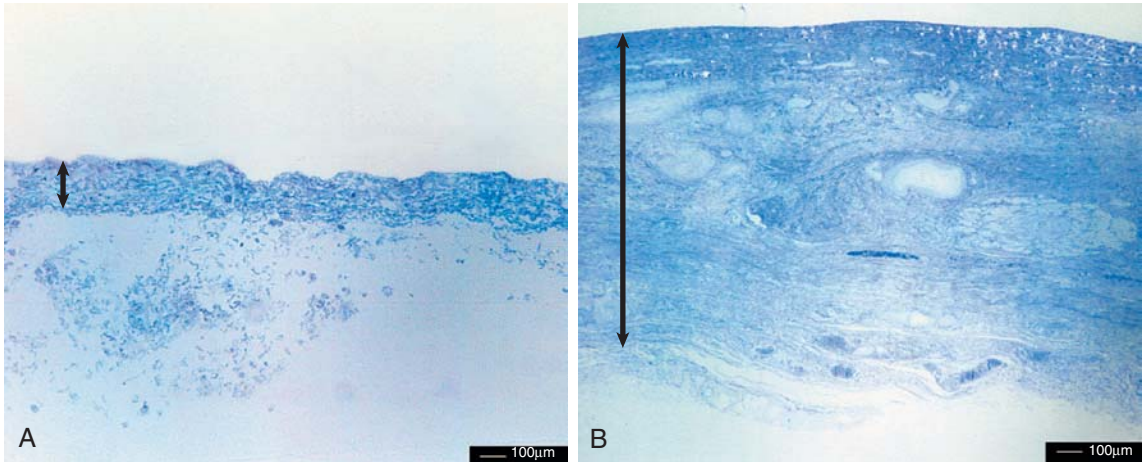

Figure 97-8 Morphologic changes in the parietal peritoneal membrane. A, Normal. **B,** A patient who has been on peritoneal dialysis (PD) for 10 years. Note the marked thickening of the submesothelial compact zone *(arrows)* (toludine blue).

prevented by use of ultralow-GDP dialysis fluid. Equally important, this study showed that achievement of less ultrafiltration early in the course of PD is associated with preservation of residual kidney function.[26] This supports the main strategy clinicians should adopt in preserving the membrane—prescribing to maintain adequate but not excessive ultrafiltration, which will only drive thirst and increase the risk of volume depletion.

Encapsulating Peritoneal Sclerosis

A minority of patients on PD develop EPS, in which the bowel is enveloped in a thick cocoon of fibrous tissue, causing intestinal obstruction (Fig. 97-10).[17] It is variable in severity but may be life-threatening, causing death from malnutrition or intra-abdominal catastrophe; but with experienced management by a multidisciplinary team, overall survival compares well with that of matched controls. The current definition of this syndrome requires both clinical signs and symptoms of bowel obstruction leading to weight loss and malnutrition (with or without features of systemic inflammation) combined with either typical features on imaging (CT scanning) or confirmation of fibrous cocooning at laparotomy. Although ultrafiltration failure, especially when it is associated with loss of osmotic conductance, is a risk factor, there are important differences, suggesting that this is at least in part a different pathologic process. It is predominantly a disease of visceral as opposed to parietal membrane, is usually associated with another risk factor or trigger (such

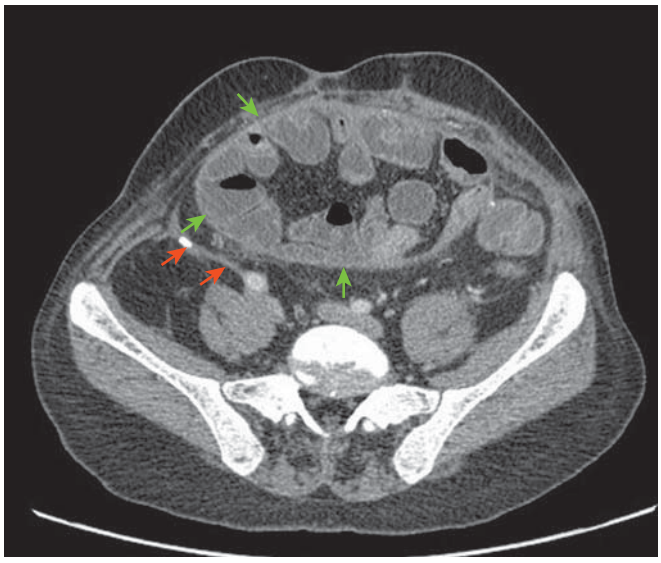

Figure 97-10 Encapsulating peritoneal sclerosis. Abdominal CT scan from a patient with encapsulating peritoneal sclerosis. *Red arrows* indicate thickened parietal peritoneum with calcification; *green arrows* indicate thickened visceral peritoneum forming a cocoon containing loops of bowel.

as severe peritonitis or stopping of PD, including for transplantation), and frequently has a systemic inflammatory phase; biopsy material more often shows inflammation and fibrinous exudates.

The single most important risk factor for EPS is time on PD; at 5 years the incidence is 2% to 3%, whereas by 10 years, this rises to 6% to 20%.[17] There is increasing evidence that the most successful treatment is surgery in the form of extensive adhesion lysis and excision of the peritoneum while avoiding enterotomy, especially when there are obstructive symptoms.[19] This should be undertaken by an experienced surgical team, which can achieve cure rates of 70% to 80%. Parenteral nutrition can be used, mainly as a preparation for surgery but occasionally as a long-term solution. In about 50% of patients, symptoms are less severe and gradually resolve. There appears to be little role for preemptive screening by CT scanning, but this is helpful in diagnosis. Most commonly, the condition develops after transfer from PD to either HD or transplantation; but if it develops in a patient on PD, the consensus is that PD should be stopped to avoid continued exposure to nonphysiologic dialysis solutions. Other strategies, such as continued irrigation, dual-modality treatment with PD and HD, and use of antifibrotic drugs such as tamoxifen, are practiced, but an evidence base for such management is lacking.

NUTRITIONAL AND METABOLIC COMPLICATIONS

Undernutrition

Cross-sectional surveys of patients receiving PD show that about 40% have evidence of mild and 8% severe protein-calorie depletion as judged by the subjective global assessment of nutritional state. Malnutrition is an adverse risk factor for morbidity and mortality of patients on PD and often associated with inflammation. The assessment and management of malnutrition are discussed further in Chapter 87. It has been recommended that ideally, PD patients should consume daily at least 1.2 to 1.3 g of protein per kilogram of body weight. In practice, many patients take only about 0.8 g/kg/day and seem to be nutritionally stable. It is likely that they have achieved a steady state but with a lower total body nitrogen or lean body mass.

Peritoneal dialysis patients have abnormal eating behavior with smaller meals, slow eating, and impaired gastric emptying compared

with normal individuals. The full peritoneal cavity may produce easy satiety, and some patients complain of feeling bloated. However, studies have shown that there is no actual difference in food consumption with or without dialysate in the abdomen. Amino acid–based dialysate improves nitrogen balance in malnourished patients, but the long-term nutritional benefit is marginal.[27]

One obvious contributing factor is protein loss through the peritoneum, which averages 8 g/day. It is proportional to effective membrane area and so is most marked during peritonitis and in patients with fPSTR. The ensuing hypoalbuminemia exacerbates the extravascular extracellular fluid (ECF) expansion in these patients.[28]

Acid-Base Status

Correction of acidosis is best achieved by use of dialysate with higher levels of potential buffer,[29] but if necessary, oral bicarbonate may be added. There is evidence that correction of acidosis, by whatever means, to within the upper half of the normal range for serum bicarbonate reduces protein catabolism, resulting in weight gain and increased midarm muscle circumference.[30] The use of amino acid–containing dialysate fluid can worsen acid-base status, requiring close monitoring.

Lipids and Obesity

Peritoneal dialysis results in a significant daily glucose absorption, which may range from 80 to 200 g/day, producing 300 to 800 kcal. The resultant effect is a tendency for patients on CAPD to develop features of metabolic syndrome: central obesity, hyperglycemia, dyslipidemia, and hyperinsulinemia; they may even develop frank diabetes, although there is no evidence that this is more common than in hemodialysis patients. These problems can be reduced by use of icodextrin and amino acid solutions in place of glucose with better glycemic control in diabetics.[31] Blood glucose monitoring in diabetic patients using icodextrin must not use glucose dehydrogenase pyrroloquinoline quinone (GDH-PQQ) test strips as this will lead to falsely high estimates and risk of severe hypoglycemia. The benefits of using lipid-lowering agents (e.g., simvastatin and ezetimibe) seen in chronic kidney disease to prevent cardiovascular events extend to PD patients.[32]

Despite these concerns, there is no evidence to suggest that PD should be avoided in obese patients. The survival advantage seen in HD associated with a higher body mass index is not seen with PD.[33]

CHAPTER 98

Dialytic Therapies for Drug Overdose and Poisoning

Nigel S. Kanagasundaram and Andrew Lewington

Poisoning and drug overdose, whether intentional or accidental, remains a common medical emergency, accounting for around 140,000 hospital admissions per year in the United Kingdom (nearly 1% of all admissions).[1] Most human exposures, however, do not require hospital admission; around 70% of the approximately 2.3 million cases in the United States in 2011 were managed at the site of the incident, in a non–health care facility.[2] The spectrum of agents ingested is wide, ranging from overdose of prescription or proprietary drugs to poisoning with nonpharmacologic substances and recreational drugs.

The pattern of toxin ingestion has changed over the years but also varies according to geographic location. Frequently implicated agents in industrialized societies include analgesics (acetaminophen, opioids, salicylates), antidepressants, sedatives, and antipsychotics. Barbiturate poisoning is now less common but was in the past a major contributor. Pesticides remain a frequent cause of poisoning in areas of the developing world.[3]

Changes in legislation have been instituted in attempts to affect availability of potential toxins; in the United Kingdom, for instance, paraquat was withdrawn from sale in July 2008, although occasional exposures continue as a result of residual stored product.[4] U.K. legislation limiting pack size of paracetamol (acetaminophen) in 1998 has been followed by a significant reduction in the number of deaths from paracetamol overdose.[5]

Data in the United States indicate a low mortality rate—1995 fatalities for 2.3 million episodes in 2011.[2] However, poisoning remains a major cause of death in young people.[3]

The mainstays of management include hemodynamic, respiratory, and other supportive care, prevention of further drug absorption (oral activated charcoal in specific patients), neutralization of drug toxicity (e.g., intravenous *N*-acetylcysteine after significant acetaminophen overdose or digoxin immune Fab [Digibind] for digitoxicity), and enhancement of drug elimination.

Extracorporeal therapy is one method of achieving poison removal, either by dialysis or by a nondialytic technique such as hemoperfusion. These enhanced elimination techniques are only occasionally needed, with around 2300 patients recorded as requiring extracorporeal therapy in the United States in 2011.[2] In that report the treatment was predominantly hemodialysis (HD) with only 14 patients recorded as receiving hemoperfusion, the decline of which is perhaps explained by the increasing rarity of theophylline and barbiturate overdose—historically, the main indications for this technique.

Aspects of the management of poisoning beyond those related to extracorporeal therapies are well covered through resources such as Toxbase in the United Kingdom (www.toxbase.org) and the American Association of Poison Control Centers (www.aapcc.org). Other local and regional poison information services are linked through the website of the European Association of Poisons Centres and Clinical Toxicologists (www.eapcct.org).

TREATMENT MODALITIES

Intermittent Hemodialysis and Hemofiltration

Diffusion against a steep concentration gradient, the physical process used in intermittent HD, encourages the rapid removal of the smaller solutes that are the usual agents of overdose. Clearances can be enhanced by increasing dialyzer efficiency (indicated by the K_oA, the urea mass transfer area coefficient) or membrane surface area. Larger-solute removal can be enhanced by increasing dialyzer flux when intermittent HD is used (for toxins >500 d and up to 10,000 d, e.g., desferrioxamine [deferoxamine] aminoglycosides) or by switching to hemofiltration (usually applied continuously; see later), in which the physical process of higher volume convection and larger membrane pore size can allow removal of toxins up to approximately 40,000 d.

A range of physical and biologic factors determines whether a given toxin can be eliminated by HD and whether that elimination is actually therapeutic (Box 98-1). In addition to molecular weight, other important physical characteristics relevant to dialyzability are water solubility and the degree of protein binding.

For each individual patient, it should be determined whether HD is expected to contribute significantly to total toxin removal. Dialysis will have a limited impact if the rate of drug removal is significantly faster by endogenous routes. The risks of therapy (e.g., acute transfer to a specialist center, vascular access, anticoagulation) also have to be balanced against the clinical relevance of any gain in drug elimination. If endogenous elimination is minimal—either because these routes are naturally limited or because of toxin-associated attenuation of elimination (e.g., liver or renal failure)—HD can be effective. It is generally accepted that if at least 30% can be added to total body clearance by extracorporeal treatment, its use is justified. This is not a threshold that is readily calculated at the bedside without knowledge of endogenous clearance rates and the expected contribution from exogenous therapy. The summary of product characteristics may help determine the endogenous clearance rates (at least for pharmaceuticals; available from, for instance, www.medicines.org.uk/emc/) but may not account for the impact of disease on specific endogenous routes of elimination. An estimate of the clearances of a variety of solutes of different molecular weights by a dialyzer can be obtained from its product insert. For hemofiltration (see the later discussion of continuous renal replacement therapy [CRRT]), an estimate of clearance can be provided by the ultrafiltration rate.

The efficacy of toxin removal is also influenced by its theoretical volume of distribution (V_D). Substances confined to the bloodstream

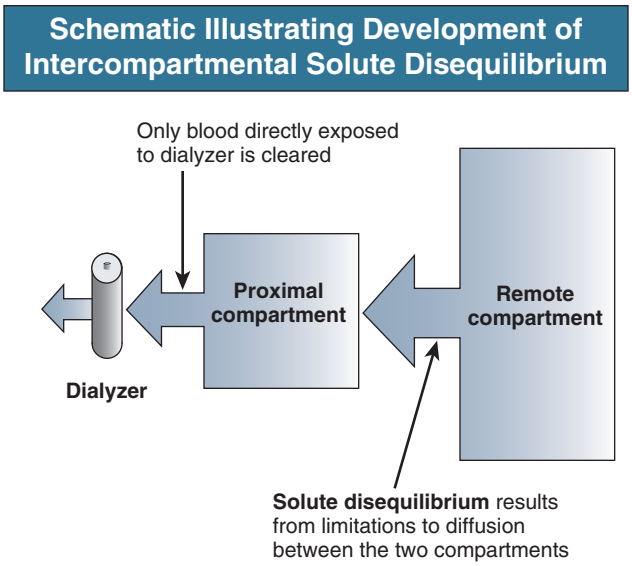

Figure 98-1 Intercompartmental solute disequilibrium. Access of dialyzer to toxin is limited by disequilibrium, which retains toxin in remote compartment.

Factors Affecting Toxin Removal by Hemodialysis

will have a low V_D (approximately 0.07 l/kg body weight); those distributed in the extracellular space, a V_D of approximately 0.2 l/kg; and those confined to total body water, approximately 0.6 l/kg. Higher distribution volumes are, however, not uncommonly found in those substances with avid tissue binding or sequestration. As V_D increases, more solute must be removed for achievement of a particular blood level. The ideal solute would therefore have a low distribution volume, which would also be a single, well-mixed compartment that was directly accessible by the dialysis process. However, as shown in Figure 98-1, solute is often distributed across at least one remote body compartment that is not directly accessible during HD. If there is any resistance to solute movement between the accessible proximal and the remote compartments, disequilibrium will develop over the course of the dialysis session, reducing the overall efficiency of toxin removal. This may be significant, as in the case of lithium, and will manifest as a large postdialysis rebound in blood levels as solute re-equilibrates from the remote compartment. A significant solute rebound to a potentially toxic level may be missed if the immediate postdialysis blood level is relied on as a measure of elimination (Fig. 98-2).

Extending the HD session beyond 4 hours can to some extent ameliorate rebound, but intermittent HD is an inherently inefficient process that depends on the solute concentration presented to the dialyzer. Most solute removal occurs at the start of dialysis. Any gains in solute removal will be disproportionately low in comparison to

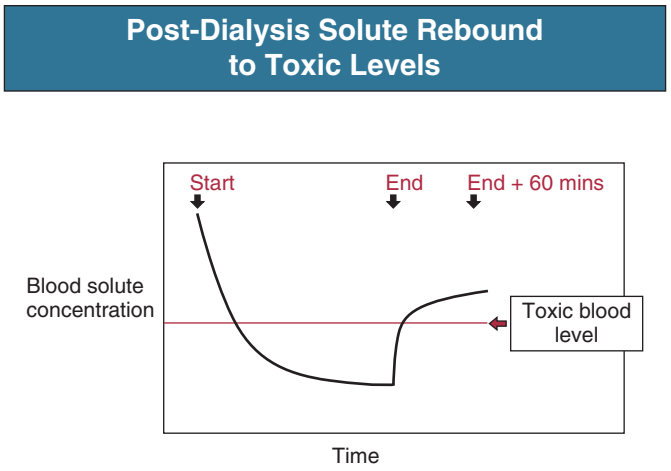

Figure 98-2 Postdialysis rebound. Falling solute concentration during dialysis with rapid postdialysis rebound to toxic levels.

the increases in dialysis time. An alternative or adjunctive solution is to increase dialysis session frequency.

Compartmentalization need not preclude HD-related toxin removal, but the closer its distribution is to a single compartment, the easier that removal becomes.

In summary, intermittent HD is usually the first-choice extracorporeal modality because of its common availability, the rapidity of toxin removal, and the low molecular weight of the common agents of poisoning. The role of other renal replacement modalities is less clear because of a lack of published data.

Peritoneal Dialysis

Peritoneal dialysis is rarely used in the treatment of poisoning because of the comparatively slow rate of clearance, the risks associated with acute peritoneal dialysis catheter insertion, and the widespread availability of extracorporeal techniques (at least in the industrialized world). It may have a role in the treatment of poisoning in children because the lower clearance may be sufficient for their smaller solute distribution volumes. There may, in addition, be technical challenges making HD less satisfactory, especially in the very young.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy may be used when intermittent HD is not immediately available or when more rapid solute removal would be compromised by significant intercompartmental disequilibrium. For small-solute clearances, continuous hemofiltration and continuous HD have near kinetic equivalence. Full saturation of dialysate effluent in continuous HD, because of its slow flow rates, gives it a small-solute concentration similar to both the ultrafiltrate from hemofiltration and plasma water as it leaves the hollow-fiber device. CRRT gives better longer-term solute clearances (over the course of several days) but does not provide the rapidity of elimination afforded by intermittent HD when minimizing toxin exposure is a high priority. Delivered small-solute clearances of CRRT can be maximized by combining techniques in the form of continuous hemodiafiltration. If it is logistically possible, an ideal combination may be initial use of intermittent HD for rapid reduction of toxin levels, with continuous therapy then being applied to ameliorate any postdialysis rebound when this is predicted. Although combining some of the advantages of both continuous and intermittent

Figure 98-3 A charcoal hemoperfusion cartridge.

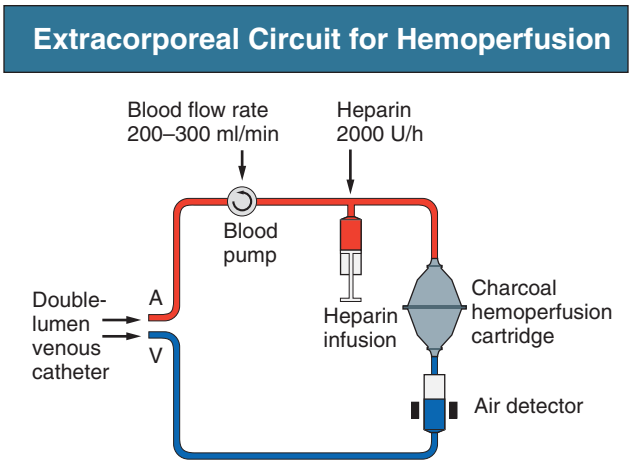

Figure 98-4 Extracorporeal circuit for hemoperfusion.

techniques, the role for hybrid modalities, such as sustained low-efficiency dialysis (SLED), requires further evaluation.

Although small-solute clearances are similar in continuous hemofiltration and continuous HD, the former should be used in preference if larger toxins (as described earlier for intermittent HD) require removal.

Renal replacement therapy is also indicated for acute kidney injury (AKI), which can result from ingestion of a variety of different agents (e.g., acetaminophen), and for other complications of poisoning such as pulmonary edema, electrolyte and acid-base disturbances, and hypothermia and hyperthermia.

Because renal replacement therapy modalities are often applied for drug elimination in the absence of any actual renal dysfunction or serious electrolyte disturbance, careful monitoring for evolving biochemical abnormalities is required. Hypokalemia can be corrected by adjusting the dialysate or replacement fluid composition and by supplementation. Hypophosphatemia can be addressed with standard supplements. At least for intermittent HD, the risk of developing a metabolic alkalosis can be attenuated by using a dialysate bicarbonate concentration at the lower end of the physiologic range, provided there is no coexistent renal impairment and no metabolic acidosis or the risk of it. Manipulation of the bicarbonate concentration of premanufactured replacement or dialysate fluid in CRRT is not practical; this is another advantage of intermittent HD in this setting because it affords flexibility of bicarbonate dialysate concentration if a severe metabolic alkalosis is present.

Hemoperfusion

The technique involves the extracorporeal circulation of blood through a hemoperfusion cartridge (Fig. 98-3) containing an adsorbent material such as activated charcoal or a resin. The charcoal sorbent particles are coated with a polymer to increase biocompatibility and reduce the risk of thrombocytopenia. Hemoperfusion removes those substances that can bind to the adsorbent material. It is effective at removing uncharged molecules through competitive binding, especially those that are significantly plasma protein bound and lipophilic. As with HD and hemofiltration, the likely proportional contribution to total toxin elimination should be considered before hemoperfusion is begun.

Other than the cartridge itself and the lack of dialysate and other replacement fluid circuits, the disposables and hardware are those used for standard intermittent HD (Fig. 98-4). Hemoperfusion is much less widely available than HD or hemofiltration but may have its principal usefulness in the removal of protein-bound drugs that are not eliminated effectively by those modalities.[6]

Standard anticoagulation protocols may be insufficient for hemoperfusion because heparin is also adsorbed. A larger unfractionated heparin initial bolus and maintenance dose (e.g., ≥2000 U/h) is usually required, with subsequent adjustments guided by regular monitoring of clotting times during the procedure. The cartridge manufacturer's instructions should be reviewed carefully, because some require specific priming with dextrose solution to prevent hypoglycemia. Other complications include hypocalcemia, charcoal embolization, leukopenia, thrombocytopenia, and adsorption of coagulation factors.

Saturation of the adsorbent material limits the duration of treatment with any individual hemoperfusion cartridge to around 3 hours, although this is usually adequate for a significant lowering of toxin blood levels. Continuous hemoperfusion can help attenuate the postsession rebound that can occur with intermittent treatment, with cartridges being changed every 4 hours.

If a toxin is equally well removed by intermittent HD and hemoperfusion, intermittent HD should be used preferentially, because it also allows fluid, electrolyte, and other metabolic control. Combined hemoperfusion-HD has also been used but only rarely, and its role is not defined.

Other Modalities

There are a few reports of the use of plasma exchange and MARS (molecular adsorbent recirculating system) in poisoning. In principle, both should be useful for those toxins that are strongly protein bound. Plasma exchange can also clear the red cell fragments and free hemoglobin that result from poisoning with sodium chlorate or other agents that can cause hemolysis.

WHEN SHOULD EXTRACORPOREAL REMOVAL BE COMMENCED?

The use of extracorporeal therapy should be considered at an early stage when it is recognized that general supportive therapy including the use of activated charcoal and administration of recognized antidotes will not be effective in removing specific drugs and toxins, particularly in the setting of AKI. The common indications for extracorporeal drug removal are shown in Table 98-1.

Principles guiding the decision to initiate extracorporeal therapy are shown in Box 98-2.

Some Poisonings for Which Extracorporeal Removal May Be Indicated

Hemodialysis	Hemofiltration	Hemoperfusion
Alcohols	Aminoglycosides	*Amanita* mushroom
Ethanol	Desferrioxamine	Barbiturate
Methanol	Sodium edetate	Carbamazepine
Ethylene glycol	Theophylline	Meprobamate
Isopropanol		Theophylline
β-Blockers		
Atenolol		
Sotalol		
Lithium		
Meprobamate		
Metformin		
Salicylates		
Theophylline		

Table 98-1 Some poisonings for which extracorporeal removal may be indicated.

Criteria for Considering Extracorporeal Therapy for a Removable Substance

- Toxic blood levels (if a threshold of toxicity can be defined)
- Serious clinical manifestations despite optimal support
- Delayed action possible (e.g., ethylene glycol, methanol, paraquat)
- Metabolic effects (e.g., acidosis)
- Endogenous routes of clearance, impaired (e.g., liver or renal failure)

Box 98-2 Criteria for considering extracorporeal therapy for poisoning.

EXTRACORPOREAL THERAPY FOR SPECIFIC DRUGS AND POISONS

Alcohols

Ethylene glycol and methanol can be found in antifreeze, de-icing solutions, and windscreen cleaning fluid. The ingestion of as little as 1 g of either methanol or ethylene glycol per kilogram is considered as potentially lethal and results in significant toxicity. Poisoning should be suspected in any patient presenting with nausea, vomiting, abdominal pain, impaired consciousness, severe metabolic acidosis, and AKI. Without prompt treatment there will be resulting optic nerve damage, convulsions, coma, and ultimately death. The urine should be examined for the presence of needle shaped crystals of calcium oxalate monohydrate which are pathognomonic for ethylene glycol toxicity. The toxicity results from metabolism of ethylene glycol and methanol by alcohol dehydrogenase to the toxic metabolites glycolic acid and formic acid respectively. Formic acid causes injury to the basal ganglia and the retina, resulting in blindness. Ethylene glycol is metabolized to glycolic acid and oxalate, resulting in renal tubular injury and obstruction. The associated severe acidosis facilitates the ability of the toxic metabolites to penetrate the cells and cause further injury. Poisoning with ethylene glycol or methanol results in a raised anion gap acidosis and an elevated plasma osmolal gap. However, the raised osmolal gap is not pathognomonic and can also occur with overdoses of excessive alcohol, isopropanol, and diabetic ketoacidosis.

Early recognition of ethylene glycol methanol poisoning is essential, allowing institution of treatment to inhibit hepatic alcohol dehydrogenase with ethanol or fomepizole. Fomepizole has now replaced ethanol as first-line therapy[7,8]; it is safe with minimal side effects, and although it is expensive, this can be offset when compared with the increased cost of HD and intensive care unit admission if fomepizole is not used.

Fomepizole should be prescribed if there is a clear history of ethylene glycol and/or methanol ingestion with an osmolal gap of greater than 10 (indicating significant toxicity) or if the ethylene glycol–methanol blood level is over 20 mg/dl. Fomepizole is administered as a loading dose of 15 mg/kg intravenously. This is followed by 10 mg/kg every 12 hours for four doses and then 15 mg/kg every 12 hours until the metabolic acidosis has resolved and the serum concentration of ethylene glycol and methanol is below 20 mg/dl, or below 10 mg/dl in the presence of end organ damage. If the blood pH is less than 7.3, an infusion of sodium bicarbonate should be commenced at 1 to 2 mEq/kg to maintain the pH above 7.35. Patients who have ingested methanol should also receive folinic acid 50 mg intravenously every 6 hours to enhance the metabolism of formic acid. The administration of thiamine 100 mg intravenously or pyridoxine 50 mg intravenously should be considered in patients with poor nutritional status who have sustained an overdose of ethylene glycol. If fomepizole is not available, intravenous 10% ethanol should be administered as a loading dose of 800 mg/kg followed by an infusion of 80 to 160 mg/kg/h to achieve a serum ethanol concentration of about 1 to 1.5 g/l. Ethanol should be administered until no ethylene glycol or methanol is detectable in the blood.

Immediate HD is recommended if ingestion of ethylene glycol or methanol is confirmed with serum concentration above 50 mg/dL in the setting of severe metabolic acidosis or the presence of end organ damage such as AKI or visual disturbance. It is important to recognize that fomepizole is removed by HD. Therefore if a loading dose of fomepizole has already been administered, a continuous infusion of 1 to 1.5 mg/kg/h should be prescribed for the duration of the HD. Similarly, if ethanol has been used as a competitive inhibitor of alcohol dehydrogenase, its dose will have to be doubled because of its removal by HD.

For optimal clearance the dialyzer should have a large surface area (>1.5 m^2), and the blood flow rate should be greater than 300 ml/min. Bicarbonate buffer should be used and serum concentrations of ethylene glycol and methanol should be measured 2 hours after cessation of treatment to take account of rebound. HD should continue until the pH has normalized and the concentration of ethylene glycol or methanol is below 25 mg/dl.

Patients who have ingested large quantities of ethylene glycol and methanol may require further HD. Continuous extracorporeal treatment is less effective in removing ethylene glycol and methanol but may be used if intermittent HD is not available.

β-Blockers

Symptomatic β-blocker overdose will present within 2 hours of ingestion in the majority of patients, with bradycardia and hypotension. Clinical presentation may also include changes in mental status, seizures, bronchospasm, hypoglycemia and cardiogenic shock in severe overdoses. An increased risk of severe toxicity occurs in patients who have co-ingested other drugs that act on the cardiovascular system. Bradycardia can be treated with intravenous atropine at 0.5 to 1 mg, and bronchospasm can be treated initially with high-dose nebulized salbutamol or albuterol. Intravenous fluids (crystalloid) should be administered to treat hypotension. Symptomatic hypoglycemia requires intravenous dextrose. Activated charcoal should be administered orally to all patients presenting within 1 to 2 hours of β-blocker overdose.

Extracorporeal removal of β-blockers is rarely required and only in those patients who have not improved despite maximal medical therapy. Extracorporeal removal is effective only in hydrophilic, minimally protein-bound drugs such as atenolol, sotalol, nadolol, and acebutolol. Propranolol, timolol, and metoprolol are not removed. Intermittent HD is recommended in hemodynamically stable patients. Continuous venovenous hemodialysis (CVVHD) or continuous venovenous hemodiafiltration (CVVHDF) may be considered in patients who are hemodynamically unstable. There are very few data regarding the effectiveness of β-blocker removal using continuous venovenous hemofiltration (CVVH).

Lithium

Patients with severe lithium poisoning may present with arrhythmias, hypotension, confusion, coma, or seizures. HD is recommended if the serum lithium concentration is above 4 mEq/l or above 2.5 mEq/l in a patient with central nervous system manifestations. Lithium (molecular weight 74 d) is removed easily by HD because of its low molecular weight and negligible protein binding. The clearance of lithium by HD is superior to that achieved by the kidneys, which is limited by significant proximal tubule reabsorption of lithium. Because lithium equilibrates relatively slowly between the extracellular and intracellular compartments, a rebound increase in serum levels of lithium follow HD.[9] Therefore, extended[10] or frequent HD treatment may be needed to minimize the impact of disequilibrium. Serum lithium levels should be checked 6 hours after completion of treatment to guide further therapy. Continuous modalities including CVVHD and CVVH may be advantageous and have been used successfully.[11]

Metformin

Metformin (molecular weight 166 d) is a biguanide hypoglycemic drug used to treat patients with diabetes mellitus. Metformin acts by enhancing the suppression of gluconeogenesis by insulin, reducing glucagon-stimulated gluconeogenesis and increasing the uptake of glucose by muscle and adipose cells. Patients who have taken an overdose of metformin may present with tachypnea, nausea, abdominal pain, tachycardia, hypotension, and, in the setting of AKI, a severe lactic acidosis. Metformin is normally excreted unmetabolized from the kidneys and therefore accumulates if there is reduced kidney function. There is lactic acidosis because metformin inhibits hepatic gluconeogenesis from lactate, and promotes the conversion of glucose to lactate in the small intestine. Medical management will involve the intravenous administration of sodium bicarbonate. In patients who are unresponsive to medical management or who also present with AKI, extracorporeal therapy will be necessary to correct the acidosis. Intermittent HD is effective, and more recently there have been reports of continuous extracorporeal therapy including CVVH being successful.[12]

Salicylates

The clinical manifestations of salicylate overdose include fever, sweating, tinnitus, epigastric pain, nausea, vomiting, diarrhea, vertigo, and blurring of vision. In severe overdoses clinical presentation may progress to depression of mental status, noncardiogenic pulmonary edema, and death. Salicylate intoxication initially results in activation of the respiratory center with hyperventilation and a respiratory alkalosis. This is then followed by a metabolic acidosis caused by the accumulation of lactic acid and ketoacids. Therefore the patient may present with either a respiratory alkalosis or a mixed respiratory alkalosis–metabolic acidosis. Diagnosis is based on the presenting history and clinical examination and confirmed with serum salicylate levels. Moderate toxicity is occurs with salicylate levels greater than 50 mg/dl. Ingestion of enteric-coated salicylate preparations may delay peak levels for up to 36 hours.

Gastric lavage should be attempted up to 12 hours after ingestion if the airway is protected, and activated charcoal should be administered orally. Hypoglycemia should be treated with intravenous dextrose.

Increased salicylate tissue penetration and toxicity can occur with only small decreases in the blood pH as a result of increased concentration of nonionized salicylate. Intravenous sodium bicarbonate should be given to decrease tissue penetration and facilitate the excretion of salicylate through the kidneys. Sodium bicarbonate can be administered as an initial bolus of 1 to 2 mEq of sodium bicarbonate per kilogram and then as an infusion of 100 to 150 mEq of sodium bicarbonate in 1 L of 5% dextrose titrated to maintain a urinary pH above 7.5. Sodium bicarbonate infusion should not be used if the patient has oliguric AKI, pulmonary edema, or cerebral edema because of the risk of precipitating further volume overload and end organ injury.

Extracorporeal therapy is indicated in patients who do not respond to the medical management just described. It is also indicated in patients who have AKI (preventing salicylate excretion), pulmonary edema, or altered mental status or in whom the serum salicylate concentration is greater than 100 mg/dl. Intermittent HD has the advantage over hemoperfusion because of its more rapid correction of associated electrolyte abnormalities and acidemia. There are few data on the use of CVVH for salicylate poisoning.

Theophylline

The clinical presentation of theophylline overdose includes nausea, vomiting, diarrhea, gastrointestinal hemorrhage, hypokalemia, seizures, arrhythmias, and hypotension. Overdose may be acute or chronic in nature. Indications for extracorporeal removal of theophylline after acute intoxication include a serum level above 80 mg/l, or a serum level above 60 mg/l in patients older than 65 years, or a history of epilepsy, recurrent seizure activity, liver disease, cardiac failure, or ischemic heart disease. Indications for extracorporeal removal after chronic intoxication include a theophylline level higher than 40 mg/l in a patient older than 65 years or in any patient who has had seizure activity or an arrhythmia. Theophylline is readily cleared by either HD or hemoperfusion as a result of its low volume of distribution and minimal protein binding.[13] High-efficiency HD is more effective in removing theophylline than hemoperfusion and is associated with fewer side effects. CVVH can be used but requires a more sustained period of treatment.

Valproate

Valproate (molecular weight 144 d) overdose may present with clinical features that include mild confusion, lethargy, nausea, vomiting, tachycardia, hypotension, metabolic acidosis, and electrolyte disturbances (hyponatremia and hypocalcemia). Extracorporeal therapy is rarely indicated for the removal of valproate except in patients with refractory metabolic acidosis or hemodynamic instability. Valproate is poorly cleared despite a low molecular weight and a low volume of distribution as a result of its high degree of protein binding. However, at higher serum levels above 100 mg/dl, the valproate protein binding sites become saturated, resulting in unbound free drug. HD has the advantage over hemoperfusion because it not only readily clears the unbound drug but also reverses associated

metabolic abnormalities.[14] Despite a number of case reports detailing the use of extracorporeal removal of valproate, there is no clear-cut evidence that it improves clinical outcomes.

CHAPTER 99

Plasma Exchange

Jeremy Levy

The place of plasma exchange (plasmapheresis) in the management of renal disease has become clearer in the last 10 years, with increasing numbers of controlled studies comparing therapeutic plasma exchange with other treatments. Despite this, in many renal diseases the quality of published data still remains poor, and the precise role for plasma exchange unclear. Plasma exchange came into widespread clinical use after early reports of beneficial effects in Goodpasture disease in the mid-1970s. It is used to remove many large-molecular-weight substances from plasma, including pathogenic antibodies, cryoglobulins, and lipoproteins. Newer techniques have also been developed to allow more selective removal of plasma components, such as double-filtration plasma exchange, cryofiltration, and immunoadsorption with or without immobilized ligands.

TECHNIQUES

Plasma exchange can be carried out either by centrifugal cell separators or, more commonly in renal units, with hollow-fiber plasma filters and standard hemodialysis equipment (Figs. 99-1 and 99-2). Centrifugal devices allow withdrawal of plasma from a bowl with either synchronous or intermittent return of blood cells to the patient.[1] There is no upper limit to the molecular weight of proteins removed by this method. The bowls and circuits are single use and disposable and require relatively low blood flow rates (90 to 150 ml/min). Platelet loss can be a particular problem with centrifugal devices, and platelet counts can decrease by as much as 50%. Membrane plasma filtration uses highly permeable hollow fibers with membrane pores 0.2 to 0.5 µm. Plasma readily passes through the membrane while the cells are simultaneously returned to the patient. All immunoglobulins will cross the membrane (IgG more efficiently than IgM); however, some large immune complexes and cryoglobulins may not be adequately cleared, although many membranes allow for clearance of molecules up to 3 million daltons. There is no loss of platelets, but hemolysis can occur if transmembrane pressures are too high (a rare complication). Blood flow rates required are higher (100 to 300 ml/min); there is no increase in rate of plasma filtration at higher blood flows, but an increased risk of hemolysis. Membranes used in plasma filters are polysulfone, polypropylene, cellulose diacetate, polymethylmethacrylate, or polyacrylonitrile.[1] It has been suggested that the adsorptive properties of the membrane for cytokines and other biomolecules may account for some of the beneficial effects of plasma filtration. There have been occasional reports of mild adverse reactions in patients taking angiotensin-converting enzyme (ACE) inhibitors when plasma is filtered with ethylene vinyl alcohol or acrylic copolymer membranes. Reuse of plasma filters is not advised, but performance data do not indicate a major loss of function during routine plasma exchange. For patients with severe renal failure, sequential hemodialysis and plasma exchange can easily be performed with plasmafiltration.

Vascular access is usually achieved using standard central venous catheters, but if a patient already has an arteriovenous (AV) fistula, then of course this can be used. However, sometimes it is also possible to perform plasma exchange using peripheral access through large-bore, short, intravenous cannulas, placed in the antecubital fossa, especially with centrifugal devices because the blood flow rates required are low. Single-needle access using an AV fistula is also relatively easy to accommodate, especially for centrifugal plasma exchange, in which the blood removal and return can be asynchronous, but also for membrane filtration. Anticoagulation is almost always needed and must be carefully managed in patients with a bleeding risk, for example, those with thrombotic microangiopathy (TMA), recent or ongoing pulmonary hemorrhage, or a recent renal biopsy. In general, citrate is used for centrifugal plasma exchange, and heparin for membrane plasma filtration; however, citrate has particular advantages in patients at higher bleeding risk in view of its lack of systemic anticoagulant actions.[1] When heparin is used, higher doses may be needed than in hemodialysis as a result of increased losses during the procedure (heparin is protein bound). Bolus doses of unfractionated heparin of 2000 to 5000 U are given initially, and then 500 to 2000 U/hr. Anticoagulant is administered prefilter.

Both methods of plasma exchange require large volumes of colloid replacement. A single plasma volume exchange will lower plasma macromolecule levels by approximately 60%, and five exchanges over 5 to 10 days will clear 90% of the total body immunoglobulin (Fig. 99-3).[1,2] For most patients, this is achieved by removing 50 ml of plasma per kilogram of body weight at each procedure (approximately 4 liters for a 75-kg person). Daily plasma exchange is likely to be most effective in rapidly depleting total body load in view of redistribution of immunoglobulins from the extravascular compartments, but there is no good evidence that intensity of exchanges has a major effect on outcomes except in patients with hemolytic uremic syndrome (HUS) with poor prognostic markers (see later discussion). Indeed, alternate-day exchanges are of proven efficacy in antineutrophil cytoplasmic antibody (ANCA)–associated diseases. Replacement with crystalloid is contraindicated because of the need to maintain colloid oncotic pressure. Synthetic gelatin–based plasma expanders or hydroxyethyl starch (Hespan) can be used as part of a replacement regimen but have been reported to cause a coagulopathy in patients with sepsis, and have a shorter half-life than human albumin, which is the mainstay replacement fluid. The major disadvantage of albumin solutions is the lack of clotting factors, with the potential development of depletion coagulopathy after plasma exchange. Fresh-frozen plasma (FFP) should be given, usually in addition to human albumin solution, in patients at particular risk of bleeding. If partial replacement is with FFP this should be given late during the exchange so that the constituents are not removed by the ongoing plasma exchange. However, almost all the serious complications of plasma exchange (hypotension,

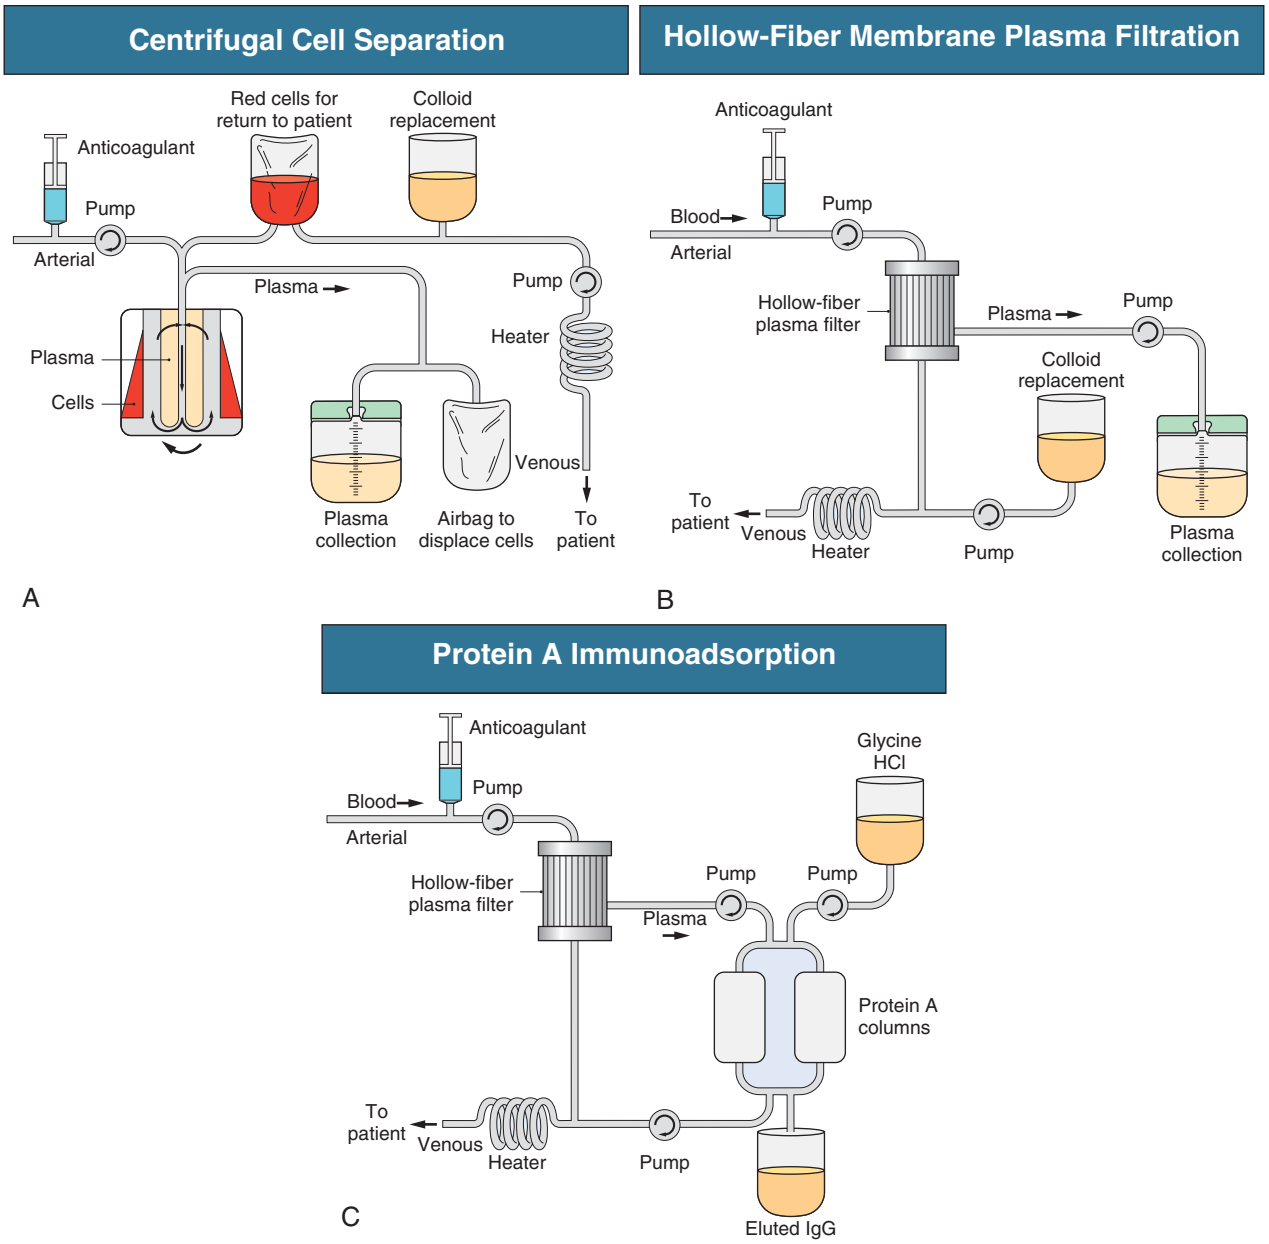

Figure 99-1 Plasma exchange and immunoadsorption techniques. Techniques include centrifugal cell separation **(A),** hollow-fiber membrane plasma filtration **(B),** and protein A immunoadsorption **(C).**

anaphylaxis, citrate-induced paresthesia, urticaria) have been reported in patients receiving FFP rather than albumin (see later discussion).[1,3] Both human products carry a tiny risk of transmission of infectious diseases, especially viral. Standard regimens for plasma exchange are summarized in Table 99-1. Human albumin solution (4% to 5%) should be used for all exchanges except in thrombotic microangiopathies (in which plasma should provide the total exchange), and FFP should form part of the exchange when bleeding risk is high (ongoing pulmonary hemorrhage or within 48 hours of biopsy or surgery). If fibrinogen levels decrease to below 1.25 to 1.5 g/l or prothrombin time is increased 2 to 3 seconds above normal, then FFP should be administered.

Double-filtration plasma exchange (or cascade filtration) uses membrane filtration to separate cells from plasma, and then a secondary plasma filtration (pore size 0.01 to 0.03 μm) to remove plasma solutes based on molecular size. Most albumin is therefore returned to the patient, together with lower-molecular-weight proteins, reducing the need for replacement fluids. Cryofiltration uses a similar principle but exposes the filtrate to 4° C during the procedure, with the aim of precipitating cryoproteins. These techniques are not widely available.

Selective and specific immunoadsorption techniques are increasingly available. Protein A immunoadsorption has been used to remove immunoglobulin alone from plasma, without the need for replacement fluids and without depletion of clotting factors and complement (see Fig. 99-1, *C*). Protein A selectively binds the Fc domains of immunoglobulin molecules, and the immunoadsorption columns can be repeatedly regenerated. Columns have been used for 1 year for a single patient on up to 30 occasions; however, the repeated acid stripping during regeneration does reduce the efficacy of antibody binding. This technique has been used to treat conditions in which autoantibodies are thought to play a key pathogenic role

Regimens for Plasma Exchange in Renal Disease

Indication	Anti–Glomerular Basement Membrane Antibody (anti-GBM) Disease	Small-Vessel Vasculitis	Cryoglobulinemia	Recurrent FSGS After Transplantation	HUS/TTP
Duration of treatment	Daily, at least 14 days until anti-GBM antibodies 20% of baseline	Daily, 7-10 days depending on clinical response	At least 7-10 days or until clinical response	Daily, at least 10 days initially, then continuing less frequently, often for months	Daily for 7-10 days or until platelet count 80-100 $\times 10^9$/l (sometimes needed twice daily)
Exchange volume	50 ml/kg each treatment	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease
Replacement fluid	Human albumin 5% (unless bleeding risk)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	Fresh-frozen plasma (FFP) or cryo-poor FFP
Additions to replacement fluid	20 ml 10% calcium gluconate (occasionally more), 3 ml 15% KCl if not dialysis dependent, heparin 5000-10,000 U (unless citrate anticoagulation)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease (may need more calcium because of increased volume of FFP-containing citrate)
Immunosuppression	See Chapter 24	See Chapter 25	See Chapter 21	See Chapter 29	See Chapter 29
Variations	FFP 5-8 ml/kg as part of exchange volume if hemorrhage risk (renal biopsy in last 48 hr, lung hemorrhage, platelets <40 $\times 10^9$/l, fibrinogen <1.5 g/l); immunoadsorption may be as effective	As for anti-GBM disease Immunoadsorption may be as effective	As for anti-GBM disease	As for anti-GBM disease; may need to include replacement immunoglobulins if continuing long term; immunoadsorption may be as effective	

Table 99-1 **Practical regimens for plasma exchange in renal disease.** *FSGS,* Focal segmental glomerulosclerosis; *HCV,* hepatitis C virus; *HUS,* hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura.

and usually in place of plasma exchange, such as in Goodpasture disease, rheumatoid arthritis, systemic lupus, or systemic vasculitis, and to remove anti-ABO or anti–human leukocyte antigen (HLA) antibodies in highly sensitized transplant recipients. In general, the reported efficacy has been equal to that of plasma exchange, although if used long term, immunoadsorption can be much more cost-effective in single patients because there is no requirement for replacement albumin or plasma. Specific ligands have also been immobilized onto columns for more specific removal of potentially pathogenic serum factors; ligands used include anti–human IgG, C1q, phenylalanine, hydrophobic amino acids, acetylcholine receptor, and β-adrenoreceptor peptides, and blood group–related oligosaccharides. Immunoadsorption of all varieties is not widely available because the initial column costs are high and few centers have much clinical experience. Costs of all other plasma exchange modalities are dominated by the costs of replacement albumin and plasma; equipment costs do not vary much among modalities, and all require skilled and trained nursing staff. Plasma filtration requires minimal extra support or training for dialysis nurses because the equipment is very similar to normal hemodialysis machines.

COMPLICATIONS

The complication rate of plasma exchange is not high.[3] The Swedish registry reported no fatalities during 20,485 procedures, and an overall adverse incidence rate of only 4.3% of all exchanges (0.9% for severe adverse events) of which 27% were paresthesias, 19% transient hypotension, 13% urticaria, and 8% nausea.[4] The Canadian apheresis registry has collected data on 144,432 apheresis procedures since 1981 and reported adverse events occurring in 12% of procedures (mostly minor), and overall in 40% of patients. Severe events occurred in only 0.4% of procedures. Three deaths were probably related directly to the procedure: one from a transfusion-related acute lung injury and two from complications from central venous catheters.[5] An overall complication rate of 1.4% has been reported in more than 15,000 treatments in patients receiving albumin, and 20% in patients receiving FFP.[1,3,5,6] Plasma exchange by centrifugation had a lower risk for adverse events than by filtration.

Other complications directly attributable to plasma exchange include citrate-induced hypocalcemia (presenting with perioral tingling and paresthesias) and citrate-induced metabolic alkalosis. Citrate is usually present in FFP (up to 14% by volume) or is administered in the extracorporeal circuit as an anticoagulant; it binds free calcium in plasma. Symptomatic hypocalcemia can be averted by infusing 10 to 20 ml of 10% calcium gluconate during each plasma exchange. Alkalosis is rare and is caused by metabolism of citrate to bicarbonate and failure to excrete the latter in patients with renal impairment.

Plasma exchange predictably increases the risk of bleeding as a result of depletion of coagulation factors in patients receiving albumin as sole replacement colloid. Prothrombin time is increased by 30%, and partial thromboplastin time by 100% after a single plasma volume exchange. Patients at risk of bleeding (pulmonary hemorrhage, postbiopsy, postoperative) should receive FFP (300 to 600 ml) with replacement fluids. Dilutional hypokalemia is avoided by adding potassium to the replacement albumin. An increased incidence of infection secondary to hypogammaglobulinemia has not been confirmed in recent series.[3-6] Sepsis related to intravenous access is the most common infectious complication of plasma exchange. Hypotension can occur for a variety of reasons related to extracorporeal circuits, sepsis, and allergic reactions, but also if saline is used for exchanges with a concomitant reduction in serum oncotic pressure during the procedure. Cascade filtration can lead to hemolysis (in up to 20% patients) but rarely necessitates transfusion.

MECHANISMS OF ACTION

Plasma exchange removes large-molecular-weight substances from the plasma, including antibodies, complement components, immune complexes, endotoxin, lipoproteins, and von Willebrand factor (vWF) multimers. The pathogenicity of autoantibodies in anti–glomerular basement membrane (anti-GBM) disease (Goodpasture disease) provided the impetus for development of plasma exchange therapy, but it is now clear that antibodies, although necessary, are not alone sufficient to cause the necrotizing glomerulonephritis (GN) in that disease. Therefore, plasma exchange may well have benefits in addition to clearance of autoantibodies. The clearance of antibodies from patients is variable and depends on a number of factors, including the rate of equilibration of macromolecules between the intravascular and extravascular compartments. IgM antibodies are cleared more effectively by centrifugal plasma exchange than other classes of immunoglobulin because they are retained in the vascular compartment almost wholly. A rebound increase in antibody production will occur unless there is concomitant immunosuppression to prevent resynthesis.

Plasma exchange has also been shown to remove immune complexes, which may have clinical significance in cryoglobulinemia and systemic lupus, and fibrinogen and complement components. There is no good evidence that removal of cytokines has any clinical significance. Plasma exchange reduces plasma viscosity, with consequent improved blood flow in the microvasculature.

INDICATIONS FOR PLASMA EXCHANGE

Evidence to support specific indications for plasma exchange is variable in quality. Direct comparison between randomized controlled trials can be unsatisfactory because of variations in dose and frequency of plasma exchange and in immunosuppressive and other adjunctive therapy. The American Society for Apheresis (ASFA) reviewed all indications for plasma exchange in 2010 and summarized available trial data.[7,8] In this chapter, evidence from available randomized trials is discussed alongside observational data. The indications are summarized in Tables 99-2 and 99-3.

Anti–Glomerular Basement Membrane Antibody Disease (Goodpasture Disease)

Plasma exchange removes anti-GBM antibodies very effectively. Most patients can be depleted of pathogenic antibodies after 7 to 10 plasma volume exchanges if further antibody synthesis is inhibited by the concurrent use of cyclophosphamide and corticosteroids. Before the introduction of this therapy, the mortality from Goodpasture disease was higher than 90%, and only 11% of patients who were not dialysis dependent at presentation survived with preserved renal function. The use of plasma exchange improved the outcome considerably: 70% to 90% of patients now survive. However, only 50% of survivors retain independent renal function, and no more than 10% of those who are dialysis dependent at presentation. There has been only one small controlled trial of plasma exchange in the treatment of Goodpasture disease, which used a low intensity of plasma exchange.[7,9] A total of 17 patients were randomized to receive corticosteroids and cyclophosphamide, with or without plasma exchange. Only two of the eight who received plasma exchange developed

Conditions for Which There Is Strong Evidence for the Benefit of Plasma Exchange					
Indication	**Randomized Controlled Trials (No. of Patients)**	**Controlled Trials (No. of Patients)**	**Case Series (No. of Patients)**	**Replacement Fluid**	**Comments**
ANCA-associated systemic vasculitis	8 (300)	1 (26)	22 (347)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Proven of benefit only in dialysis-dependent patients. Should consider daily exchanges in fulminant cases or with pulmonary hemorrhage.
Anti–glomerular basement membrane antibody disease	1 (17)	0	17 (430)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Minimum course 14 days to remove antibodies effectively. Especially beneficial in nonoliguric patients pre-dialysis. Patients with creatinine >5.5 mg/dl (500 μmol/l) unlikely to benefit.
Cryoglobulinemia	0 (1 using immunoadsorption; 17 patients)	0	18 (195)	Albumin	Long-term maintenance treatment needed in some patients. Ensure blood warmer on return lines or warm replacement fluids.
Thrombotic thrombocytopenic purpura	7 (301)	2 (133)	17 (915)	Plasma or cryo-poor plasma	Daily. Often with corticosteroids. The only treatment that has improved mortality.
ABO-incompatible kidney transplantation	0	0	21 (>700)	Albumin ± plasma (compatible with donor and recipient or AB)	Used pretransplant to reduce titers of antibodies and often continued for a few days after surgery to allow successful transplantation
Antibody-mediated kidney transplant rejection	3 (61)	8 (342)	35 (499)	Albumin	Daily or alternate day. Significantly better evidence for benefit has emerged in the last 15 years.
HLA desensitization for transplantation (in highly sensitized patients)	0	4 (240)	28 (436)	Albumin	Always in combination with immunosuppression and continued until cross-match negative. Usually five plasma exchanges are needed to reduce Ab levels sufficiently.

Table 99-2 Conditions for which there is strong evidence for the benefit of plasma exchange. *ANCA,* Antineutrophil cytoplasmic antibody; *HLA,* human leukocyte antigen.

Conditions for Which There Is Some Evidence for the Benefit of Plasma Exchange					
Indication	**Randomized Controlled Trial (No. of Patients)**	**Controlled Trials (No. of Patients)**	**Case Series (No. of Patients)**	**Replacement Fluid**	**Comments**
Catastrophic antiphospholipid antibody syndrome	0	0	6 (60)	Plasma	Should be done daily. Combination of plasma exchange or IVIG, heparin, and corticosteroids (from registry data) gives best outcomes.
Recurrent FSGS after transplantation	0	2 (19)	43 (117)	Albumin	Often in combination with cyclophosphamide or rituximab. May need long-term maintenance treatment.
Atypical hemolytic uremic syndrome	0	0	8 (50)	Plasma or cryo-poor plasma	Daily plasma exchange initially. Eculizumab likely to reduce the use of long-term plasma exchange.
Myeloma	5 (182)	0	6 (105)	Albumin	Daily or alternate day for 7-10 exchanges. Despite negative randomized trial in 2005, plasma exchange should be considered if high light-chain load, severe renal failure, and oliguria persist despite conservative management.
Rapidly progressive glomerulonephritis (may include patients with ANCA-associated disease in older literature)	7 (196)	0	21 (295)	Albumin	No good evidence for benefit in immune complex disease of any cause.
Scleroderma	0	3 (75)	6 (60)	Albumin	No good evidence for benefit, but some patients have reported improvement with therapeutic trial of plasma exchange.
Systemic lupus (not nephritis)	1 (20)	1 (4)	14 (128)	Albumin	For cerebritis, lupus-associated TTP, severe hemolysis, or pulmonary hemorrhage.

Table 99-3 Conditions for which there is some evidence for the benefit of plasma exchange. *aHUS,* Atypical hemolytic uremic syndrome; *FSGS,* focal segmental glomerulosclerosis; *IVIG,* intravenous immunoglobulin.

end-stage renal disease (ESRD) compared with six of the nine who received drugs alone.

Long-term data from 71 patients with Goodpasture disease confirmed the benefit of a treatment regimen including plasma exchange because most patients with mild to moderate renal failure retained independent renal function over 10 to 25 years,[10] and renal recovery was possible even in some of those with the most severe renal disease. Combining all the available published data for patients with Goodpasture disease, 76% of patients presenting with serum creatinine below 5.5 to 6.8 mg/dl (500 to 600 µmol/l) will retain renal function, in contrast to 8% of those who are dialysis dependent at presentation.

Recommendation

All patients presenting predialysis should receive intensive plasma exchange with daily 4-liter exchanges initially for 14 days (regimen shown in Table 99-2). For dialysis-dependent patients, we recommend plasma exchange with immunosuppression only for those who have biopsy or clinical evidence of recent-onset disease. Pulmonary hemorrhage is an independent indication for plasma exchange. Treatment of Goodpasture disease is discussed further in Chapter 24.

Small-Vessel Vasculitis

The majority of patients with rapidly progressive glomerulonephritis (RPGN), other than anti-GBM disease, have small-vessel vasculitis with ANCA detectable in their serum, and there is increasing evidence that these autoantibodies are pathogenic. Plasma exchange was initially introduced in such patients because of the similarity of the histologic changes to those seen in Goodpasture disease, and the supposition that immune complexes may be instrumental in disease pathogenesis. Several trials of plasma exchange in non–anti-GBM RPGN have been reported.[7,11] Most of the early trials included patients with a variety of diseases, used a low intensity of plasma exchange, and often excluded those with oligoanuria. These trials showed no overall benefit of plasma exchange in addition to conventional immunosuppression; however, those patients with the most severe disease did seem to benefit. Combining the results of the controlled trials, 31 of 42 (74%) dialysis-dependent patients treated with plasma exchange recovered renal function compared with only 8 of 25 (32%) treated with drugs alone. The most recent randomized, controlled trial (MEPEX Methylprednisolone or Plasma Exchange in severe ANCA-associated vasculitis) randomized 137 patients with ANCA-associated systemic vasculitis and serum creatinine above 5.5 mg/dl (500 µmol/l) to plasma exchange or intravenous methylprednisolone in addition to oral corticosteroids and cyclophosphamide.[11] Sixty-nine percent of patients recovered renal function when treated with plasma exchange compared with 49% of those receiving intravenous methylprednisolone, although this difference was not maintained at 3 years. An ongoing trial is examining the possible benefit of plasma exchange in patients with less severe ANCA associated vasculitis (the PEXIVAS [Plasma Exchange and Glucocorticoid Dosing in the Treatment of Anti-Neutrophil Cytoplasm Antibody-Associated Vasculitis] trial). Patients with both ANCA and anti-GBM antibodies (so-called double-positive patients) and RPGN do not seem to respond well to plasma exchange and rarely, if ever, recover renal function.[12]

Recommendation

We perform plasma exchange in patients with small-vessel vasculitis who present with severe renal failure (serum creatinine >5.5 mg/dl [approximately 500 µmol/l] or dialysis dependent) or pulmonary hemorrhage. The regimen is shown in Table 99-2.

Other Crescentic Glomerulonephritis

Crescent formation is a common histologic finding in a number of other patterns of GN, including postinfectious GN, GN associated with infective endocarditis, IgA nephropathy, membranoproliferative glomerulonephritis (MPGN), and membranous nephropathy. Such patients were often included in in studies of treatment of RPGN, and plasma exchange has been used in the treatment of a number of these conditions. Over 400 patients with such diseases have been treated with plasma exchange with no good evidence for any benefit in crescentic GN not caused by anti-GBM disease or vasculitis.[7,8] In crescentic IgA nephropathy, there are anecdotal reports of short-term benefit in patients with severe renal impairment, but longer-term follow-up has proved disappointing.

Recommendation

We reserve plasma exchange in IgA nephropathy and other GN for patients with rapidly deteriorating renal function and extensive fresh crescents in the biopsy specimen.

Focal Segmental Glomerulosclerosis

Plasma exchange and protein A immunoadsorption have been used to treat patients with primary focal segmental glomerulosclerosis (FSGS) or recurrent disease after transplantation. The results have been less good in primary disease, as less than 40% of patients achieve either partial or complete remission,[7,8,13] and we do not recommend plasma exchange in this setting. Plasma exchange for recurrent disease is discussed later and in Chapter 108.

Thrombotic Microangiopathies

In both HUS and thrombotic thrombocytopenic purpura (TTP), endothelial activation leads to TMA, but through distinct mechanisms. There are no randomized controlled trials.

Infection-Associated Hemolytic Uremic Syndrome

Infections leading to HUS cause diarrhea, most commonly Shiga toxins (Stx-associated HUS). The prognosis is generally good, especially in childhood. Most children will recover fully with supportive care and management of fluid and electrolyte imbalance and hypertension. Two controlled trials of plasma infusion (at least 10 ml/kg daily) in childhood HUS complicated by dialysis-dependent renal failure showed no clinical benefit (as determined by hypertension, renal dysfunction, and proteinuria) in either short- or medium-term follow-up.[14] There has been no study of plasma exchange in childhood Stx-associated HUS. Plasma exchange and infusion have not been subjected to any controlled trials in adult Stx-associated HUS, but uncontrolled observations suggest possible benefit.[7,15] The 2011 outbreak of enterohemorrhagic and Stx-producing *Escherichia coli* O104:H4 in Europe led to 855 confirmed cases of HUS, but despite severe illness in many patients a retrospective analysis of 491 treated patients did not support any major benefit of plasma exchange in addition to intensive supportive care.[16]

Thrombotic Thrombocytopenic Purpura

Patients with TTP usually have a defective vWF cleaving protease (ADAMTS13), an enzyme that normally degrades large vWF multimers, either because of an inherited deficiency or autoantibodies directed against the protease. Accumulation of vWF multimers leads to systemic platelet activation under conditions of high shear stress (the microcirculation) and thrombosis. The rationale for plasma infusion and plasma exchange in TTP is therefore to replenish vWF cleaving protease, to remove antibodies against it, and to remove the

large vWF multimers from circulation. There are well-designed randomized controlled trials in the treatment of TTP.

The first prospective, controlled trial compared plasma infusion with plasma exchange (1 to 1.5 plasma volumes at least seven times in the first 9 days).[17] All patients received aspirin and dipyridamole. Of patients receiving plasma exchange, 47% had a platelet count exceeding 150×10^9 cells/l and no new neurologic features, compared with only 25% of those receiving plasma infusion over the first 2 weeks. At 6 months, survival was substantially better in those given plasma exchange (50% versus 78%). More recent series using plasma exchange have reported mortality rates as low as 15%,[7] and there may be an association of reduced early mortality with more intensive plasma exchange. Renal impairment is not an independent predictor of poor outcome in TTP and does not in itself warrant more intensive therapy, and clinical course does not correlate with ADAMTS13 activity. Fever, age older than 40 years, and hemoglobin below 9 g/dl have been associated with a worse outcome. Whether FFP or its cryosupernatant fraction is better as replacement fluid remains unclear.

Thrombotic thrombocytopenic purpura may also be induced by drugs, including ticlopidine, clopidogrel, mitomycin C, cyclosporine, tacrolimus, gemcitabine, and quinine, and the evidence for benefit of plasma exchange in this context is poor.[7]

Atypical Hemolytic Uremic Syndrome

The less common forms of HUS in which there is no clear diarrheal prodrome (atypical HUS) are now known to be commonly caused by mutations, polymorphisms, or acquired dysregulation of the complement pathway, especially of factor H, factor I, and membrane cofactor protein, leading to uninhibited activation of complement. Other causes include infections or drugs that cause platelet or leukocyte activation and complement activation and consumption. Direct activation of endothelial cells may also be a cause. Plasma exchange and infusion have not been evaluated in controlled trials in atypical HUS, but uncontrolled series suggest benefit, and current guidelines recommend early initiation of plasma exchange with FFP (see Chapter 29), both to remove potential complement inhibitors or autoantibody and to replace absent or defective complement regulators.[7] TMA occurring after renal transplantation has also responded to plasma exchange.

Recommendation

We use plasma exchange in all adults with TTP or atypical HUS and perform all exchanges against FFP or cryo-poor FFP.

Systemic Lupus

Plasma exchange has been used extensively in patients with lupus. Most studies have included patients with diverse patterns of disease, often with only mild renal involvement. A randomized, prospective trial could show no benefit of plasma exchange over conventional immunosuppression for renal, serologic, or clinical outcomes, both in the short and long terms.[18] However, patients with crescentic lupus nephritis and those with the most severe renal dysfunction (dialysis dependency) were excluded. Anecdotal evidence suggests that plasma exchange may benefit patients with systemic lupus and crescentic GN, pulmonary hemorrhage, cerebral lupus, catastrophic antiphospholipid syndrome, severe antibody-induced hemolysis, lupus-associated TTP, or severe lupus unresponsive to conventional drugs or in patients for whom cytotoxic therapy has been withdrawn because of bone marrow suppression or other toxicity. Immunoadsorption may be more successful in the severe forms of lupus nephritis. A variety of techniques have been used, including standard protein A and anti-Ig absorption, and also phenylalanine, tryptophan, and dextran sulfate ligands, all of which bind immunoglobulin, rheumatoid factors, and immune complexes to varying degrees and all of which have been reported to induce remission in patients with severe disease after failure of conventional therapy.

Recommendation

We reserve plasma exchange for lupus patients with rapidly progressive renal failure and class IV lupus nephritis with crescents, for patients with severe neurologic involvement or severe hemolysis, for patients with myelosuppression who are thought unable to tolerate cyclophosphamide, and for those with catastrophic antiphospholipid syndrome. The treatment of lupus is further discussed in Chapter 26.

Cryoglobulinemia

In type I cryoglobulinemia, usually associated with myeloma or lymphoma, a monoclonal immunoglobulin causes hyperviscosity and cryoprecipitation. Such antibodies are easily removed by plasma exchange, often with immediate clinical benefit. Cytotoxic agents are used simultaneously to inhibit further paraprotein production. There are no controlled trials of the use of plasma exchange, but symptoms are closely related to the presence of the cryoimmunoglobulin, and hence treatment with plasma exchange appears effective.[7]

Patients with type II (mixed essential) cryoglobulinemia develop a monoclonal antibody (usually IgM) with specificity for a second, usually polyclonal, immunoglobulin. Type II cryoglobulins occur most commonly in association with hepatitis C virus infection and lymphoma. The resulting immune complexes can be deposited in the microcirculation and are particularly associated with MPGN (see Chapter 21). Plasma exchange is effective at clearing the immune complexes, although in long-term follow-up the cryoglobulins often recur, and sustained benefit has not been clearly demonstrated. However, many of the acute features of cryoglobulinemia do resolve with plasma exchange, particularly arthralgia, skin lesions, and digital necrosis, and patients with RPGN can recover renal function. Concomitant immunosuppression with cytotoxic agents or, more commonly now, rituximab may prevent resynthesis of the cryoproteins, although some patients require long-term intermittent plasma exchange to control symptoms. Immunosuppressive treatment should be used with caution in patients with hepatitis C virus–associated cryoglobulinemia, who may respond to antiviral therapy including interferon and ribavirin. A single randomized controlled trial in 17 patients with hepatitis C–associated cryoglobulinemia added immunoadsorption apheresis (with dextran sulfate) to antivirals and immunosuppression and showed significant clinical improvements.[19]

Cryofiltration apheresis (in which a normal plasma filter is used to separate plasma, which is then cooled to precipitate the cryoglobulin before return to the patient) selectively removes cryoglobulins, avoids large volumes of replacement fluids, and avoids deficiency of clotting factors, but needs to be combined with immunosuppression to prevent synthesis of further cryoglobulin. Few centers currently perform this technique, especially since the widespread introduction of rituximab for cryoglobulinemia.

Myeloma

Plasma exchange may have benefit in myeloma with either cast nephropathy or light-chain renal toxicity, although the most important therapy seems to be urgent initiation of chemotherapy, especially thalidomide, lenalidomide, or bortezomib. Two small controlled trials performed over 15 years ago provided conflicting

results.[7] A large prospective, controlled trial was reported in which 97 patients with myeloma and progressive acute kidney injury (creatinine >200 µmol/l [2.3 mg/dl] with an increase >50 µmol/l over the previous 2 weeks despite conventional management) were randomized to receive plasma exchange (five to seven sessions of 50 ml/kg over 10 days) in addition to chemotherapy (VAD [vincristine, adriamycin and dexamethasone] or melphalan and prednisolone).[20] This study showed no benefit of plasma exchange on mortality or recovery of renal function. However, patients had a wide degree of renal dysfunction and relatively few had a renal biopsy performed to confirm cast nephropathy. A retrospective review suggested that those with myeloma and high light-chain loads or severe renal failure may benefit if plasma exchange reduces light chains rapidly.[21] A single study using bortezomib in patients with renal disease and myeloma showed significant improvements even in patients with dialysis-requiring renal failure but without plasma exchange. Promising early data suggest that HD using novel membranes allowing the removal of large-molecular-weight molecules and lengthy dialysis sessions (6 to 8 hours) may prove superior to plasma exchange in removing light chains and improving renal function, and a trial is ongoing.

Recommendation

We reserve plasma exchange in myeloma for patients with high light-chain loads and cast nephropathy on biopsy.

Transplantation

Antibody-Mediated Rejection

Studies in the 1980s suggested that combining plasma exchange with cyclophosphamide could deplete circulating antibodies in patients with vascular or antibody-mediated rejection, but a review of 157 patients included in five trials could not demonstrate any significant difference in the outcome of acute vascular rejection in patients treated with or without plasma exchange.[7,8] More recently, at least 11 trials including more than 300 patients with more clearly defined antibody-mediated rejection, and case series of more than 500 patients, have suggested that plasma exchange, usually combined with intravenous immunoglobulin (IVIG) and/or rituximab, but sometimes antithymocyte globulin, may effectively reverse 55% to 100% of such rejection episodes.[7]

There is no convincing evidence that plasma exchange has any role in the treatment of chronic rejection.

Anti–Human Leukocyte Antigen Antibodies

Highly sensitized patients with preformed anti-HLA antibodies have been treated before and after transplantation with plasma exchange or immunoadsorption to reduce cytotoxic antibody levels, often with high-dose IVIG.[7] Patients usually received intensive immunoadsorption or plasma exchange before transplantation to ensure a current negative cross-match immediately before transplantation; some received longer-term immunoadsorption or plasma exchange in combination with immunosuppressive therapies in the months preceding transplantation. Most recent studies have shown that patients with donor-specific antibody titers of less than 1 : 32 often have these depleted completely with preoperative plasma exchange, allowing successful renal transplantation. Such patients do have an increased risk of antibody-mediated rejection—approximately 40%—but despite this, 90% have 1-year graft survival.

ABO-Incompatible Renal Transplantation

Plasma exchange is widely used to remove natural anti-A or anti-B blood group antibodies from the recipient before living donor transplantation from an ABO-incompatible donor. Various protocols are in use, but all rely on depletion of specific antibody over 2 to 5 days before transplantation by exchanging a single plasma volume for human albumin solution (in addition to routine immunosuppression, sometimes including rituximab and IVIG). Plasma exchange is sometimes continued for one or two sessions after transplantation or if antibody-mediated rejection occurs.[22] One-year graft survival rates of up to 85% have been reported with such protocols, although rejection episodes are more common than in ABO-compatible transplants. Patients with increasingly high antibody titers are being treated in this way. More recently, immunoadsorption using synthetic A- or B-oligosaccharide epitopes linked to Sepharose has been developed. Such columns specifically remove anti-A or anti-B antibodies, but any clinical benefit remains uncertain, and the costs are high.

Recurrent Focal Segmental Glomerulosclerosis

Plasma exchange, double-filtration plasma exchange, and protein A immunoadsorption have all been used to treat recurrence of nephrotic syndrome after transplantation in patients with recurrent FSGS.[7,23,24] An incompletely defined circulating factor causing increased permeability of glomerular capillaries can be found in most patients with recurrent FSGS. There are no controlled trials of plasma treatments in recurrent FSGS, and most series are small. One study demonstrated an 82% reduction in urinary protein excretion in eight patients with recurrent nephrosis during plasma protein adsorption; however, the effect was transient and persisted for less than 2 months in seven of the eight patients.[23] Other investigators have obtained remissions (complete and partial) in up to 80% of patients, and a significant reduction in graft loss resulting from recurrent disease compared with historic controls.[24] More intensive treatment regimens have led to more persistent remissions. All three apheresis modalities have also been used prophylactically in patients deemed to be at high risk of recurrence, with variable success.

Recommendations

We recommend use of plasma exchange for patients with recurrent disease, initially daily for 7 to 10 days. If proteinuria is successfully reversed, this may need to be continued less frequently (weekly, then every other week, then monthly), for 2 to 3 days on each occasion. Management of recurrent FSGS is discussed further in Chapter 108.

SECTION XVIII

Transplantation

CHAPTER 100

Immunologic Principles in Kidney Transplantation

Karl L. Womer

Important to an effective immune response is the ability of T cells to recognize a wide variety of nonself antigens, which allows for restrained immune activation and subsequent antigen-specific killing. This task is accomplished through the generation of a diverse repertoire of T cells in a single individual with specificity for an enormous number of potential foreign antigens presented as peptides on the surface of major histocompatibility complex (MHC) molecules. Variations in MHC structure from individual to individual increase the variety of peptides that can be presented to T cells, which protects the species as a whole by ensuring adequate T cell responses to a given foreign organism in at least one member of the population. Although slight, these MHC polymorphisms are recognized as foreign after kidney transplantation between non–genetically identical humans and induce alloresponses that in the absence of immunosuppression result in rejection of the allograft (see Box 100-1 for graft terminology). In this chapter, basic immunologic principles important to the field of kidney transplantation are reviewed.

ISCHEMIA-REPERFUSION INJURY

The immunologic responses after kidney transplantation occur in well-defined stages,[1] as depicted in Figure 100-1. Initial insults to the graft during donor organ procurement and subsequent transplantation into the recipient are referred to as ischemia-reperfusion injury (IRI). The pathogenesis of IRI involves biochemical, cellular, vascular endothelial, and tissue-specific factors, with inflammation as a common feature.[2] Acute ischemia leads to tissue damage and endothelial cell activation that initiates the innate or antigen-nonspecific immune response. Innate immunity occurs rapidly, with limited specificity, and without memory and includes both cellular elements (neutrophils, macrophages, dendritic cells [DCs], and natural killer [NK] cells) and molecular components (Toll-like receptors [TLRs], complement proteins, chemokines, and cytokines, among others).

Toll-like receptors are expressed by a number of cells, including monocytes and macrophages, lymphocytes, DCs, NK cells, neutrophils, and epithelial and endothelial cells. Engagement of TLRs by endogenous molecules called *danger-associated molecular patterns* (DAMPs) that are released by cells during IRI leads to release of cytokines, including tumor necrosis factor α (TNF-α) and interleukin (IL)–6. These proinflammatory mediators induce tubular epithelial cell production of the chemokine CXCL8 (IL-8), which attracts neutrophils by activation of their surface chemokine receptor, CXCR2. Neutrophil accumulation is the prime cellular mediator of microvascular plugging and local tissue destruction in IRI. In the next phase, monocyte or macrophage infiltration occurs and likely contributes to extension of early injury as well as repair.[3] These events contribute to delayed graft function and amplify the adaptive or antigen-specific phase of transplantation immunity (T cells and antibody-producing B cells) that can negatively affect long-term graft survival. NK cells likely also function as a bridge between innate and adaptive immunity in IRI, in part through bidirectional crosstalk between NK cells and DCs that plays a relevant role in the mechanisms leading to activation and maturation of DCs.[4] Likewise, whereas activation of the complement system plays an important role in IRI as a manifestation of the innate immune system, complement may also regulate adaptive immune responses. T and B cells constitute the primary arms of the adaptive immune response, but they also play an important role in the acute and possibly healing phases of IRI.[2] The immunologic events described here are not specific to allografts, as they also occur in syngeneic grafts during IRI.

ANTIGEN PRESENTATION

Antigen-Presenting Cells

Antigen-presenting cells (APCs) are specialized cells capable of activating T cells. Antigen is endocytosed by APCs and then displayed by MHC molecules on their surface. T cells recognize and interact with the antigen-MHC complex to become activated. DCs, macrophages, and B cells are all considered "professional APCs," although DCs are the most potent at antigen presentation. Alloimmune responses are initiated by activation of APCs (mostly DCs) through innate immune recognition systems, as described previously. DCs are highly versatile cells, determining whether the environment indicates that antigen should lead to an immune response or alternatively to tolerance.[5] In the graft and surrounding tissues after transplantation, DCs of either donor or host origin become activated and move to T cell areas of secondary lymphoid organs (SLOs).

The trafficking pattern of naive T cells is restricted to SLOs, such as the lymph node and spleen, but also possibly to tertiary lymphoid structures formed in tissues after inflammation, including those in allografts.[6] They traverse from blood to lymphoid organs, where they pass through the T cell areas and become activated on encounter with donor antigen (alloantigen) presented by activated DCs in the context of MHC molecules. Thus, the movement of DCs and naive T cells is coordinated to bring them into contact in the T cell areas of SLOs, which appears essential for effective priming.[7] Once activated, T cells are able to leave SLOs via lymph vessels to enter the blood and ultimately peripheral tissues, particularly into sites of inflammation. B cells are activated when antigen engages their antigen receptors, initially in the border of T cell and B cell areas of SLOs, where helper T cell function is provided.[8]

Antigen experienced memory cells may be activated by other APCs, such as graft endothelium.[9] Patients normally have no preexisting immunoreactivity to alloantigen, unless they have been exposed to alloantigen through pregnancy, blood transfusion, or prior transplantation. However, microbial antigens that cross-react with alloantigens (molecular or antigenic mimicry) can lead to the generation of alloantigen-specific memory cells through a process termed *heterologous immunity.*[10]

Graft Terminology

Autograft (autologous graft): A graft from one part of the body to another. Examples include skin and vascular grafts. No rejection occurs.

Isograft (isogenic or syngeneic graft): A graft from one member of a species to a genetically identical member of the same species. Examples include grafts between identical twins and between members of the same inbred rodent strain. No rejection typically occurs.

Allograft (allogeneic graft): A graft between nonidentical members of the same species. Examples include grafts between unrelated or related nonidentical humans and between members of different inbred rodent strains. Rejection occurs by lymphocytes reactive to alloantigens on the graft (i.e., alloresponse).

Xenografts (xenogeneic grafts): A graft between members of different species. Examples include pig or baboon to human, and rat to mouse. Rejection occurs by lymphocytes reactive to xenoantigen on the graft (i.e., xenoresponse).

Box 100-1 Graft terminology.

T Cell Ontogeny and Major Histocompatibility Complex Specificity

Allografts induce alloimmune responses because of the recognition of nonself antigens (e.g., MHC) from the graft by recipient T cells. During T cell ontogeny during embryogenesis, multilineage bone marrow precursors migrate to the thymus, where ultimate rearrangement of the T cell receptor (TCR) gene occurs, resulting in irrevocable T cell commitment. TCR gene rearrangement is random and ensures that a diverse repertoire of T cells exists to be able to respond to the enormous number of potential foreign antigens.[11] The mature T cell repertoire is determined in the thymus by two processes, positive and negative selection. Positive selection is dependent on a certain degree of antigen-specific T cell affinity to self-MHC molecules expressed on thymic cortical epithelial cells. This process ensures that mature T cells will interact effectively with MHC to allow recognition of foreign antigen in the context of self-MHC. Negative selection then occurs by deletion of T cells with excessively high affinity for self-peptide and MHC, thereby preventing release of high-affinity T cells with autoimmune potential.

Mature T cells expressing their clone-specific TCRs then exit the thymus as either CD4 or CD8 T cells. The TCRs of CD4 T cells (also called *helper T cells*) are selected to interact with class II MHC molecules, whereas the TCRs of CD8 T cells (precursors of cytotoxic T lymphocytes or CTLs) interact with class I MHC molecules. A fundamental principle of immunology is that T cells do not recognize intact foreign proteins directly, but instead as peptides presented by self-MHC on APCs. However, allelic variation among MHC molecules from individual to individual is quite small, resulting in similarities between donor and recipient MHC structure. Thus, unique to the transplant setting, recipient TCRs have a strong affinity for intact donor MHC molecules and can recognize them directly, which explains in large part the high proportion of T cells responding to alloantigen.[12] In fact, only $1/10^5$ to $1/10^6$ T cells will respond to any given nominal antigen (e.g., peptide derived from tetanus toxin or influenza hemagglutinin). However, the frequency of T cells that respond to foreign MHC molecules (alloantigens) is much higher (up to 5% to 10% of all T cells).

Pathways of Allorecognition

Recipient T cells may encounter alloantigen by either the direct or indirect pathways of allorecognition (Fig. 100-2). As previously

Generation of Alloimmune Responses

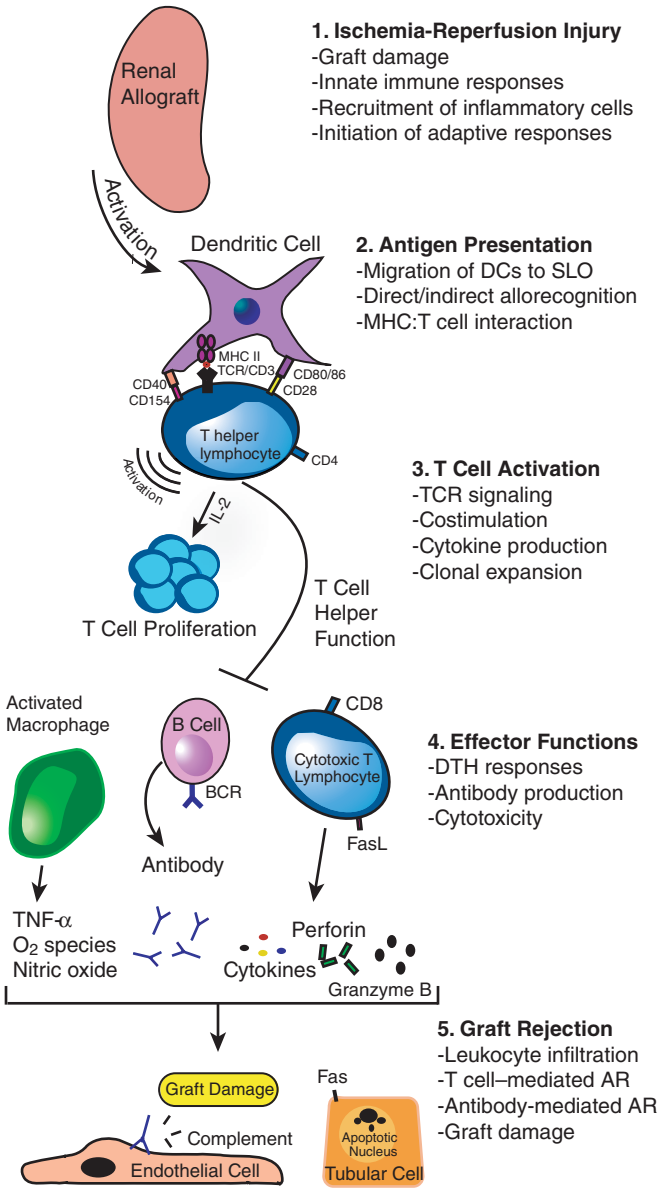

Figure 100-1 Generation of alloimmune responses. Immunologic responses after renal transplantation represent a series of well-defined stages that result in rejection of the allograft in the absence of exogenous immunosuppression. Graft damage after ischemia-reperfusion injury during procurement and transplantation activates innate (antigen-nonspecific) immune responses, which recruit inflammatory cells and initiate adaptive (antigen-specific) immune responses. After activation, dendritic cells *(DCs)* of donor (direct pathway) or recipient (indirect pathway) origin migrate to secondary lymphoid organs *(SLO),* where they present alloantigen to T cells through major histocompatibility *(MHC)* structures on their cell surface. Following T cell receptor *(TCR)* signaling and appropriate costimulation, T cells become activated to produce large amounts of cytokine and undergo clonal expansion. CD4 T cells provide help to B cells, CD8 T cells, and macrophages for the production of alloantibody, cellular cytotoxicity, and delayed-type hypersensitivity *(DTH)* responses, respectively. These effector functions result in destruction of the graft by acute rejection, which may be T cell and/or antibody mediated. *AR,* Acute rejection; *IL-2,* interleukin-2; *TNF-α,* tumor necrosis factor α.

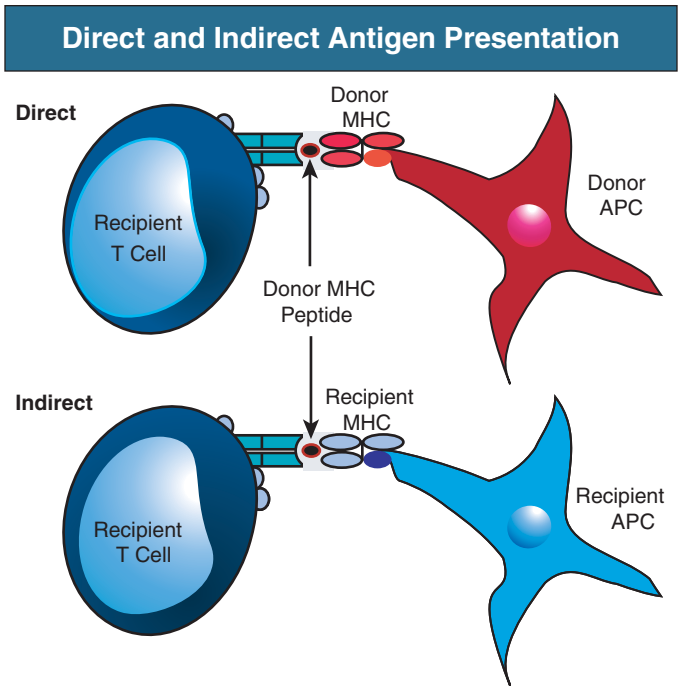

Figure 100-2 Direct and indirect antigen presentation. In direct allorecognition, donor antigen *(shown in red)* is presented to recipient T cells as a peptide in the context of intact donor major histocompatibility complex *(MHC)* molecules on the surface of donor antigen- presenting cells *(APCs)*. In indirect allorecognition, the donor antigen is processed by recipient APCs and presented as a peptide in the context of recipient MHC molecules.

alluded to, direct antigen presentation involves recipient T cell recognition of donor MHC peptides in the peptide groove of intact donor MHC molecules on the surface of donor APCs. By this mechanism, donor APCs migrate from the graft to recipient lymphoid organs and activate alloreactive recipient T cells to initiate the alloimmune response. It has been suggested that the direct pathway may be particularly active early after transplantation, when a large number of donor APCs are present in the allograft. However, direct antigen presentation may also occur later when recipient T cells recognize intact donor MHC molecules on cells of the graft (e.g., endothelium). The best evidence of direct allorecognition is the strong *in vitro* response generated in the mixed lymphocyte reaction (MLR), whereby lymphocytes are cultured with allogeneic APCs. B cells also recognize intact donor MHC antigen via their B cell receptors (BCRs).

Indirect antigen recognition is the physiologic mechanism of foreign antigen presentation. Foreign antigen is taken up by APCs, processed intracellularly, and then presented as peptides on MHC molecules. During indirect allorecognition, donor MHC molecules are shed from the graft and processed by recipient APCs, where they are presented as peptides to recipient T cells in the context of recipient MHC molecules.[13] Because donor MHC molecules are continually shed from the graft and presented by recipient APCs, indirect allorecognition may play a larger role in the late alloresponse, including chronic rejection. However, the relative contribution of direct versus indirect allorecognition to the alloresponse at different time points after transplantation remains the subject of debate.

Major Histocompatibility Complex

Class I and II MHC molecules are designed for presentation of antigen from different sources for different purposes (Fig. 100-3).

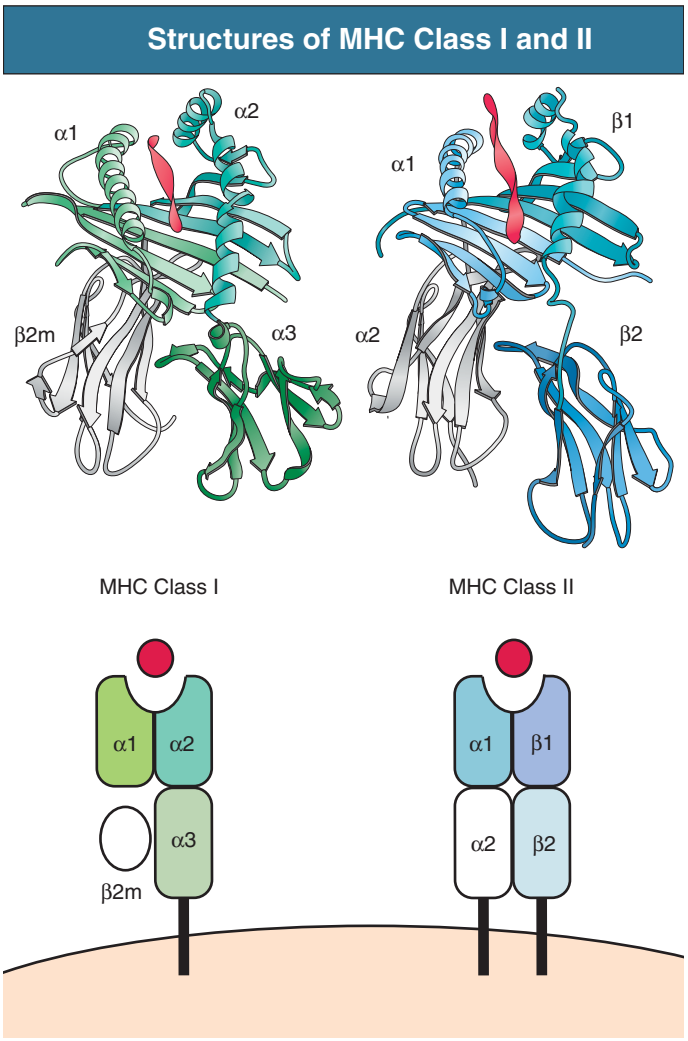

Figure 100-3 Structures of major histocompatibility complex (MHC) class I and II. MHC class I is composed of a heavy chain divided into α1, α2, and α3 domains noncovalently associated with β_2-microglobulin *(β2m)*. The α1 and α2 domains each form a long α helix and β sheet to make up the floor and walls of the peptide-binding groove (peptide indicated by *red ribbon*). MHC class II is a dimer composed of α and β chains. Each chain is divided into two domains, with α1 and β1 domains forming the two α helices and β pleated sheet that surround the peptide-binding groove.

The class I system is designed to sample cytosolic proteins to detect tumors or intracellular pathogens, such as virus and intracellular bacteria. Class I molecules are recognized by CD8 T cells and thus provide a surveillance mechanism to target infected or malignant cells for destruction by CTLs. The class II system is designed to sample extracellular proteins that have been taken up and processed by APCs. Class II molecules are recognized by CD4 T helper cells and allow for the generation of immune responses to invading pathogens that are phagocytosed by APCs. Cross-presentation is a process by which certain APCs take up, process, and present extracellular antigen on class I molecules to CD8 T cells.[14] This mechanism is necessary for immunity against tumors and viruses that do not infect APCs. MHC products also play other important roles, including the positive and negative selection of developing T cells described earlier, stimulation of naive and memory T cells that is necessary for their survival (homeostatic proliferation), the induction of T cell tolerance and anergy, and interaction with NK cells and other inhibitory and activating receptors.

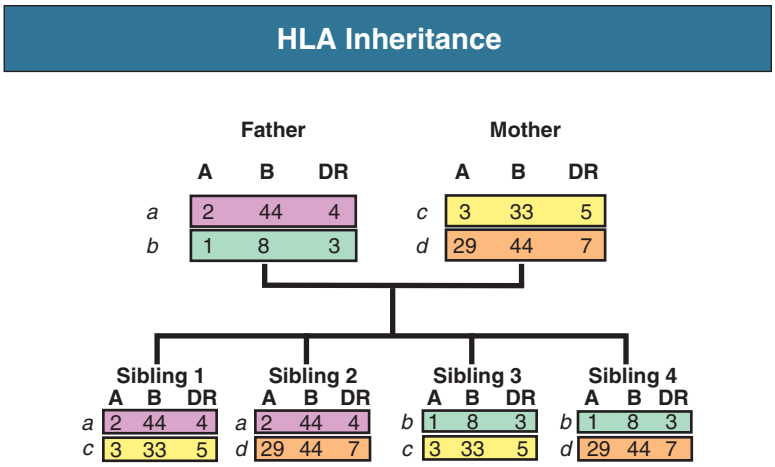

Figure 100-4 Human leukocyte antigen (HLA) inheritance. HLA antigens are inherited and expressed in a Mendelian co-dominant fashion, whereby one copy of each HLA gene, called a *haplotype* (e.g., a, b, c, d), is inherited from each parent. Efforts are made to match both class I (HLA-A and HLA-B) and class II (HLA-DR) antigens.

The MHC gene locus (in humans, human leukocyte antigen [HLA]) maps to a 3.5-million–base-pair region on the short arm of chromosome 6 and is divided into three regions: the class II region, the class III region, and the class I region. Only the class I and II regions encode proteins involved in antigen presentation. The key MHC genes are the class I genes (HLA-A, HLA-B, and HLA-C) and the class II genes (HLA-DP, HLA-DQ, and HLA-DR). The class I and II proteins share overall structural homology but are functionally different.[15] The molecular structure of MHC class I and II proteins is presented in Figure 100-3.

Class I proteins are expressed on virtually all nucleated cells, although the amount expressed varies. Class II proteins have a more restricted cell distribution, generally limited to bone marrow–derived professional APCs, including DCs, B cells, macrophages, and Langerhans cells, but also other cells, including renal parenchymal and endothelial cells. Both class I and II antigens can be induced on a variety of cells by interferon-γ (IFN-γ) in synergy with other cytokines during rejection episodes.

Human Leukocyte Antigen Typing and Transplantation
